## ABOUT THE AUTHORS

**HARVEY LODISH** is Professor of Biology and Professor of Biological Engineering at the Massachusetts Institute of Technology and a Founding Member of the Whitehead Institute for Biomedical Research. Dr. Lodish is also a member of the National Academy of Sciences and the American Academy of Arts and Sciences and was President (2004) of the American Society for Cell Biology. He is well known for his work on cell-membrane physiology, particularly the biosynthesis of many cell-surface proteins, and on the cloning and functional analysis of several cell-surface receptor proteins, such as the erythropoietin and TGF- $\beta$  receptors. His laboratory also studies long noncoding RNAs and microRNAs that regulate the development and function of hematopoietic cells and adipocytes. Dr. Lodish teaches undergraduate and graduate courses in cell biology and biotechnology.

*Photo credit: John Soares.*

**ARNOLD BERK** holds the UCLA Presidential Chair in Molecular Cell Biology in the Department of Microbiology, Immunology, and Molecular Genetics and is a member of the Molecular Biology Institute at the University of California, Los Angeles. Dr. Berk is also a fellow of the American Academy of Arts and Sciences. He is one of the discoverers of RNA splicing and of mechanisms for gene control in viruses. His laboratory studies the molecular interactions that regulate transcription initiation in mammalian cells, focusing in particular on adenovirus regulatory proteins. He teaches an advanced undergraduate course in cell biology of the nucleus and a graduate course in biochemistry. *Photo credit: Penny Jennings/UCLA Department of Chemistry & Biochemistry.*

**CHRIS A. KAISER** is the Amgen Inc. Professor in the Department of Biology at the Massachusetts Institute of Technology. He is also a former Department Head and former Provost. His laboratory uses genetic and cell biological methods to understand how newly synthesized membrane and secretory proteins are folded and stored in the compartments of the secretory pathway. Dr. Kaiser is recognized as a top undergraduate educator at MIT, where he has taught genetics to undergraduates for many years. *Photo credit: Chris Kaiser.*

**MONTY KRIEGER** is the Whitehead Professor in the Department of Biology at the Massachusetts Institute of Technology and a Senior Associate Member of the Broad Institute of MIT and Harvard. Dr. Krieger is also a member of the National Academy of Sciences. For his innovative teaching of undergraduate biology and human physiology as well as graduate cell biology courses, he has received numerous awards. His laboratory has made contributions to our understanding of membrane trafficking through the Golgi apparatus and has cloned and characterized receptor proteins important for pathogen recognition and the movement of cholesterol into and out of cells, including the HDL receptor. *Photo credit: Monty Krieger.*

**ANTHONY BRETSCHER** is Professor of Cell Biology at Cornell University and a member of the Weill Institute for Cell and Molecular Biology. His laboratory is well known for identifying and characterizing new components of the actin cytoskeleton and elucidating the biological functions of those components in relation to cell polarity and membrane traffic. For this work, his laboratory exploits biochemical, genetic, and cell biological approaches in two model systems, vertebrate epithelial cells and the budding yeast. Dr. Bretscher teaches cell biology to undergraduates at Cornell University. *Photo credit: Anthony Bretscher.*

**HIDDE PLOEGH** is Professor of Biology at the Massachusetts Institute of Technology and a member of the Whitehead Institute for Biomedical Research. One of the world's leading researchers in immune-system behavior, Dr. Ploegh studies the various tactics that viruses employ to evade our immune responses and the ways our immune system distinguishes friend from foe. Dr. Ploegh teaches immunology to undergraduate students at Harvard University and MIT. *Photo credit: Hidde Ploegh.*

**ANGELIKA AMON** is Professor of Biology at the Massachusetts Institute of Technology, a member of the Koch Institute for Integrative Cancer Research, and Investigator at the Howard Hughes Medical Institute. She is also a member of the National Academy of Sciences. Her laboratory studies the molecular mechanisms that govern chromosome segregation during mitosis and meiosis and the consequences—aneuploidy—when these mechanisms fail during normal cell proliferation and cancer development. Dr. Amon teaches undergraduate and graduate courses in cell biology and genetics. *Photo credit: Pamela DiFraia/Koch Institute/MIT.*

**KELSEY C. MARTIN** is Professor of Biological Chemistry and Psychiatry and interim Dean of the David Geffen School of Medicine at the University of California, Los Angeles. She is the former Chair of the Biological Chemistry Department. Her laboratory studies the ways in which experience changes connections between neurons in the brain to store long-term memories—a process known as synaptic plasticity. She has made important contributions to elucidating the molecular and cell biological mechanisms that underlie this process. Dr. Martin teaches basic principles of neuroscience to undergraduates, graduate students, dental students, and medical students. *Photo credit: Phuong Pham.*

COVER IMAGE: Dr. Tomas Kirchhausen and Dr. Lei Lu

**ABOUT THE COVER:** Imaging of the intracellular organelles of a live human HeLa cell shows the dramatic morphological changes that accompany the process of cell division. The membrane of the endoplasmic reticulum (ER) is labeled green by a fluorescently tagged component of the translocon (GFP-Sec61 $\beta$ ) and chromatin is labeled red by a fluorescently tagged histone (H2B-mRFP). **Front:** An interphase cell showing uncondensed chromatin filling the nucleus, with the ER as a reticulum of cisternae surrounding the nucleus and interconnected with lace-like tubules at the cell periphery. **Back:** Prior to cell division the chromatin condenses to reveal the worm-like structure of individual chromosomes, the nuclear envelope breaks down, and the ER condenses into an array of cisternae surrounding the condensed chromosomes. As cell division proceeds the replicated chromosomes will segregate equally into two daughter cells, nuclear envelopes will form in the daughter cells, and the ER will return to its characteristic reticular organization. *Cover photo: Dr. Tomas Kirchhausen & Dr. Lei Lu.*

**TO OUR STUDENTS AND TO OUR TEACHERS,**  
from whom we continue to learn,  
**AND TO OUR FAMILIES,**  
for their support, encouragement, and love

*this page left intentionally blank*

**In writing** the eighth edition of *Molecular Cell Biology*, we have incorporated many of the spectacular advances made over the past four years in biomedical science, driven in part by new experimental technologies that have revolutionized many fields. Fast techniques for sequencing DNA, allied with efficient methods to generate and study mutations in model organisms and to map disease-causing mutations in humans, have illuminated a basic understanding of the functions of many cellular components, including hundreds of human genes that affect diseases such as diabetes and cancer.

For example, advances in genomics and bioinformatics have uncovered thousands of novel long noncoding RNAs that regulate gene expression, and have generated insights into and potential therapies for many human diseases. Powerful genome editing technologies have led to an unprecedented understanding of gene regulation and function in many types of living organisms. Advances in mass spectrometry and cryoelectron microscopy have enabled dynamic cell processes to be visualized in spectacular detail, providing deep insight into both the structure and the function of biological molecules, post-translational modifications, multiprotein complexes, and organelles. Studies of specific nerve cells in live organisms have been advanced by optogenetic technologies. Advances in stem-cell technology have come from studies of the role of stem cells in plant development and of regeneration in planaria.

Exploring the most current developments in the field is always a priority in writing a new edition, but it is also important to us to communicate the basics of cell biology clearly by stripping away as much extraneous detail as possible to focus attention on the fundamental concepts of cell biology. To this end, in addition to introducing new discoveries and technologies, we have streamlined and reorganized several chapters to clarify processes and concepts for students.

## New Co-Author, Kelsey C. Martin

The new edition of *MCB* introduces a new member to our author team, leading neuroscience researcher and educator Kelsey C. Martin of the University of California, Los Angeles. Dr. Martin is Professor of Biological Chemistry and Psychiatry and interim Dean of the David Geffen School of Medicine at UCLA. Her laboratory uses *Aplysia* and mouse models to understand the cell and molecular biology of long-term memory formation. Her group has made important contributions to elucidating the molecular and cell biological mechanisms by which experience changes connections between neurons in the brain to store

long-term memories—a process known as synaptic plasticity. Dr. Martin received her undergraduate degree in English and American Language and Literature at Harvard University. After serving as a Peace Corps volunteer in the Democratic Republic of the Congo, she earned an MD and PhD at Yale University. She teaches basic neurobiology to undergraduate, graduate, dental, and medical students.

## Revised, Cutting-Edge Content

The eighth edition of *Molecular Cell Biology* includes new and improved chapters:

- “Molecules, Cells, and Model Organisms” (Chapter 1) is an improved and expanded introduction to cell biology. It retains the overviews of evolution, molecules, different forms of life, and model organisms used to study cell biology found in previous editions. In this edition, it also includes a survey of eukaryotic organelles, which was previously found in Chapter 9.
- “Culturing and Visualizing Cells” (Chapter 4) has been moved forward (previously Chapter 9) as the techniques used to study cells become ever more important. Light-sheet microscopy, super-resolution microscopy, and two-photon excitation microscopy have been added to bring this chapter up to date.
- All aspects of mitochondrial and chloroplast structure and function have been collected in “Cellular Energetics” (Chapter 12). This chapter now begins with the structure of the mitochondrion, including its endosymbiotic origin and organelle genome (previously in Chapter 6). The chapter now discusses the role of mitochondria-associated membranes (MAMs) and communication between mitochondria and the rest of the cell.
- Cell signaling has been reframed to improve student accessibility. “Signal Transduction and G Protein–Coupled Receptors” (Chapter 15) begins with an overview of the concepts of cell signaling and methods for studying it, followed by examples of G protein–coupled receptors performing multiple roles in different cells. “Signaling Pathways That Control Gene Expression” (Chapter 16) now focuses on gene expression, beginning with a new discussion of Smads. Further examples cover the major signaling pathways that students will encounter in cellular metabolism, protein degradation, and cellular differentiation. Of particular interest is a new section on Wnt and Notch signaling pathways controlling stem-cell differentiation in planaria. The chapter ends by describing how signaling pathways are integrated

**FIGURE 4-21** Two-photon excitation microscopy allows deep penetration for intravital imaging. (a) In conventional point-scanning confocal microscopy, absorption of a single photon results in an electron jumping to the excited state. In two-photon excitation, two lower-energy photons arrive almost instantaneously and induce the electron to jump to the excited state. (b) Two-photon microscopy can be used to observe cells up to 1 mm deep within a living animal immobilized on the microscope stage. (c) Neurons in a lobster were imaged using two-photon excitation microscopy.

[Part (c) unpublished data from Peter Kloppenburg and Warren R. Zipfel.]

to form a cellular response in insulin and glucagon control of glucose metabolism.

- Our new co-author, Kelsey C. Martin, has extensively revised and updated “Cells of the Nervous System” (Chapter 22) to include several new developments in the field. Optogenetics, a technique that uses channelrhodopsins and light to perturb the membrane potential of a cell, can be used in live animals to link neural pathways with behavior. The formation and pruning of neural pathways in the central nervous system is under active investigation, and a new discussion of signals that govern these processes focuses on the cell-cell contacts involved. This discussion leads to an entirely new section on learning and memory, which explores the signals and molecular mechanisms underlying synaptic plasticity.

## Increased Clarity, Improved Pedagogy

As experienced teachers of both undergraduate and graduate students, we are always striving to improve student understanding. Being able to visualize a molecule in action can have a profound effect on a student’s grasp of the molecular processes within a cell. With this in mind, we have updated many of the molecular models for increased clarity and added models where they can deepen student understanding. From the precise fit required for tRNA charging, to the conservation of ribosome structure, to the dynamic strength of tropomyosin and troponin in muscle contraction, these figures communicate the complex details of molecular structure that cannot be conveyed in schematic diagrams alone. In conjunction with these new models, their schematic icons have been revised to more accurately represent them, allowing students a smooth transition between the molecular details of a structure and its function in the cell.

## New Discoveries, New Methodologies

- Model organisms *Chlamydomonas reinhardtii* (for study of flagella, chloroplast formation, photosynthesis, and phototaxis) and *Plasmodium falciparum* (novel organelles and a complex life cycle) (Ch. 1)
- Intrinsically disordered proteins (Ch. 3)
- Chaperone-guided folding and updated chaperone structures (Ch. 3)
- Unfolded proteins and the amyloid state and disease (Ch. 3)
- Hydrogen/deuterium exchange mass spectrometry (HXMS) (Ch. 3)
- Phosphoproteomics (Ch. 3)
- Two-photon excitation microscopy (Ch. 4)
- Light-sheet microscopy (Ch. 4)
- Super-resolution microscopy (Ch. 4)

**FIGURE 5-19** (a) Translating nucleic acid sequence into amino acid sequence requires two steps. Step 1: An aminoacyl-tRNA synthetase couples a specific amino acid to its corresponding tRNA. Step 2: The anticodon base-pairs with a codon in the mRNA specifying that amino acid. (b) Molecular model of the human mitochondrial aminoacyl-tRNA synthetase for Phe in complex with tRNA<sup>Phe</sup>.

- Three-dimensional culture matrices and 3D printing (Ch. 4)
- Ribosome structural comparison across domains shows conserved core (Ch. 5)
- CRISPR–Cas9 system in bacteria and its application in genomic editing (Ch. 6)
- Chromosome conformation capture techniques reveal topological domains in chromosome territories within the nucleus (Ch. 8)
- Mapping of DNase I hypersensitive sites reveals cell developmental history (Ch. 9)
- Long noncoding RNAs involved in X inactivation in mammals (Ch. 9)
- ENCODE databases (Ch. 9)
- Improved discussion of mRNA degradation pathways and RNA surveillance in the cytoplasm (Ch. 10)
- Nuclear bodies: P bodies, Cajal bodies, histone locus bodies, speckles, paraspeckles, and PML nuclear bodies (Ch. 10)

- GLUT1 molecular model and transport cycle (Ch. 11)
- Expanded discussion of the pathway for import of PTS1-bearing proteins into the peroxisomal matrix (Ch. 13)
- Expanded discussion of Rab proteins and their role in vesicle fusion with target membranes (Ch. 14)
- Human G protein–coupled receptors of pharmaceutical importance (Ch. 15)
- The role of Smads in chromatin modification (Ch. 16)

**FIGURE 6-43b** Cas9 uses a guide RNA to identify and cleave a specific DNA sequence.

**FIGURE 16-31** Gradients of Wnt and Notum guide regeneration of a head and tail by planaria. [Part (b) Jessica Witchley and Peter Reddien.]

- Wnt concentration gradients in planarian development and regeneration (Ch. 16)
- Inflammatory hormones in adipose cell function and obesity (Ch. 16)
- Regulation of insulin and glucagon function in control of blood glucose (Ch. 16)
- Use of troponins as an indicator of the severity of a heart attack (Ch. 17)
- Neurofilaments and keratins involved in skin integrity, epidermolysis bullosa simplex (Ch. 18)
- New structures and understanding of function of dynein and dynactin (Ch. 18)
- Expanded discussion of lamins and their role in nuclear membrane structure and dynamics during mitosis (Ch. 18)
- Diseases associated with cohesin defects (Ch. 19)
- The Hippo pathway (Ch. 19)
- Spindle checkpoint assembly and nondisjunction and aneuploidy in mice; nondisjunction increases with maternal age (Ch. 19)
- Expanded discussion of the functions of the extracellular matrix and the role of cells in assembling it (Ch. 20)
- Mechanotransduction (Ch. 20)
- Structure of cadherins and their cis and trans interactions (Ch. 20)
- Cadherins as receptors for class C rhinoviruses and asthma (Ch. 20)
- Improved discussion of microfibrils in elastic tissue and in LTBP-mediated TGF- $\beta$  signaling (Ch. 20)
- Tunneling nanotubes (Ch. 20)
- Functions of WAKs in plants as pectin receptors (Ch. 20)

- Pluripotency of mouse ES cells and the potential of differentiated cells derived from iPS and ES cells in treating various diseases (Ch. 21)
- Pluripotent ES cells in planaria (Ch. 21)
- Cells in intestinal crypts that dedifferentiate to replenish intestinal stem cells (Ch. 21)
- Cdc42 and feedback loops that control cell polarity (Ch. 21)
- Prokaryotic voltage-gated Na<sup>+</sup> channel structure, allowing comparison with voltage-gated K<sup>+</sup> channels (Ch. 22)
- Optogenetics techniques for linking neural circuits with behavior (Ch. 22)
- Mechanisms of synaptic plasticity that govern learning and memory (Ch. 22)

**Figure 22-8** Neurogenesis in the adult brain. Newly born neurons were labeled with GFP in the dentate gyrus of control mice and mice that were allowed to exercise on a running wheel. [Chunmei Zhao and Fred H. Gage.]

- Inflammasomes and non-TLR nucleic acid sensors (Ch. 23)
- Expanded discussion of somatic hypermutation (Ch. 23)
- Improved discussion of the MHC molecule classes; MHC-peptide complexes and their interactions with T-cells (Ch. 23)
- Lineage commitment of T cells (Ch. 23)
- Tumor immunology (Ch. 23)
- The characteristics of cancer cells and how they differ from normal cells (Ch. 24)
- How carcinogens lead to mutations and how mutations accumulate to cancer (Ch. 24)

## Medical Connections

Many advances in basic cellular and molecular biology have led to new treatments for cancer and other human diseases. Examples of such medical advances are woven throughout the chapters to give students an appreciation for the clinical applications of the basic science they are learning. Many of these applications hinge on a detailed understanding of multiprotein complexes in cells—complexes that catalyze cell movements; regulate DNA transcription,

replication, and repair; coordinate metabolism; and connect cells to other cells and to proteins and carbohydrates in their extracellular environment.

- Stereoisomers of small molecules as drugs—sterically pure molecules have different effects from mixtures (Ch. 2)
- Cholesterol is hydrophobic and must be transported by lipoprotein carriers LDL and HDL (Ch. 2)
- Essential amino acids must be provided in livestock feed (Ch. 2)
- Saturated, unsaturated, and trans fats: their molecular structures and nutritional consequences (Ch. 2)
- Protein misfolding and amyloids in neurodegenerative diseases such as Alzheimer's and Parkinson's (Ch. 3)
- Small molecules that inhibit enzyme activity can be used as drugs (aspirin) or in chemical warfare (sarin gas) (Ch. 3)
- Small-molecule inhibitors of the proteasome are used to treat certain cancers (Ch. 3)
- Disruptions of GTPases, GAPs, GEFs, and GDIs by mutations and pathogens cause a wide variety of diseases (Ch. 3)
- 3-D printing technology may be used to grow replacement organs (Ch. 4)
- The high-resolution structures of ribosomes can help identify small-molecule inhibitors of bacterial, but not eukaryotic, ribosomes (Ch. 5)
- Mutations in mismatch repair proteins lead to hereditary nonpolyposis colorectal cancer (Ch. 5)
- Nucleotide excision-repair proteins were identified in patients with xeroderma pigmentosum (Ch. 5)
- Human viruses HTLV, HIV-1, and HPV initiate infection by binding to specific cell-surface molecules, and some integrate their genomes into the host cell's DNA (Ch. 5)
- The sickle-cell allele is an example of one that exhibits both dominant and recessive properties depending on the phenotype being examined (Ch. 6)
- DNA microarrays can be useful as medical diagnostic tools (Ch. 6)
- Recombinant DNA techniques are used to mass-produce therapeutically useful proteins such as insulin and G-CSF (Ch. 6)
- Most cases of genetic diseases are caused by inherited rather than de novo mutations (Ch. 6)
- A *CFTR* knockout mouse line is useful in studying cystic fibrosis (Ch. 6)
- ABO blood types are determined by the carbohydrates attached to glycoproteins on the surfaces of erythrocytes (Ch. 7)

- Atherosclerosis, marked by accumulation of cholesterol, other lipids, and other biological substances in an artery, is responsible for the majority of deaths due to cardiovascular disease in the United States (Ch. 7)
- Microsatellite repeats have a tendency to expand and can cause neuromuscular diseases such as Huntington disease and myotonic dystrophy (Ch. 8)
- L1 transposable elements can cause genetic diseases by inserting into new sites in the genome (Ch. 8)
- Exon shuffling can result in bacterial resistance to antibiotics, a growing challenge in hospitals (Ch. 8)
- The *NF1* gene, which is mutated in patients with neurofibromatosis, is an example of how bioinformatics techniques can be used to identify the molecular basis of a genetic disease (Ch. 8)
- Telomerase is abnormally activated in most cancers (Ch. 8)
- TFIIF subunits were first identified based on mutations in those subunits that cause defects in DNA repair associated with a stalled RNA polymerase (Ch. 9)
- HIV encodes the Tat protein, which inhibits termination of transcription by RNA polymerase II (Ch. 9)
- Synthetic oligonucleotides are being used in treatment of Duchenne muscular dystrophy (DMD) (Ch. 10)
- Mutations in splicing enhancers can cause exon skipping, as in spinal muscular atrophy (Ch. 10)
- Expansion of microsatellite repeats in genes expressed in neurons can alter their relative abundance in different regions of the central nervous system, resulting in neurological disorders (Ch. 10)
- Thalassemia commonly results from mutations in globin-gene splice sites that decrease splicing efficiency but do not prevent association of the pre-mRNA with snRNPs (Ch. 10)
- Genes encoding components of the mTORC1 pathway are mutated in many cancers, and mTOR inhibitors combined with other therapies may suppress tumor growth (Ch. 10)
- Aquaporin 2 levels control the rate of water resorption from urine being formed by the kidney (Ch. 11)
- Certain cystic fibrosis patients are being treated with a small molecule that allows a mutant protein to traffic normally to the cell surface (Ch. 11)
- SGLT2 inhibitors are in development or have been approved for treatment of type II diabetes (Ch. 11)
- Antidepressants and other therapeutic drugs, as well as drugs of abuse, target Na<sup>+</sup>-powered symporters because of their role in the reuptake and recycling of neurotransmitters (Ch. 11)

- Drugs that inhibit the  $\text{Na}^+/\text{K}^+$  ATPase in cardiac muscle cells are used in treating congestive heart failure (Ch. 11)
- Oral rehydration therapy is a simple, effective means of treating cholera and other diseases caused by intestinal pathogens (Ch. 11)
- Mutations in CIC-7, a chloride ion channel, result in defective bone resorption characteristic of the hereditary bone disease osteopetrosis (Ch. 11)
- The sensitivity of mitochondrial ribosomes to the aminoglycoside class of antibiotics, including chloramphenicol, can cause toxicity in patients (Ch. 12)
- Mutations and large deletions in mtDNA cause certain diseases, such as Leber's hereditary optic neuropathy and Kearns-Sayre syndrome (Ch. 12)
- Cyanide is toxic because it blocks ATP production in mitochondria (Ch. 12)
- Reduction in amounts of cardiolipin, as well as an abnormal cardiolipin structure, results in the heart and skeletal muscle defects and other abnormalities that characterize Barth's syndrome (Ch. 12)
- Reactive oxygen species are by-products of electron transport that can damage cells (Ch. 12)
- ATP/ADP antiporter activity was first studied over 2000 years ago through the examination of the effects of poisonous herbs (Ch. 12)
- There are two related subtypes of thermogenic fat cells (Ch. 12)
- A hereditary form of emphysema results from misfolding of proteins in the endoplasmic reticulum (Ch. 13)
- Autosomal recessive mutations that cause defective peroxisome assembly can lead to several developmental defects often associated with craniofacial abnormalities, such as those associated with Zellweger syndrome (Ch. 13)
- Certain cases of cystic fibrosis are caused by mutations in the CFTR protein that prevent movement of this chloride channel from the ER to the cell surface (Ch. 14)
- Study of lysosomal storage diseases has revealed key elements of the lysosomal sorting pathway (Ch. 14)
- The hereditary disease familial hypercholesterolemia results from a variety of mutations in the *LDLR* gene (Ch. 14)
- Therapeutic drugs using the  $\text{TNF}\alpha$ -binding domain of  $\text{TNF}\alpha$  receptor are used to treat arthritis and other inflammatory conditions (Ch. 15)
- Monoclonal antibodies that bind HER2 and thereby block signaling by EGF are useful in treating breast tumors that overexpress HER2 (Ch. 15)
- The agonist isoproterenol binds more strongly to epinephrine-responsive receptors on bronchial smooth muscle

- cells than does epinephrine, and is used to treat bronchial asthma, chronic bronchitis, and emphysema (Ch. 15)
- Some bacterial toxins (e.g., *Bordetella pertussis*, *Vibrio cholerae*, certain strains of *E. coli*) catalyze a modification of a G protein in intestinal cells, increasing intracellular cAMP, which leads to loss of electrolytes and fluids (Ch. 15)
  - Nitroglycerin decomposes to NO, a natural signaling molecule that, when used to treat angina, increases blood flow to the heart (Ch. 15)
  - PDE inhibitors elevate cGMP in vascular smooth muscle cells and have been developed to treat erectile dysfunction (Ch. 15)
  - Many tumors contain inactivating mutations in either TGF- $\beta$  receptors or Smad proteins and are resistant to growth inhibition by TGF- $\beta$  (Ch. 16)
  - Epo and G-CSF are used to boost red blood cells and neutrophils, respectively, in patients with kidney disease and during certain cancer therapies that affect blood cell formation in the bone marrow (Ch. 16)
  - Many cases of SCID result from a deficiency in the IL-2 receptor gamma chain and can be treated by gene therapy (Ch. 16)
  - Mutant Ras proteins that bind but cannot hydrolyze GTP, and are therefore locked in an active GTP-bound state, contribute to oncogenic transformation (Ch. 16)
  - Potent and selective inhibitors of Raf are being clinically tested in patients with melanomas caused by mutant Raf proteins (Ch. 16)
  - The deletion of the *PTEN* gene in multiple types of advanced cancers results in the loss of the PTEN protein, contributing to the uncontrolled growth of cells (Ch. 16)
  - High levels of free  $\beta$ -catenin, caused by aberrant hyperactive Wnt signaling, are associated with the activation of growth-promoting genes in many cancers (Ch. 16)
  - Inappropriate activation of Hh signaling associated with primary cilia is the cause of several types of tumors (Ch. 16)
  - Increased activity of ADAMs can promote cancer development and heart disease (Ch. 16)
  - The brains of patients with Alzheimer's disease accumulate amyloid plaques containing aggregates of the  $\text{A}\beta_{42}$  peptide (Ch. 16)
  - Diabetes mellitus is characterized by impaired regulation of blood glucose, which can lead to major complications if left untreated (Ch. 16)
  - Hereditary spherocytic anemias can be caused by mutations in spectrin, band 4.1, and ankyrin (Ch. 17)
  - Duchenne muscular dystrophy affects the protein dystrophin, resulting in progressive weakening of skeletal muscle (Ch. 17)

- Hypertrophic cardiomyopathies result from various mutations in proteins of the heart contractile machinery (Ch. 17)
- Blood tests that measure the level of cardiac-specific troponins are used to determine the severity of a heart attack (Ch. 17)
- Some drugs (e.g., colchicine) bind tubulin dimers and restrain them from polymerizing into microtubules, whereas others (e.g., taxol) bind microtubules and prevent depolymerization (Ch. 18)
- Defects in LIS1 cause Miller-Dieker lissencephaly in early brain development, leading to abnormalities (Ch. 18)
- Some diseases, such as ADPKD and Bardet-Biedl syndrome, have been traced to defects in primary cilia and intraflagellar transport (Ch. 18)
- Keratin filaments are important to maintaining the structural integrity of epithelial tissues by mechanically reinforcing the connections between cells (Ch. 18)
- Mutations in the human gene for lamin A cause a wide variety of diseases termed laminopathies (Ch. 18)
- In cohesinopathies, mutations in cohesion subunits or cohesion loading factors disrupt expression of genes critical for development, resulting in limb and craniofacial abnormalities and intellectual disabilities (Ch. 19)
- Aneuploidy leads to misregulation of genes and can contribute to cancer development (Ch. 19)
- Aneuploid eggs are largely caused by chromosome mis-segregation in meiosis I or nondisjunction, leading to miscarriage or Down syndrome (Ch. 19)
- The protein CDHR3 enables class C rhinoviruses (RV-C) to bind to airway epithelial cells, enter them, and replicate, causing respiratory diseases and exacerbating asthma (Ch. 20)
- The cadherin desmoglein is the predominant target of autoantibodies in the skin disease pemphigus vulgaris (Ch. 20)
- Some pathogens, such as hepatitis C virus and the enteric bacterium *Vibrio cholerae*, have evolved to exploit the molecules in tight junctions (Ch. 20)
- Mutations in connexin genes cause a variety of diseases (Ch. 20)
- Defects in the glomerular basement membrane can lead to renal failure (Ch. 20)
- In cells deprived of ascorbate, the pro- $\alpha$  collagen chains are not hydroxylated sufficiently to form the structural support of collagen necessary for healthy blood vessels, tendons, and skin, resulting in scurvy (Ch. 20)
- Mutations affecting type I collagen and its associated proteins cause a variety of diseases, including osteogenesis imperfecta (Ch. 20)
- A variety of diseases, often involving skeletal and cardiovascular abnormalities (e.g., Marfan syndrome), result from mutations in the genes encoding the structural proteins of elastic fibers or the proteins that contribute to their proper assembly (Ch. 20)
- Connections between the extracellular matrix and cytoskeleton are defective in muscular dystrophy (Ch. 20)
- Leukocyte-adhesion deficiency is caused by a genetic defect that results in the leukocytes' inability to fight infection, thereby increasing susceptibility to repeated bacterial infections (Ch. 20)
- The stem cells in transplanted bone marrow can generate all types of functional blood cells, which makes such transplants useful for patients with certain hereditary blood diseases as well as cancer patients who have received irradiation or chemotherapy (Ch. 21)
- Channelopathies, including some forms of epilepsy, are caused by mutations in genes that encode ion channels (Ch. 22)
- The topical anesthetic lidocaine works by binding to amino acid residues along the voltage-gated Na<sup>+</sup> channel, locking it in the open but occluded state (Ch. 22)
- The cause of multiple sclerosis is not known, but seems to involve either the body's production of auto-antibodies that react with myelin basic protein or the secretion of proteases that destroy myelin proteins (Ch. 22)
- Peripheral myelin is a target of autoimmune disease, mainly involving the formation of antibodies against P<sub>0</sub> (Ch. 22)
- The key role of VAMP in neurotransmitter exocytosis can be seen in the mechanism of action of botulinum toxin (Ch. 22)
- Neurotransmitter transporters are targets of a variety of drugs of abuse (e.g., cocaine) as well as therapeutic drugs commonly used in psychiatry (e.g., Prozac, Zoloft, Paxil) (Ch. 22)
- Nicotinic acetylcholine receptors produced in brain neurons are important in learning and memory; loss of these receptors is observed in schizophrenia, epilepsy, drug addiction, and Alzheimer's disease (Ch. 22)
- Studies suggest that the voltage-gated Na<sup>+</sup> channel Nav1.7 is a key component in the perception of pain (Ch. 22)
- People vary significantly in sense of smell (Ch. 22)
- Synaptic translation of localized mRNAs is critical to the formation and the experience-dependent plasticity of neural circuits, and alterations in this process result in neurodevelopmental and cognitive disorders (Ch. 22)
- The immunosuppressant drug cyclosporine inhibits calcineurin activity through the formation of a

cyclosporine-cyclophilin complex, thus enabling successful allogenic tissue transplantation (Ch. 23)

- Vaccines elicit protective immunity against a variety of pathogens (Ch. 23)
- Increased understanding of the molecular cell biology of tumors is revolutionizing the way cancers are diagnosed and treated (Ch. 24)

## Plant Biology Connections

Developments in agriculture, environmental science, and alternative energy production have demonstrated that the molecular cell biology of plants is increasingly relevant to our lives. Understanding photosynthesis and chloroplasts is just the beginning of plant biology. Throughout the text, we have highlighted plant-specific topics, including aspects of cell structure and function that are unique to plants, plant development, and plant biotechnology applications directed toward solving problems in agriculture and medicine. ■

- Vascular plants have rigid cell walls and use turgor pressure to stand upright and grow (Ch. 11)
- Transgenic plants have been produced that overexpress the vacuolar  $\text{Na}^+/\text{H}^+$  antiporter, and can therefore grow successfully in soils containing high salt concentrations (Ch. 11)
- Editing of plant mitochondrial RNA transcripts can convert cytosine residues to uracil residues (Ch. 12)
- Photosynthesis is an important process for synthesizing ATP (Ch. 12)
- Chloroplast DNAs are evolutionarily younger and show less structural diversity than mitochondrial DNAs (Ch. 12)
- Chloroplast transformation has led to engineered plants that are resistant to infections as well as plants that can be used to make protein drugs (Ch. 12)
- In giant green algae such as *Nitella*, the cytosol flows rapidly due to use of myosin V (Ch. 17)
- Formation of the spindle and cytokinesis have unique features in plants (Ch. 18)
- Meristems are niches for stem cells in plants (Ch. 21)
- A negative feedback loop maintains the size of the shoot apical stem-cell population (Ch. 21)
- The root meristem resembles the shoot meristem in structure and function (Ch. 21)

## MEDIA AND SUPPLEMENTS

**LaunchPad for *Molecular Cell Biology*** is a robust teaching and learning tool with all instructor and student resources as well as a fully interactive e-Book.

### Student Resources

Interactive **Case Studies** guide students through applied problems related to important concepts; topics include cancer, diabetes, and cystic fibrosis.

"We isolated proteins from the cells, ran protein samples out on 8 percent polyacrylamide gels, and transferred the proteins to nitrocellulose membranes for blotting with HER-specific antibodies. Based on the RT-PCR data, which antibody or antibodies do you think we tested?"

A.  $\alpha$ -HER1 antibody ☒ Yes ☒ No ✓  
B.  $\alpha$ -HER2 antibody ☒ Yes ☒ No ✓  
C.  $\alpha$ -HER3 antibody ☒ Yes ☒ No ✓  
D.  $\alpha$ -HER4 antibody ☒ Yes ☒ No ✓

Feedback  
Correct.

"Since the RT-PCR data showed expression of HER2 and HER3, we performed two Western blots, one using the  $\alpha$ -HER2 antibody and the other using the  $\alpha$ -HER3 antibody. The expected molecular weight of HER2 is approximately 138 kDa, and the expected molecular weight of HER3 is about 135 kDa."

$\alpha$ -HER2 antibody				$\alpha$ -HER3 antibody			
MW	Normal	PC	PCX	MW	Normal	PC	PCX
140 kDa				140 kDa			
130 kDa				130 kDa			

MW = molecular weight standard  
Normal = normal pancreatic cells  
PC = pancreatic cells not expressing protein X  
PCX = pancreatic cells expressing protein X

**Case Study** "To Kill a Cancer Cell" leads students through the experiments needed to identify a perturbed signaling pathway.

Over 60 **Animations** based on key figures from the text illustrate difficult or important structures and processes.

**Animation** of Figure 16-3b depicts signal transduction in the TGF- $\beta$ /Smad pathway.

**Concept Check** quizzes test student understanding of the most important concepts of each section.

**LearningCurve**, a self-paced adaptive quizzing tool for students, tailors questions to their target difficulty level and encourages them to incorporate content from the text into their study routine.

A collection of **Videos** shows students real cell processes as they appear in the lab.

**Analyze the Data** questions ask students to apply critical thinking and data analysis skills to solving complex problems.

**Classic Experiments** introduce students to the details of a historical experiment important to the cell and molecular biology fields.

### Instructor Resources

All **Figures and Photos** from the text are optimized for classroom presentation and provided in several formats and with and without labels.

A comprehensive **Test Bank** provides a variety of questions for creating quizzes and exams.

**Lecture Slides** built around high-quality versions of text figures provide a starting point for in-class presentations.

**Clicker Questions** in slide format help instructors promote active learning in the classroom.

A PDF **Solutions Manual** provides answers to the Review the Concepts questions at the end of each chapter. An answer key for Analyze the Data questions is also included.

## ACKNOWLEDGMENTS

In updating, revising, and rewriting this book, we were given invaluable help by many colleagues. We thank the following people who generously gave of their time and expertise by making contributions to specific chapters in their areas of interest, providing us with detailed information about their courses, or by reading and commenting on one or more chapters:

David Agard, *University of California, San Francisco, and Howard Hughes Medical Institute*  
Ann Aguanno, *Marymount Manhattan College*  
Stephen Amato, *Northeastern University*  
Shivanthi Anandan, *Drexel University*  
Kenneth Balazovich, *University of Michigan*  
Amit Banerjee, *Wayne State University*  
Lisa Banner, *California State University, Northridge*  
Benjamin Barad, *University of California, San Francisco*  
Kenneth Belanger, *Colgate University*  
Andrew Bendall, *University of Guelph*  
Eric Betzig, *Howard Hughes Medical Institute*  
Subhrajit Bhattacharya, *Auburn University*  
Ashok Bidwai, *West Virginia University*  
David Bilder, *University of California, Berkeley*  
Elizabeth Blinstrup-Good, *University of Illinois*

We would also like to express our gratitude and appreciation to all those who contributed to the resources on LaunchPad. A full list of these contributors is posted on the *Molecular Cell Biology*, Eighth Edition, LaunchPad.

This edition would not have been possible without the careful and committed collaboration of our publishing partners at W. H. Freeman and Company. We thank Kate Ahr Parker, Beth Cole, Will Moore, Liz Geller, Norma Sims Roche, Blake Logan, Janice Donnola, Jennifer MacMillan, Sheena Goldstein, Teri Stratford, Nandini Ahuja, Abigail Fagan, Felicia Ruocco, Hilary Newman, Amy Thorne, Kathleen Wisneski, and Paul Rohloff for their labor and for their willingness to work overtime to produce a book that excels in every way.

In particular, we would like to acknowledge the talent and commitment of our text editors, Erica Champion and

Heather Moffat. They are remarkable editors. Thank you for all you've done in this edition.

We are also indebted to H. Adam Steinberg for his pedagogical insight and his development of beautiful molecular models and illustrations.

We would like to acknowledge those whose direct contributions to previous editions continue to influence in this edition, especially Ruth Steyn.

Thanks to our own staff: Sally Bittancourt, Diane Bush, Mary Anne Donovan, Carol Eng, James Evans, George Kokkinogenis, Julie Knight, Guicky Waller, Nicki Watson, and Rob Welsh.

Finally, special thanks to our families for inspiring us and for granting us the time it takes to work on such a book and to our mentors and advisers for encouraging us in our studies and teaching us much of what we know: (*Harvey Lodish*) my wife, Pamela; my children and grandchildren Heidi and Eric Steinert and Emma and Andrew Steinert; Martin Lodish, Kristin Schardt, and Sophia, Joshua, and

Tobias Lodish; and Stephanie Lodish, Bruce Peabody, and Isaac and Violet Peabody; mentors Norton Zinder and Sydney Brenner; and also David Baltimore and Jim Darnell for collaborating on the first editions of this book; (*Arnold Berk*) my wife Sally, Jerry Berk, Shirley Berk, Angelina Smith, David Clayton, and Phil Sharp; (*Chris A. Kaiser*) my wife Kathy O'Neill, my mentors David Botstein and Randy Schekman; (*Monty Krieger*) my wife Nancy Krieger, parents I. Jay Krieger and Mildred Krieger, children Joshua and Ilana Krieger and Jonathan Krieger and Sofia Colucci, and grandchild Joaquin Krieger; my mentors Robert Stroud, Michael Brown, and Joseph Goldstein; (*Anthony Bretscher*) my wife Janice and daughters Heidi and Erika, and advisers A. Dale Kaiser and Klaus Weber; (*Hidde Ploegh*) my wife Anne Mahon; (*Angelika Amon*) my husband Johannes Weis, Theresa and Clara Weis, Gerry Fink and Frank Solomon; (*Kelsey C. Martin*) my husband Joel Braslow, children Seth, Ben, Sam, and Maya, father George M. Martin, and mentors Ari Helenius and Eric Kandel.

## CONTENTS IN BRIEF

### **Part I Chemical and Molecular Foundations**

- 1 Molecules, Cells, and Model Organisms 1
- 2 Chemical Foundations 31
- 3 Protein Structure and Function 67
- 4 Culturing and Visualizing Cells 129

### **Part II Biomembranes, Genes, and Gene Regulation**

- 5 Fundamental Molecular Genetic Mechanisms 167
- 6 Molecular Genetic Techniques 223
- 7 Biomembrane Structure 271
- 8 Genes, Genomics, and Chromosomes 301
- 9 Transcriptional Control of Gene Expression 353
- 10 Post-transcriptional Gene Control 417

### **Part III Cellular Organization and Function**

- 11 Transmembrane Transport of Ions and Small Molecules 473
- 12 Cellular Energetics 513
- 13 Moving Proteins into Membranes and Organelles 583
- 14 Vesicular Traffic, Secretion, and Endocytosis 631
- 15 Signal Transduction and G Protein–Coupled Receptors 673
- 16 Signaling Pathways That Control Gene Expression 719
- 17 Cell Organization and Movement I: Microfilaments 775
- 18 Cell Organization and Movement II: Microtubules and Intermediate Filaments 821
- 19 The Eukaryotic Cell Cycle 873

### **Part IV Cell Growth and Differentiation**

- 20 Integrating Cells into Tissues 921
- 21 Stem Cells, Cell Asymmetry, and Cell Death 975
- 22 Cells of the Nervous System 1025
- 23 Immunology 1079
- 24 Cancer 1135

# CONTENTS

Preface

## Part I Chemical and Molecular Foundations

### 1 Molecules, Cells, and Model Organisms 1

#### 1.1 The Molecules of Life 5

Proteins Give Cells Structure and Perform Most Cellular Tasks 7

Nucleic Acids Carry Coded Information for Making Proteins at the Right Time and Place 7

Phospholipids Are the Conserved Building Blocks of All Cellular Membranes 9

#### 1.2 Prokaryotic Cell Structure and Function 10

Prokaryotes Comprise Two Kingdoms: Archaea and Eubacteria 10

*Escherichia coli* Is Widely Used in Biological Research 11

#### 1.3 Eukaryotic Cell Structure and Function 12

The Cytoskeleton Has Many Important Functions 12

The Nucleus Contains the DNA Genome, RNA Synthetic Apparatus, and a Fibrous Matrix 12

Eukaryotic Cells Contain a Large Number of Internal Membrane Structures 14

Mitochondria Are the Principal Sites of ATP Production in Aerobic Cells 18

Chloroplasts Contain Internal Compartments in Which Photosynthesis Takes Place 18

All Eukaryotic Cells Use a Similar Cycle to Regulate Their Division 18

#### 1.4 Unicellular Eukaryotic Model Organisms 19

Yeasts Are Used to Study Fundamental Aspects of Eukaryotic Cell Structure and Function 19

Mutations in Yeast Led to the Identification of Key Cell Cycle Proteins 21

vii Studies in the Alga *Chlamydomonas reinhardtii* Led to the Development of a Powerful Technique to Study Brain Function 22

The Parasite That Causes Malaria Has Novel Organelles That Allow It to Undergo a Remarkable Life Cycle 22

### 1.5 Metazoan Structure, Differentiation, and Model Organisms 24

Multicellularity Requires Cell-Cell and Cell-Matrix Adhesions 24

Epithelia Originated Early in Evolution 24

Tissues Are Organized into Organs 24

Genomics Has Revealed Important Aspects of Metazoan Evolution and Cell Function 24

Embryonic Development Uses a Conserved Set of Master Transcription Factors 25

Planaria Are Used to Study Stem Cells and Tissue Regeneration 27

Invertebrates, Fish, Mice, and Other Organisms Serve as Experimental Systems for Study of Human Development and Disease 28

Genetic Diseases Elucidate Important Aspects of Cell Function 28

The Following Chapters Present Much Experimental Data That Explains How We Know What We Know About Cell Structure and Function 29

### 2 Chemical Foundations 31

#### 2.1 Covalent Bonds and Noncovalent Interactions 33

The Electronic Structure of an Atom Determines the Number and Geometry of the Covalent Bonds It Can Make 33

Electrons May Be Shared Equally or Unequally in Covalent Bonds 34

Covalent Bonds Are Much Stronger and More Stable Than Noncovalent Interactions 36

Ionic Interactions Are Attractions Between Oppositely Charged Ions 36

Hydrogen Bonds Are Noncovalent Interactions That Determine the Water Solubility of Uncharged Molecules 37

Van der Waals Interactions Are Weak Attractive Interactions Caused by Transient Dipoles 38

The Hydrophobic Effect Causes Nonpolar Molecules to Adhere to One Another	39	NAD <sup>+</sup> and FAD Couple Many Biological Oxidation and Reduction Reactions	63
Molecular Complementarity Due to Noncovalent Interactions Leads to a Lock-and-Key Fit Between Biomolecules	40	<b>3 Protein Structure and Function</b>	<b>67</b>
<b>2.2 Chemical Building Blocks of Cells</b>	<b>41</b>	<b>3.1 Hierarchical Structure of Proteins</b>	<b>69</b>
Amino Acids Differing Only in Their Side Chains Compose Proteins	42	The Primary Structure of a Protein Is Its Linear Arrangement of Amino Acids	69
Five Different Nucleotides Are Used to Build Nucleic Acids	45	Secondary Structures Are the Core Elements of Protein Architecture	70
Monosaccharides Covalently Assemble into Linear and Branched Polysaccharides	46	Tertiary Structure Is the Overall Folding of a Polypeptide Chain	72
Phospholipids Associate Noncovalently to Form the Basic Bilayer Structure of Biomembranes	48	There Are Four Broad Structural Categories of Proteins	72
<b>2.3 Chemical Reactions and Chemical Equilibrium</b>	<b>51</b>	Different Ways of Depicting the Conformation of Proteins Convey Different Types of Information	74
A Chemical Reaction Is in Equilibrium When the Rates of the Forward and Reverse Reactions Are Equal	52	Structural Motifs Are Regular Combinations of Secondary Structures	75
The Equilibrium Constant Reflects the Extent of a Chemical Reaction	52	Domains Are Modules of Tertiary Structure	76
Chemical Reactions in Cells Are at Steady State	52	Multiple Polypeptides Assemble into Quaternary Structures and Supramolecular Complexes	78
Dissociation Constants of Binding Reactions Reflect the Affinity of Interacting Molecules	53	Comparing Protein Sequences and Structures Provides Insight into Protein Function and Evolution	79
Biological Fluids Have Characteristic pH Values	54	<b>3.2 Protein Folding</b>	<b>81</b>
Hydrogen Ions Are Released by Acids and Taken Up by Bases	55	Planar Peptide Bonds Limit the Shapes into Which Proteins Can Fold	81
Buffers Maintain the pH of Intracellular and Extracellular Fluids	55	The Amino Acid Sequence of a Protein Determines How It Will Fold	81
<b>2.4 Biochemical Energetics</b>	<b>57</b>	Folding of Proteins in Vivo Is Promoted by Chaperones	82
Several Forms of Energy Are Important in Biological Systems	57	Protein Folding Is Promoted by Proline Isomerases	86
Cells Can Transform One Type of Energy into Another	58	Abnormally Folded Proteins Can Form Amyloids That Are Implicated in Diseases	87
The Change in Free Energy Determines If a Chemical Reaction Will Occur Spontaneously	58	<b>3.3 Protein Binding and Enzyme Catalysis</b>	<b>89</b>
The $\Delta G^\circ$ of a Reaction Can Be Calculated from Its $K_{eq}$	60	Specific Binding of Ligands Underlies the Functions of Most Proteins	89
The Rate of a Reaction Depends on the Activation Energy Necessary to Energize the Reactants into a Transition State	60	Enzymes Are Highly Efficient and Specific Catalysts	90
Life Depends on the Coupling of Unfavorable Chemical Reactions with Energetically Favorable Ones	61	An Enzyme's Active Site Binds Substrates and Carries Out Catalysis	91
Hydrolysis of ATP Releases Substantial Free Energy and Drives Many Cellular Processes	61	Serine Proteases Demonstrate How an Enzyme's Active Site Works	92
ATP Is Generated During Photosynthesis and Respiration	62	Enzymes in a Common Pathway Are Often Physically Associated with One Another	96
		<b>3.4 Regulating Protein Function</b>	<b>97</b>
		Regulated Synthesis and Degradation of Proteins Is a Fundamental Property of Cells	97
		The Proteasome Is a Molecular Machine Used to Degrade Proteins	97

Ubiquitin Marks Cytosolic Proteins for Degradation in Proteasomes	99	Growth of Cells in Two-Dimensional and Three-Dimensional Culture Mimics the In Vivo Environment	133
Noncovalent Binding Permits Allosteric, or Cooperative, Regulation of Proteins	100	Hybridomas Produce Abundant Monoclonal Antibodies	135
Noncovalent Binding of Calcium and GTP Are Widely Used as Allosteric Switches to Control Protein Activity	101	A Wide Variety of Cell Biological Processes Can Be Studied with Cultured Cells	136
Phosphorylation and Dephosphorylation Covalently Regulate Protein Activity	102	Drugs Are Commonly Used in Cell Biological Research	136
Ubiquitinylation and Deubiquitinylation Covalently Regulate Protein Activity	103		
Proteolytic Cleavage Irreversibly Activates or Inactivates Some Proteins	104	<b>4.2 Light Microscopy: Exploring Cell Structure and Visualizing Proteins Within Cells</b>	<b>139</b>
Higher-Order Regulation Includes Control of Protein Location	105	The Resolution of the Conventional Light Microscope Is About 0.2 $\mu\text{m}$	139
<b>3.5 Purifying, Detecting, and Characterizing Proteins</b>	<b>105</b>	Phase-Contrast and Differential-Interference-Contrast Microscopy Visualize Unstained Live Cells	141
Centrifugation Can Separate Particles and Molecules That Differ in Mass or Density	106	Imaging Subcellular Details Often Requires That Specimens Be Fixed, Sectioned, and Stained	142
Electrophoresis Separates Molecules on the Basis of Their Charge-to-Mass Ratio	107	Fluorescence Microscopy Can Localize and Quantify Specific Molecules in Live Cells	143
Liquid Chromatography Resolves Proteins by Mass, Charge, or Affinity	109	Intracellular Ion Concentrations Can Be Determined with Ion-Sensitive Fluorescent Dyes	143
Highly Specific Enzyme and Antibody Assays Can Detect Individual Proteins	111	Immunofluorescence Microscopy Can Detect Specific Proteins in Fixed Cells	144
Radioisotopes Are Indispensable Tools for Detecting Biological Molecules	114	Tagging with Fluorescent Proteins Allows the Visualization of Specific Proteins in Live Cells	146
Mass Spectrometry Can Determine the Mass and Sequence of Proteins	116	Deconvolution and Confocal Microscopy Enhance Visualization of Three-Dimensional Fluorescent Objects	147
Protein Primary Structure Can Be Determined by Chemical Methods and from Gene Sequences	118	Two-Photon Excitation Microscopy Allows Imaging Deep into Tissue Samples	149
Protein Conformation Is Determined by Sophisticated Physical Methods	119	TIRF Microscopy Provides Exceptional Imaging in One Focal Plane	150
<b>3.6 Proteomics</b>	<b>122</b>	FRAP Reveals the Dynamics of Cellular Components	151
Proteomics Is the Study of All or a Large Subset of Proteins in a Biological System	122	FRET Measures Distance Between Fluorochromes	152
Advanced Techniques in Mass Spectrometry Are Critical to Proteomic Analysis	123	Super-Resolution Microscopy Can Localize Proteins to Nanometer Accuracy	153
		Light-Sheet Microscopy Can Rapidly Image Cells in Living Tissue	155
<b>4 Culturing and Visualizing Cells</b>	<b>129</b>	<b>4.3 Electron Microscopy: High-Resolution Imaging</b>	<b>156</b>
<b>4.1 Growing and Studying Cells in Culture</b>	<b>130</b>	Single Molecules or Structures Can Be Imaged Using a Negative Stain or Metal Shadowing	157
Culture of Animal Cells Requires Nutrient-Rich Media and Special Solid Surfaces	130	Cells and Tissues Are Cut into Thin Sections for Viewing by Electron Microscopy	158
Primary Cell Cultures and Cell Strains Have a Finite Life Span	131	Immunoelectron Microscopy Localizes Proteins at the Ultrastructural Level	159
Transformed Cells Can Grow Indefinitely in Culture	132	Cryoelectron Microscopy Allows Visualization of Specimens Without Fixation or Staining	160
Flow Cytometry Separates Different Cell Types	132		

Scanning Electron Microscopy of Metal-Coated Specimens Reveals Surface Features	161
---	-----

#### **4.4 Isolation of Cell Organelles** 161

Disruption of Cells Releases Their Organelles and Other Contents	162
Centrifugation Can Separate Many Types of Organelles	162
Organelle-Specific Antibodies Are Useful in Preparing Highly Purified Organelles	162
Proteomics Reveals the Protein Composition of Organelles	164

## **Part II Biomembranes, Genes, and Gene Regulation**

### **5 Fundamental Molecular Genetic Mechanisms** 167

#### **5.1 Structure of Nucleic Acids** 169

A Nucleic Acid Strand Is a Linear Polymer with End-to-End Directionality	170
Native DNA Is a Double Helix of Complementary Antiparallel Strands	170
DNA Can Undergo Reversible Strand Separation	172
Torsional Stress in DNA Is Relieved by Enzymes	174
Different Types of RNA Exhibit Various Conformations Related to Their Functions	174

#### **5.2 Transcription of Protein-Coding Genes and Formation of Functional mRNA** 176

A Template DNA Strand Is Transcribed into a Complementary RNA Chain by RNA Polymerase	176
Organization of Genes Differs in Prokaryotic and Eukaryotic DNA	179
Eukaryotic Precursor mRNAs Are Processed to Form Functional mRNAs	180
Alternative RNA Splicing Increases the Number of Proteins Expressed from a Single Eukaryotic Gene	181

#### **5.3 The Decoding of mRNA by tRNAs** 183

Messenger RNA Carries Information from DNA in a Three-Letter Genetic Code	183
The Folded Structure of tRNA Promotes Its Decoding Functions	185
Nonstandard Base Pairing Often Occurs Between Codons and Anticodons	186
Amino Acids Become Activated When Covalently Linked to tRNAs	188

#### **5.4 Stepwise Synthesis of Proteins on Ribosomes** 188

Ribosomes Are Protein-Synthesizing Machines	188
Methionyl-tRNA <sup>Met</sup> Recognizes the AUG Start Codon	190
Eukaryotic Translation Initiation Usually Occurs at the First AUG Downstream from the 5' End of an mRNA	191
During Chain Elongation Each Incoming Aminoacyl-tRNA Moves Through Three Ribosomal Sites	193
Translation Is Terminated by Release Factors When a Stop Codon Is Reached	195
Polysomes and Rapid Ribosome Recycling Increase the Efficiency of Translation	195
GTPase-Superfamily Proteins Function in Several Quality-Control Steps of Translation	195
Nonsense Mutations Cause Premature Termination of Protein Synthesis	196

#### **5.5 DNA Replication** 197

DNA Polymerases Require a Primer to Initiate Replication	197
Duplex DNA Is Unwound, and Daughter Strands Are Formed at the DNA Replication Fork	199
Several Proteins Participate in DNA Replication	199
DNA Replication Occurs Bidirectionally from Each Origin	201

#### **5.6 DNA Repair and Recombination** 203

DNA Polymerases Introduce Copying Errors and Also Correct Them	203
Chemical and Radiation Damage to DNA Can Lead to Mutations	203
High-Fidelity DNA Excision-Repair Systems Recognize and Repair Damage	204
Base Excision Repairs T-G Mismatches and Damaged Bases	205
Mismatch Excision Repairs Other Mismatches and Small Insertions and Deletions	205
Nucleotide Excision Repairs Chemical Adducts that Distort Normal DNA Shape	206
Two Systems Use Recombination to Repair Double-Strand Breaks in DNA	207
Homologous Recombination Can Repair DNA Damage and Generate Genetic Diversity	209

#### **5.7 Viruses: Parasites of the Cellular Genetic System** 212

Most Viral Host Ranges Are Narrow	212
Viral Capsids Are Regular Arrays of One or a Few Types of Protein	213

Viruses Can Be Cloned and Counted in Plaque Assays	213
Lytic Viral Growth Cycles Lead to Death of Host Cells	213
Viral DNA Is Integrated into the Host-Cell Genome in Some Nonlytic Viral Growth Cycles	216

## 6 Molecular Genetic Techniques 223

### 6.1 Genetic Analysis of Mutations to Identify and Study Genes 224

Recessive and Dominant Mutant Alleles Generally Have Opposite Effects on Gene Function	224
Segregation of Mutations in Breeding Experiments Reveals Their Dominance or Recessivity	225
Conditional Mutations Can Be Used to Study Essential Genes in Yeast	227
Recessive Lethal Mutations in Diploids Can Be Identified by Inbreeding and Maintained in Heterozygotes	228
Complementation Tests Determine Whether Different Recessive Mutations Are in the Same Gene	229
Double Mutants Are Useful in Assessing the Order in Which Proteins Function	230
Genetic Suppression and Synthetic Lethality Can Reveal Interacting or Redundant Proteins	231
Genes Can Be Identified by Their Map Position on the Chromosome	232

### 6.2 DNA Cloning and Characterization 234

Restriction Enzymes and DNA Ligases Allow Insertion of DNA Fragments into Cloning Vectors	234
Isolated DNA Fragments Can Be Cloned into <i>E. coli</i> Plasmid Vectors	236
Yeast Genomic Libraries Can Be Constructed with Shuttle Vectors and Screened by Functional Complementation	237
cDNA Libraries Represent the Sequences of Protein-Coding Genes	238
The Polymerase Chain Reaction Amplifies a Specific DNA Sequence from a Complex Mixture	239
Cloned DNA Molecules Can Be Sequenced Rapidly by Methods Based on PCR	243

### 6.3 Using Cloned DNA Fragments to Study Gene Expression 246

Hybridization Techniques Permit Detection of Specific DNA Fragments and mRNAs	246
DNA Microarrays Can Be Used to Evaluate the Expression of Many Genes at One Time	247
Cluster Analysis of Multiple Expression Experiments Identifies Co-regulated Genes	248
<i>E. coli</i> Expression Systems Can Produce Large Quantities of Proteins from Cloned Genes	249

Plasmid Expression Vectors Can Be Designed for Use in Animal Cells	251
--	-----

### 6.4 Locating and Identifying Human Disease Genes 254

Monogenic Diseases Show One of Three Patterns of Inheritance	254
DNA Polymorphisms Are Used as Markers for Linkage Mapping of Human Mutations	255
Linkage Studies Can Map Disease Genes with a Resolution of About 1 Centimorgan	256
Further Analysis Is Needed to Locate a Disease Gene in Cloned DNA	257
Many Inherited Diseases Result from Multiple Genetic Defects	257

### 6.5 Inactivating the Function of Specific Genes in Eukaryotes 259

Normal Yeast Genes Can Be Replaced with Mutant Alleles by Homologous Recombination	260
Genes Can Be Placed Under the Control of an Experimentally Regulated Promoter	260
Specific Genes Can Be Permanently Inactivated in the Germ Line of Mice	261
Somatic Cell Recombination Can Inactivate Genes in Specific Tissues	261
Dominant-Negative Alleles Can Inhibit the Function of Some Genes	262
RNA Interference Causes Gene Inactivation by Destroying the Corresponding mRNA	264
Engineered CRISPR–Cas9 Systems Allow Precise Genome Editing	266

## 7 Biomembrane Structure 271

### 7.1 The Lipid Bilayer: Composition and Structural Organization 273

Phospholipids Spontaneously Form Bilayers	273
Phospholipid Bilayers Form a Sealed Compartment Surrounding an Internal Aqueous Space	274
Biomembranes Contain Three Principal Classes of Lipids	276
Most Lipids and Many Proteins Are Laterally Mobile in Biomembranes	278
Lipid Composition Influences the Physical Properties of Membranes	279
Lipid Composition Is Different in the Exoplasmic and Cytosolic Leaflets	281
Cholesterol and Sphingolipids Cluster with Specific Proteins in Membrane Microdomains	282
Cells Store Excess Lipids in Lipid Droplets	283

<b>7.2</b>	<b>Membrane Proteins: Structure and Basic Functions</b>	<b>284</b>
	Proteins Interact with Membranes in Three Different Ways	284
	Most Transmembrane Proteins Have Membrane-Spanning $\alpha$ Helices	285
	Multiple $\beta$ Strands in Porins Form Membrane-Spanning "Barrels"	288
	Covalently Attached Lipids Anchor Some Proteins to Membranes	288
	All Transmembrane Proteins and Glycolipids Are Asymmetrically Oriented in the Bilayer	289
	Lipid-Binding Motifs Help Target Peripheral Proteins to the Membrane	290
	Proteins Can Be Removed from Membranes by Detergents or High-Salt Solutions	290
<b>7.3</b>	<b>Phospholipids, Sphingolipids, and Cholesterol: Synthesis and Intracellular Movement</b>	<b>293</b>
	Fatty Acids Are Assembled from Two-Carbon Building Blocks by Several Important Enzymes	293
	Small Cytosolic Proteins Facilitate Movement of Fatty Acids	293
	Fatty Acids Are Incorporated into Phospholipids Primarily on the ER Membrane	294
	Flippases Move Phospholipids from One Membrane Leaflet to the Opposite Leaflet	295
	Cholesterol Is Synthesized by Enzymes in the Cytosol and ER Membrane	295
	Cholesterol and Phospholipids Are Transported Between Organelles by Several Mechanisms	296
<b>8</b>	<b>Genes, Genomics, and Chromosomes</b>	<b>301</b>
<b>8.1</b>	<b>Eukaryotic Gene Structure</b>	<b>303</b>
	Most Eukaryotic Genes Contain Introns and Produce mRNAs Encoding Single Proteins	303
	Simple and Complex Transcription Units Are Found in Eukaryotic Genomes	303
	Protein-Coding Genes May Be Solitary or Belong to a Gene Family	305
	Heavily Used Gene Products Are Encoded by Multiple Copies of Genes	307
	Nonprotein-Coding Genes Encode Functional RNAs	308
<b>8.2</b>	<b>Chromosomal Organization of Genes and Noncoding DNA</b>	<b>309</b>
	Genomes of Many Organisms Contain Nonfunctional DNA	309
	Most Simple-Sequence DNAs Are Concentrated in Specific Chromosomal Locations	310

	DNA Fingerprinting Depends on Differences in Length of Simple-Sequence DNAs	311
	Unclassified Intergenic DNA Occupies a Significant Portion of the Genome	312
<b>8.3</b>	<b>Transposable (Mobile) DNA Elements</b>	<b>312</b>
	Movement of Mobile Elements Involves a DNA or an RNA Intermediate	313
	DNA Transposons Are Present in Prokaryotes and Eukaryotes	314
	LTR Retrotransposons Behave Like Intracellular Retroviruses	316
	Non-LTR Retrotransposons Transpose by a Distinct Mechanism	318
	Other Retroposed RNAs Are Found in Genomic DNA	321
	Mobile DNA Elements Have Significantly Influenced Evolution	321
<b>8.4</b>	<b>Genomics: Genome-Wide Analysis of Gene Structure and Function</b>	<b>323</b>
	Stored Sequences Suggest Functions of Newly Identified Genes and Proteins	324
	Comparison of Related Sequences from Different Species Can Give Clues to Evolutionary Relationships Among Proteins	325
	Genes Can Be Identified Within Genomic DNA Sequences	326
	The Number of Protein-Coding Genes in an Organism's Genome Is Not Directly Related to Its Biological Complexity	326
<b>8.5</b>	<b>Structural Organization of Eukaryotic Chromosomes</b>	<b>327</b>
	Chromatin Exists in Extended and Condensed Forms	328
	Modifications of Histone Tails Control Chromatin Condensation and Function	330
	Nonhistone Proteins Organize Long Chromatin Loops	335
	Additional Nonhistone Proteins Regulate Transcription and Replication	339
<b>8.6</b>	<b>Morphology and Functional Elements of Eukaryotic Chromosomes</b>	<b>341</b>
	Chromosome Number, Size, and Shape at Metaphase Are Species-Specific	341
	During Metaphase, Chromosomes Can Be Distinguished by Banding Patterns and Chromosome Painting	341
	Chromosome Painting and DNA Sequencing Reveal the Evolution of Chromosomes	342

Interphase Polytene Chromosomes Arise by DNA Amplification	343
Three Functional Elements Are Required for Replication and Stable Inheritance of Chromosomes	345
Centromere Sequences Vary Greatly in Length and Complexity	345
Addition of Telomeric Sequences by Telomerase Prevents Shortening of Chromosomes	347

## 9 Transcriptional Control of Gene Expression 353

### 9.1 Control of Gene Expression in Bacteria 356

Transcription Initiation by Bacterial RNA Polymerase Requires Association with a Sigma Factor	357
Initiation of <i>lac</i> Operon Transcription Can Be Repressed or Activated	357
Small Molecules Regulate Expression of Many Bacterial Genes via DNA-Binding Repressors and Activators	358
Transcription Initiation from Some Promoters Requires Alternative Sigma Factors	359
Transcription by $\sigma^{54}$ -RNA Polymerase Is Controlled by Activators That Bind Far from the Promoter	359
Many Bacterial Responses Are Controlled by Two-Component Regulatory Systems	360
Expression of Many Bacterial Operons Is Controlled by Regulation of Transcriptional Elongation	361

### 9.2 Overview of Eukaryotic Gene Control 363

Regulatory Elements in Eukaryotic DNA Are Found Both Close to and Many Kilobases Away from Transcription Start Sites	364
Three Eukaryotic RNA Polymerases Catalyze Formation of Different RNAs	367
The Largest Subunit in RNA Polymerase II Has an Essential Carboxy-Terminal Repeat	370

### 9.3 RNA Polymerase II Promoters and General Transcription Factors 371

RNA Polymerase II Initiates Transcription at DNA Sequences Corresponding to the 5' Cap of mRNAs	371
The TATA Box, Initiators, and CpG Islands Function as Promoters in Eukaryotic DNA	371
General Transcription Factors Position RNA Polymerase II at Start Sites and Assist in Initiation	373
Elongation Factors Regulate the Initial Stages of Transcription in the Promoter-Proximal Region	377

### 9.4 Regulatory Sequences in Protein-Coding Genes and the Proteins Through Which They Function 378

Promoter-Proximal Elements Help Regulate Eukaryotic Genes	378
Distant Enhancers Often Stimulate Transcription by RNA Polymerase II	379
Most Eukaryotic Genes Are Regulated by Multiple Transcription-Control Elements	379
DNase I Footprinting and EMSA Detect Protein-DNA Interactions	380
Activators Are Composed of Distinct Functional Domains	381
Repressors Are the Functional Converse of Activators	383
DNA-Binding Domains Can Be Classified into Numerous Structural Types	384
Structurally Diverse Activation and Repression Domains Regulate Transcription	386
Transcription Factor Interactions Increase Gene-Control Options	387
Multiprotein Complexes Form on Enhancers	388

### 9.5 Molecular Mechanisms of Transcription Repression and Activation 390

Formation of Heterochromatin Silences Gene Expression at Telomeres, near Centromeres, and in Other Regions	390
Repressors Can Direct Histone Deacetylation at Specific Genes	393
Activators Can Direct Histone Acetylation at Specific Genes	394
Chromatin-Remodeling Complexes Help Activate or Repress Transcription	395
Pioneer Transcription Factors Initiate the Process of Gene Activation During Cellular Differentiation	395
The Mediator Complex Forms a Molecular Bridge Between Activation Domains and Pol II	396

### 9.6 Regulation of Transcription-Factor Activity 398

DNase I Hypersensitive Sites Reflect the Developmental History of Cellular Differentiation	398
Nuclear Receptors Are Regulated by Extracellular Signals	400
All Nuclear Receptors Share a Common Domain Structure	400
Nuclear-Receptor Response Elements Contain Inverted or Direct Repeats	400
Hormone Binding to a Nuclear Receptor Regulates Its Activity as a Transcription Factor	402
Metazoans Regulate the RNA Polymerase II Transition from Initiation to Elongation	402
Termination of Transcription Is Also Regulated	402

<b>9.7 Epigenetic Regulation of Transcription</b>	<b>404</b>		
DNA Methylation Represses Transcription	404		
Methylation of Specific Histone Lysines Is Linked to Epigenetic Mechanisms of Gene Repression	405		
Epigenetic Control by Polycomb and Trithorax Complexes	406		
Long Noncoding RNAs Direct Epigenetic Repression in Metazoans	409		
<b>9.8 Other Eukaryotic Transcription Systems</b>	<b>412</b>		
Transcription Initiation by Pol I and Pol III Is Analogous to That by Pol II	412		
<b>10 Post-transcriptional Gene Control</b>	<b>417</b>		
<b>10.1 Processing of Eukaryotic Pre-mRNA</b>	<b>419</b>		
The 5' Cap Is Added to Nascent RNAs Shortly After Transcription Initiation	420		
A Diverse Set of Proteins with Conserved RNA-Binding Domains Associate with Pre-mRNAs	421		
Splicing Occurs at Short, Conserved Sequences in Pre-mRNAs via Two Transesterification Reactions	423		
During Splicing, snRNAs Base-Pair with Pre-mRNA	424		
Spliceosomes, Assembled from snRNPs and a Pre-mRNA, Carry Out Splicing	426		
Chain Elongation by RNA Polymerase II Is Coupled to the Presence of RNA-Processing Factors	428		
SR Proteins Contribute to Exon Definition in Long Pre-mRNAs	428		
Self-Splicing Group II Introns Provide Clues to the Evolution of snRNAs	429		
3' Cleavage and Polyadenylation of Pre-mRNAs Are Tightly Coupled	430		
Nuclear Exoribonucleases Degrade RNA That Is Processed Out of Pre-mRNAs	432		
RNA Processing Solves the Problem of Pervasive Transcription of the Genome in Metazoans	432		
<b>10.2 Regulation of Pre-mRNA Processing</b>	<b>435</b>		
Alternative Splicing Generates Transcripts with Different Combinations of Exons	435		
A Cascade of Regulated RNA Splicing Controls <i>Drosophila</i> Sexual Differentiation	435		
Splicing Repressors and Activators Control Splicing at Alternative Sites	437		
		RNA Editing Alters the Sequences of Some Pre-mRNAs	439
<b>10.3 Transport of mRNA Across the Nuclear Envelope</b>	<b>440</b>		
Phosphorylation and Dephosphorylation of SR Proteins Imposes Directionality on mRNP Export Across the Nuclear Pore Complex	441		
Balbani Rings in Insect Larval Salivary Glands Allow Direct Visualization of mRNP Export Through NPCs	442		
Pre-mRNAs in Spliceosomes Are Not Exported from the Nucleus	443		
HIV Rev Protein Regulates the Transport of Unspliced Viral mRNAs	444		
<b>10.4 Cytoplasmic Mechanisms of Post-transcriptional Control</b>	<b>445</b>		
Degradation of mRNAs in the Cytoplasm Occurs by Several Mechanisms	445		
Adenines in mRNAs and lncRNAs May Be Post-transcriptionally Modified by N <sup>6</sup> Methylation	447		
Micro-RNAs Repress Translation and Induce Degradation of Specific mRNAs	447		
Alternative Polyadenylation Increases miRNA Control Options	450		
RNA Interference Induces Degradation of Precisely Complementary mRNAs	450		
Cytoplasmic Polyadenylation Promotes Translation of Some mRNAs	451		
Protein Synthesis Can Be Globally Regulated	452		
Sequence-Specific RNA-Binding Proteins Control Translation of Specific mRNAs	455		
Surveillance Mechanisms Prevent Translation of Improperly Processed mRNAs	456		
Localization of mRNAs Permits Production of Proteins at Specific Regions Within the Cytoplasm	457		
<b>10.5 Processing of rRNA and tRNA</b>	<b>461</b>		
Pre-rRNA Genes Function as Nucleolar Organizers	461		
Small Nucleolar RNAs Assist in Processing Pre-rRNAs	462		
Self-Splicing Group I Introns Were the First Examples of Catalytic RNA	466		
Pre-tRNAs Undergo Extensive Modification in the Nucleus	466		
Nuclear Bodies Are Functionally Specialized Nuclear Domains	468		

## Part III Cellular Organization and Function

### 11 Transmembrane Transport of Ions and Small Molecules 473

#### 11.1 Overview of Transmembrane Transport 474

- Only Gases and Small Uncharged Molecules Cross Membranes by Simple Diffusion 474
- Three Main Classes of Membrane Proteins Transport Molecules and Ions Across Cellular Membranes 475

#### 11.2 Facilitated Transport of Glucose and Water 477

- Uniport Transport Is Faster and More Specific than Simple Diffusion 477
- The Low  $K_m$  of the GLUT1 Uniporter Enables It to Transport Glucose into Most Mammalian Cells 478
- The Human Genome Encodes a Family of Sugar-Transporting GLUT Proteins 480
- Transport Proteins Can Be Studied Using Artificial Membranes and Recombinant Cells 480
- Osmotic Pressure Causes Water to Move Across Membranes 481
- Aquaporins Increase the Water Permeability of Cellular Membranes 481

#### 11.3 ATP-Powered Pumps and the Intracellular Ionic Environment 483

- There Are Four Main Classes of ATP-Powered Pumps 484
- ATP-Powered Ion Pumps Generate and Maintain Ionic Gradients Across Cellular Membranes 485
- Muscle Relaxation Depends on  $\text{Ca}^{2+}$  ATPases That Pump  $\text{Ca}^{2+}$  from the Cytosol into the Sarcoplasmic Reticulum 486
- The Mechanism of Action of the  $\text{Ca}^{2+}$  Pump Is Known in Detail 486
- Calmodulin Regulates the Plasma-Membrane Pumps That Control Cytosolic  $\text{Ca}^{2+}$  Concentrations 489
- The  $\text{Na}^+/\text{K}^+$  ATPase Maintains the Intracellular  $\text{Na}^+$  and  $\text{K}^+$  Concentrations in Animal Cells 489
- V-Class  $\text{H}^+$  ATPases Maintain the Acidity of Lysosomes and Vacuoles 489
- ABC Proteins Export a Wide Variety of Drugs and Toxins from the Cell 491
- Certain ABC Proteins “Flip” Phospholipids and Other Lipid-Soluble Substrates from One Membrane Leaflet to the Other 493
- The ABC Cystic Fibrosis Transmembrane Regulator Is a Chloride Channel, Not a Pump 494

#### 11.4 Nongated Ion Channels and the Resting Membrane Potential 495

- Selective Movement of Ions Creates a Transmembrane Electric Gradient 495
- The Resting Membrane Potential in Animal Cells Depends Largely on the Outward Flow of  $\text{K}^+$  Ions Through Open  $\text{K}^+$  Channels 497
- Ion Channels Are Selective for Certain Ions by Virtue of a Molecular “Selectivity Filter” 497
- Patch Clamps Permit Measurement of Ion Movements Through Single Channels 500
- Novel Ion Channels Can Be Characterized by a Combination of Oocyte Expression and Patch Clamping 501

#### 11.5 Cotransport by Symporters and Antiporters 502

- $\text{Na}^+$  Entry into Mammalian Cells Is Thermodynamically Favored 502
- $\text{Na}^+$ -Linked Symporters Enable Animal Cells to Import Glucose and Amino Acids Against High Concentration Gradients 503
- A Bacterial  $\text{Na}^+/\text{Amino Acid}$  Symporter Reveals How Symport Works 504
- A  $\text{Na}^+$ -Linked  $\text{Ca}^{2+}$  Antiporter Regulates the Strength of Cardiac Muscle Contraction 504
- Several Cotransporters Regulate Cytosolic pH 505
- An Anion Antiporter Is Essential for Transport of  $\text{CO}_2$  by Erythrocytes 506
- Numerous Transport Proteins Enable Plant Vacuoles to Accumulate Metabolites and Ions 507

#### 11.6 Transcellular Transport 508

- Multiple Transport Proteins Are Needed to Move Glucose and Amino Acids Across Epithelia 508
- Simple Rehydration Therapy Depends on the Osmotic Gradient Created by Absorption of Glucose and  $\text{Na}^+$  509
- Parietal Cells Acidify the Stomach Contents While Maintaining a Neutral Cytosolic pH 509
- Bone Resorption Requires the Coordinated Function of a V-Class Proton Pump and a Specific Chloride Channel 510

### 12 Cellular Energetics 513

#### 12.1 First Step of Harvesting Energy from Glucose: Glycolysis 515

- During Glycolysis (Stage I), Cytosolic Enzymes Convert Glucose to Pyruvate 516
- The Rate of Glycolysis Is Adjusted to Meet the Cell’s Need for ATP 516
- Glucose Is Fermented When Oxygen Is Scarce 518

## **12.2 The Structure and Functions of Mitochondria**

Mitochondria Are Multifunctional Organelles	520
Mitochondria Have Two Structurally and Functionally Distinct Membranes	520
Mitochondria Contain DNA Located in the Matrix	523
The Size, Structure, and Coding Capacity of mtDNA Vary Considerably Among Organisms	525
Products of Mitochondrial Genes Are Not Exported	526
Mitochondria Evolved from a Single Endosymbiotic Event Involving a <i>Rickettsia</i> -Like Bacterium	527
Mitochondrial Genetic Codes Differ from the Standard Nuclear Code	527
Mutations in Mitochondrial DNA Cause Several Genetic Diseases in Humans	528
Mitochondria Are Dynamic Organelles That Interact Directly with One Another	528
Mitochondria Are Influenced by Direct Contacts with the Endoplasmic Reticulum	529

## **12.3 The Citric Acid Cycle and Fatty Acid Oxidation**

In the First Part of Stage II, Pyruvate Is Converted to Acetyl CoA and High-Energy Electrons	533
In the Second Part of Stage II, the Citric Acid Cycle Oxidizes the Acetyl Group in Acetyl CoA to CO <sub>2</sub> and Generates High-Energy Electrons	533
Transporters in the Inner Mitochondrial Membrane Help Maintain Appropriate Cytosolic and Matrix Concentrations of NAD <sup>+</sup> and NADH	535
Mitochondrial Oxidation of Fatty Acids Generates ATP	536
Peroxisomal Oxidation of Fatty Acids Generates No ATP	537

## **12.4 The Electron-Transport Chain and Generation of the Proton-Motive Force**

Oxidation of NADH and FADH <sub>2</sub> Releases a Significant Amount of Energy	539
Electron Transport in Mitochondria Is Coupled to Proton Pumping	539
Electrons Flow “Downhill” Through a Series of Electron Carriers	540
Four Large Multiprotein Complexes Couple Electron Transport to Proton Pumping Across the Inner Mitochondrial Membrane	542
The Reduction Potentials of Electron Carriers in the Electron-Transport Chain Favor Electron Flow from NADH to O <sub>2</sub>	546
The Multiprotein Complexes of the Electron-Transport Chain Assemble into Supercomplexes	546
Reactive Oxygen Species Are By-Products of Electron Transport	547

Experiments Using Purified Electron-Transport Chain Complexes Established the Stoichiometry of Proton Pumping	549
The Proton-Motive Force in Mitochondria Is Due Largely to a Voltage Gradient Across the Inner Membrane	550

## **12.5 Harnessing the Proton-Motive Force to Synthesize ATP**

The Mechanism of ATP Synthesis Is Shared Among Bacteria, Mitochondria, and Chloroplasts	552
ATP Synthase Comprises F <sub>0</sub> and F <sub>1</sub> Multiprotein Complexes	553
Rotation of the F <sub>1</sub> γ Subunit, Driven by Proton Movement Through F <sub>0</sub> , Powers ATP Synthesis	554
Multiple Protons Must Pass Through ATP Synthase to Synthesize One ATP	555
F <sub>0</sub> c Ring Rotation Is Driven by Protons Flowing Through Transmembrane Channels	556
ATP-ADP Exchange Across the Inner Mitochondrial Membrane Is Powered by the Proton-Motive Force	556
The Rate of Mitochondrial Oxidation Normally Depends on ADP Levels	558
Mitochondria in Brown Fat Use the Proton-Motive Force to Generate Heat	558

## **12.6 Photosynthesis and Light-Absorbing Pigments**

Thylakoid Membranes in Chloroplasts Are the Sites of Photosynthesis in Plants	560
Chloroplasts Contain Large DNAs Often Encoding More Than a Hundred Proteins	560
Three of the Four Stages in Photosynthesis Occur Only During Illumination	561
Photosystems Comprise a Reaction Center and Associated Light-Harvesting Complexes	563
Photoelectron Transport from Energized Reaction-Center Chlorophyll <i>a</i> Produces a Charge Separation	564
Internal Antennas and Light-Harvesting Complexes Increase the Efficiency of Photosynthesis	566

## **12.7 Molecular Analysis of Photosystems**

The Single Photosystem of Purple Bacteria Generates a Proton-Motive Force but No O <sub>2</sub>	567
Chloroplasts Contain Two Functionally and Spatially Distinct Photosystems	567
Linear Electron Flow Through Both Plant Photosystems Generates a Proton-Motive Force, O <sub>2</sub> , and NADPH	568
An Oxygen-Evolving Complex Is Located on the Luminal Surface of the PSII Reaction Center	569
Multiple Mechanisms Protect Cells Against Damage from Reactive Oxygen Species During Photoelectron Transport	570

Cyclic Electron Flow Through PSI Generates a Proton-Motive Force but No NADPH or O <sub>2</sub>	570
Relative Activities of Photosystems I and II Are Regulated	571

## **12.8 CO<sub>2</sub> Metabolism During Photosynthesis** 573

Rubisco Fixes CO <sub>2</sub> in the Chloroplast Stroma	573
Synthesis of Sucrose Using Fixed CO <sub>2</sub> Is Completed in the Cytosol	573
Light and Rubisco Activase Stimulate CO <sub>2</sub> Fixation	574
Photorespiration Competes with Carbon Fixation and Is Reduced in C <sub>4</sub> Plants	576

## **13 Moving Proteins into Membranes and Organelles** 583

### **13.1 Targeting Proteins To and Across the ER Membrane** 585

Pulse-Chase Experiments with Purified ER Membranes Demonstrated That Secreted Proteins Cross the ER Membrane	586
A Hydrophobic N-Terminal Signal Sequence Targets Nascent Secretory Proteins to the ER	586
Cotranslational Translocation Is Initiated by Two GTP-Hydrolyzing Proteins	588
Passage of Growing Polypeptides Through the Translocon Is Driven by Translation	589
ATP Hydrolysis Powers Post-translational Translocation of Some Secretory Proteins in Yeast	591

### **13.2 Insertion of Membrane Proteins into the ER** 593

Several Topological Classes of Integral Membrane Proteins Are Synthesized on the ER	593
Internal Stop-Transfer Anchor and Signal-Anchor Sequences Determine Topology of Single-Pass Proteins	594
Multipass Proteins Have Multiple Internal Topogenic Sequences	597
A Phospholipid Anchor Tethers Some Cell-Surface Proteins to the Membrane	598
The Topology of a Membrane Protein Can Often Be Deduced from Its Sequence	599

### **13.3 Protein Modifications, Folding, and Quality Control in the ER** 601

A Preformed N-Linked Oligosaccharide Is Added to Many Proteins in the Rough ER	601
Oligosaccharide Side Chains May Promote Folding and Stability of Glycoproteins	602

Disulfide Bonds Are Formed and Rearranged by Proteins in the ER Lumen	603
Chaperones and Other ER Proteins Facilitate Folding and Assembly of Proteins	604
Improperly Folded Proteins in the ER Induce Expression of Protein-Folding Catalysts	606
Unassembled or Misfolded Proteins in the ER Are Often Transported to the Cytosol for Degradation	607

### **13.4 Targeting of Proteins to Mitochondria and Chloroplasts** 608

Amphipathic N-Terminal Targeting Sequences Direct Proteins to the Mitochondrial Matrix	609
Mitochondrial Protein Import Requires Outer-Membrane Receptors and Translocons in Both Membranes	610
Studies with Chimeric Proteins Demonstrate Important Features of Mitochondrial Protein Import	612
Three Energy Inputs Are Needed to Import Proteins into Mitochondria	613
Multiple Signals and Pathways Target Proteins to Submitochondrial Compartments	613
Import of Chloroplast Stromal Proteins Is Similar to Import of Mitochondrial Matrix Proteins	617
Proteins Are Targeted to Thylakoids by Mechanisms Related to Bacterial Protein Translocation	617

### **13.5 Targeting of Peroxisomal Proteins** 619

A Cytosolic Receptor Targets Proteins with an SKL Sequence at the C-Terminus to the Peroxisomal Matrix	619
Peroxisomal Membrane and Matrix Proteins Are Incorporated by Different Pathways	621

### **13.6 Transport Into and Out of the Nucleus** 622

Large and Small Molecules Enter and Leave the Nucleus via Nuclear Pore Complexes	622
Nuclear Transport Receptors Escort Proteins Containing Nuclear-Localization Signals into the Nucleus	624
A Second Type of Nuclear Transport Receptor Escorts Proteins Containing Nuclear-Export Signals Out of the Nucleus	625
Most mRNAs Are Exported from the Nucleus by a Ran-Independent Mechanism	627

## **14 Vesicular Traffic, Secretion, and Endocytosis** 631

### **14.1 Techniques for Studying the Secretory Pathway** 634

Transport of a Protein Through the Secretory Pathway Can Be Assayed in Live Cells	634
---	-----

Yeast Mutants Define Major Stages and Many Components in Vesicular Transport	635	The Acidic pH of Late Endosomes Causes Most Receptor-Ligand Complexes to Dissociate	662
Cell-Free Transport Assays Allow Dissection of Individual Steps in Vesicular Transport	637	The Endocytic Pathway Delivers Iron to Cells Without Dissociation of the Transferrin–Transferrin Receptor Complex in Endosomes	663
<b>14.2 Molecular Mechanisms of Vesicle Budding and Fusion</b>	<b>638</b>	<b>14.6 Directing Membrane Proteins and Cytosolic Materials to the Lysosome</b>	<b>665</b>
Assembly of a Protein Coat Drives Vesicle Formation and Selection of Cargo Molecules	638	Multivesicular Endosomes Segregate Membrane Proteins Destined for the Lysosomal Membrane from Proteins Destined for Lysosomal Degradation	665
A Conserved Set of GTPase Switch Proteins Controls the Assembly of Different Vesicle Coats	639	Retroviruses Bud from the Plasma Membrane by a Process Similar to Formation of Multivesicular Endosomes	666
Targeting Sequences on Cargo Proteins Make Specific Molecular Contacts with Coat Proteins	641	The Autophagic Pathway Delivers Cytosolic Proteins or Entire Organelles to Lysosomes	667
Rab GTPases Control Docking of Vesicles on Target Membranes	641		
Paired Sets of SNARE Proteins Mediate Fusion of Vesicles with Target Membranes	642		
Dissociation of SNARE Complexes After Membrane Fusion Is Driven by ATP Hydrolysis	644		
<b>14.3 Early Stages of the Secretory Pathway</b>	<b>645</b>	<b>15 Signal Transduction and G Protein–Coupled Receptors</b>	<b>673</b>
COPII Vesicles Mediate Transport from the ER to the Golgi	645	<b>15.1 Signal Transduction: From Extracellular Signal to Cellular Response</b>	<b>675</b>
COP1 Vesicles Mediate Retrograde Transport Within the Golgi and from the Golgi to the ER	647	Signaling Molecules Can Act Locally or at a Distance	675
Anterograde Transport Through the Golgi Occurs by Cisternal Maturation	648	Receptors Bind Only a Single Type of Hormone or a Group of Closely Related Hormones	676
		Protein Kinases and Phosphatases Are Employed in Many Signaling Pathways	676
<b>14.4 Later Stages of the Secretory Pathway</b>	<b>650</b>	GTP-Binding Proteins Are Frequently Used in Signal Transduction Pathways as On/Off Switches	677
Vesicles Coated with Clathrin and Adapter Proteins Mediate Transport from the <i>trans</i> -Golgi	651	Intracellular “Second Messengers” Transmit Signals from Many Receptors	678
Dynamin Is Required for Pinching Off of Clathrin-Coated Vesicles	652	Signal Transduction Pathways Can Amplify the Effects of Extracellular Signals	679
Mannose 6-Phosphate Residues Target Soluble Proteins to Lysosomes	653	<b>15.2 Studying Cell-Surface Receptors and Signal Transduction Proteins</b>	<b>681</b>
Study of Lysosomal Storage Diseases Revealed Key Components of the Lysosomal Sorting Pathway	655	The Dissociation Constant Is a Measure of the Affinity of a Receptor for Its Ligand	681
Protein Aggregation in the <i>trans</i> -Golgi May Function in Sorting Proteins to Regulated Secretory Vesicles	655	Binding Assays Are Used to Detect Receptors and Determine Their Affinity and Specificity for Ligands	681
Some Proteins Undergo Proteolytic Processing After Leaving the <i>trans</i> -Golgi	656	Near-Maximal Cellular Response to a Signaling Molecule Usually Does Not Require Activation of All Receptors	682
Several Pathways Sort Membrane Proteins to the Apical or Basolateral Region of Polarized Cells	657	Sensitivity of a Cell to External Signals Is Determined by the Number of Cell-Surface Receptors and Their Affinity for Ligand	683
		Hormone Analogs Are Widely Used as Drugs	683
<b>14.5 Receptor-Mediated Endocytosis</b>	<b>659</b>	Receptors Can Be Purified by Affinity Chromatography Techniques	683
Cells Take Up Lipids from the Blood in the Form of Large, Well-Defined Lipoprotein Complexes	659	Immunoprecipitation Assays and Affinity Techniques Can Be Used to Study the Activity of Signal Transduction Proteins	684
Receptors for Macromolecular Ligands Contain Sorting Signals That Target Them for Endocytosis	660		

<b>15.3 G Protein–Coupled Receptors: Structure and Mechanism</b>	<b>686</b>	Activated Phospholipase C Generates Two Key Second Messengers Derived from the Membrane Lipid Phosphatidylinositol 4,5-Bisphosphate	709
All G Protein–Coupled Receptors Share the Same Basic Structure	686	The $\text{Ca}^{2+}$ -Calmodulin Complex Mediates Many Cellular Responses to External Signals	713
Ligand-Activated G Protein–Coupled Receptors Catalyze Exchange of GTP for GDP on the $\alpha$ Subunit of a Heterotrimeric G Protein	689	DAG Activates Protein Kinase C	714
Different G Proteins Are Activated by Different GPCRs and In Turn Regulate Different Effector Proteins	691	Integration of $\text{Ca}^{2+}$ and cAMP Second Messengers Regulates Glycogenolysis	714
<b>15.4 G Protein–Coupled Receptors That Regulate Ion Channels</b>	<b>693</b>	Signal-Induced Relaxation of Vascular Smooth Muscle Is Mediated by a $\text{Ca}^{2+}$ -Nitric Oxide-cGMP-Activated Protein Kinase G Pathway	714
Acetylcholine Receptors in the Heart Muscle Activate a G Protein That Opens $\text{K}^+$ Channels	693	<b>16 Signaling Pathways That Control Gene Expression</b>	<b>719</b>
Light Activates Rhodopsin in Rod Cells of the Eye	694	<b>16.1 Receptor Serine Kinases That Activate Smads</b>	<b>722</b>
Activation of Rhodopsin by Light Leads to Closing of cGMP-Gated Cation Channels	695	TGF- $\beta$ Proteins Are Stored in an Inactive Form in the Extracellular Matrix	722
Signal Amplification Makes the Rhodopsin Signal Transduction Pathway Exquisitely Sensitive	696	Three Separate TGF- $\beta$ Receptor Proteins Participate in Binding TGF- $\beta$ and Activating Signal Transduction	722
Rapid Termination of the Rhodopsin Signal Transduction Pathway Is Essential for the Temporal Resolution of Vision	697	Activated TGF- $\beta$ Receptors Phosphorylate Smad Transcription Factors	724
Rod Cells Adapt to Varying Levels of Ambient Light by Intracellular Trafficking of Arrestin and Transducin	698	The Smad3/Smad4 Complex Activates Expression of Different Genes in Different Cell Types	724
<b>15.5 G Protein–Coupled Receptors That Activate or Inhibit Adenylyl Cyclase</b>	<b>699</b>	Negative Feedback Loops Regulate TGF- $\beta$ /Smad Signaling	725
Adenylyl Cyclase Is Stimulated and Inhibited by Different Receptor-Ligand Complexes	699	<b>16.2 Cytokine Receptors and the JAK/STAT Signaling Pathway</b>	<b>726</b>
Structural Studies Established How $\text{G}_{\alpha s}$ -GTP Binds to and Activates Adenylyl Cyclase	701	Cytokines Influence the Development of Many Cell Types	727
cAMP Activates Protein Kinase A by Releasing Inhibitory Subunits	701	Binding of a Cytokine to Its Receptor Activates One or More Tightly Bound JAK Protein Tyrosine Kinases	728
Glycogen Metabolism Is Regulated by Hormone-Induced Activation of PKA	702	Phosphotyrosine Residues Are Binding Surfaces for Multiple Proteins with Conserved Domains	730
cAMP-Mediated Activation of PKA Produces Diverse Responses in Different Cell Types	703	SH2 Domains in Action: JAK Kinases Activate STAT Transcription Factors	731
Signal Amplification Occurs in the cAMP-PKA Pathway	704	Multiple Mechanisms Down-Regulate Signaling from Cytokine Receptors	731
CREB Links cAMP and PKA to Activation of Gene Transcription	704	<b>16.3 Receptor Tyrosine Kinases</b>	<b>734</b>
Anchoring Proteins Localize Effects of cAMP to Specific Regions of the Cell	705	Binding of Ligand Promotes Dimerization of an RTK and Leads to Activation of Its Intrinsic Tyrosine Kinase	734
Multiple Mechanisms Suppress Signaling from the GPCR/cAMP/PKA Pathway	706	Homo- and Hetero-oligomers of Epidermal Growth Factor Receptors Bind Members of the Epidermal Growth Factor Family	735
<b>15.6 G Protein–Coupled Receptors That Trigger Elevations in Cytosolic and Mitochondrial Calcium</b>	<b>708</b>	Activation of the EGF Receptor Results in the Formation of an Asymmetric Active Kinase Dimer	736
Calcium Concentrations in the Mitochondrial Matrix, ER, and Cytosol Can Be Measured with Targeted Fluorescent Proteins	709	Multiple Mechanisms Down-Regulate Signaling from RTKs	737

<b>16.4 The Ras/MAP Kinase Pathway</b>	<b>739</b>	On Binding Delta, the Notch Receptor Is Cleaved, Releasing a Component Transcription Factor	761
Ras, a GTPase Switch Protein, Operates Downstream of Most RTKs and Cytokine Receptors	739	Matrix Metalloproteases Catalyze Cleavage of Many Signaling Proteins from the Cell Surface	763
Genetic Studies in <i>Drosophila</i> Identified Key Signal-Transducing Proteins in the Ras/MAP Kinase Pathway	739	Inappropriate Cleavage of Amyloid Precursor Protein Can Lead to Alzheimer's Disease	763
Receptor Tyrosine Kinases Are Linked to Ras by Adapter Proteins	741	Regulated Intramembrane Proteolysis of SREBPs Releases a Transcription Factor That Acts to Maintain Phospholipid and Cholesterol Levels	763
Binding of Sos to Inactive Ras Causes a Conformational Change That Triggers an Exchange of GTP for GDP	742		
Signals Pass from Activated Ras to a Cascade of Protein Kinases Ending with MAP Kinase	742	<b>16.8 Integration of Cellular Responses to Multiple Signaling Pathways: Insulin Action</b>	<b>766</b>
Phosphorylation of MAP Kinase Results in a Conformational Change That Enhances Its Catalytic Activity and Promotes Its Dimerization	744	Insulin and Glucagon Work Together to Maintain a Stable Blood Glucose Level	766
MAP Kinase Regulates the Activity of Many Transcription Factors Controlling Early Response Genes	745	A Rise in Blood Glucose Triggers Insulin Secretion from the $\beta$ Islet Cells	767
G Protein–Coupled Receptors Transmit Signals to MAP Kinase in Yeast Mating Pathways	746	In Fat and Muscle Cells, Insulin Triggers Fusion of Intracellular Vesicles Containing the GLUT4 Glucose Transporter to the Plasma Membrane	767
Scaffold Proteins Separate Multiple MAP Kinase Pathways in Eukaryotic Cells	746	Insulin Inhibits Glucose Synthesis and Enhances Storage of Glucose as Glycogen	769
<b>16.5 Phosphoinositide Signaling Pathways</b>	<b>748</b>	Multiple Signal Transduction Pathways Interact to Regulate Adipocyte Differentiation Through PPAR $\gamma$ , the Master Transcriptional Regulator	770
Phospholipase $C_\gamma$ Is Activated by Some RTKs and Cytokine Receptors	749	Inflammatory Hormones Cause Derangement of Adipose Cell Function in Obesity	770
Recruitment of PI-3 Kinase to Activated Receptors Leads to Synthesis of Three Phosphorylated Phosphatidylinositols	749		
Accumulation of PI 3-Phosphates in the Plasma Membrane Leads to Activation of Several Kinases	750	<b>17 Cell Organization and Movement I: Microfilaments</b>	<b>775</b>
Activated Protein Kinase B Induces Many Cellular Responses	750		
The PI-3 Kinase Pathway Is Negatively Regulated by PTEN Phosphatase	751	<b>17.1 Microfilaments and Actin Structures</b>	<b>778</b>
<b>16.6 Signaling Pathways Controlled by Ubiquitylation and Protein Degradation: Wnt, Hedgehog, and NF-<math>\kappa</math>B</b>	<b>751</b>	Actin Is Ancient, Abundant, and Highly Conserved	778
Wnt Signaling Triggers Release of a Transcription Factor from a Cytosolic Protein Complex	752	G-Actin Monomers Assemble into Long, Helical F-Actin Polymers	779
Concentration Gradients of Wnt Protein Are Essential for Many Steps in Development	753	F-Actin Has Structural and Functional Polarity	780
Hedgehog Signaling Relieves Repression of Target Genes	754	<b>17.2 Dynamics of Actin Filaments</b>	<b>781</b>
Hedgehog Signaling in Vertebrates Requires Primary Cilia	757	Actin Polymerization In Vitro Proceeds in Three Steps	781
Degradation of an Inhibitor Protein Activates the NF- $\kappa$ B Transcription Factor	757	Actin Filaments Grow Faster at (+) Ends Than at (–) Ends	782
Polyubiquitin Chains Serve as Scaffolds Linking Receptors to Downstream Proteins in the NF- $\kappa$ B Pathway	760	Actin Filament Treadmilling Is Accelerated by Profilin and Cofilin	784
		Thymosin- $\beta_4$ Provides a Reservoir of Actin for Polymerization	785
		Capping Proteins Block Assembly and Disassembly at Actin Filament Ends	785
<b>16.7 Signaling Pathways Controlled by Protein Cleavage: Notch/Delta, SREBP, and Alzheimer's Disease</b>	<b>761</b>	<b>17.3 Mechanisms of Actin Filament Assembly</b>	<b>786</b>
		Formins Assemble Unbranched Filaments	786

The Arp2/3 Complex Nucleates Branched Filament Assembly	787
Intracellular Movements Can Be Powered by Actin Polymerization	789
Microfilaments Function in Endocytosis	790
Toxins That Perturb the Pool of Actin Monomers Are Useful for Studying Actin Dynamics	791
<b>17.4 Organization of Actin-Based Cellular Structures</b>	<b>793</b>
Cross-Linking Proteins Organize Actin Filaments into Bundles or Networks	793
Adapter Proteins Link Actin Filaments to Membranes	793
<b>17.5 Myosins: Actin-Based Motor Proteins</b>	<b>796</b>
Myosins Have Head, Neck, and Tail Domains with Distinct Functions	797
Myosins Make Up a Large Family of Mechanochemical Motor Proteins	798
Conformational Changes in the Myosin Head Couple ATP Hydrolysis to Movement	800
Myosin Heads Take Discrete Steps Along Actin Filaments	802
<b>17.6 Myosin-Powered Movements</b>	<b>803</b>
Myosin Thick Filaments and Actin Thin Filaments in Skeletal Muscle Slide Past Each Other During Contraction	803
Skeletal Muscle Is Structured by Stabilizing and Scaffolding Proteins	805
Contraction of Skeletal Muscle Is Regulated by $\text{Ca}^{2+}$ and Actin-Binding Proteins	805
Actin and Myosin II Form Contractile Bundles in Nonmuscle Cells	807
Myosin-Dependent Mechanisms Regulate Contraction in Smooth Muscle and Nonmuscle Cells	808
Myosin V-Bound Vesicles Are Carried Along Actin Filaments	808
<b>17.7 Cell Migration: Mechanism, Signaling, and Chemotaxis</b>	<b>811</b>
Cell Migration Coordinates Force Generation with Cell Adhesion and Membrane Recycling	811
The Small GTP-Binding Proteins Cdc42, Rac, and Rho Control Actin Organization	813
Cell Migration Involves the Coordinate Regulation of Cdc42, Rac, and Rho	815
Migrating Cells Are Steered by Chemotactic Molecules	816

## 18 Cell Organization and Movement II: Microtubules and Intermediate Filaments

821

### 18.1 Microtubule Structure and Organization

822

Microtubule Walls Are Polarized Structures Built from $\alpha\beta$ -Tubulin Dimers	822
Microtubules Are Assembled from MTOCs to Generate Diverse Configurations	824

### 18.2 Microtubule Dynamics

827

Individual Microtubules Exhibit Dynamic Instability	827
Localized Assembly and "Search and Capture" Help Organize Microtubules	829
Drugs Affecting Tubulin Polymerization Are Useful Experimentally and in Treatment of Diseases	829

### 18.3 Regulation of Microtubule Structure and Dynamics

830

Microtubules Are Stabilized by Side-Binding Proteins + TIPs Regulate the Properties and Functions of the Microtubule (+) End	831
Other End-Binding Proteins Regulate Microtubule Disassembly	832

### 18.4 Kinesins and Dyneins: Microtubule-Based Motor Proteins

833

Organelles in Axons Are Transported Along Microtubules in Both Directions	833
Kinesin-1 Powers Anterograde Transport of Vesicles Down Axons Toward the (+) Ends of Microtubules	835
The Kinesins Form a Large Protein Superfamily with Diverse Functions	835
Kinesin-1 Is a Highly Processive Motor	836
Dynein Motors Transport Organelles Toward the (−) Ends of Microtubules	838
Kinesins and Dyneins Cooperate in the Transport of Organelles Throughout the Cell	841
Tubulin Modifications Distinguish Different Classes of Microtubules and Their Accessibility to Motors	842

### 18.5 Cilia and Flagella: Microtubule-Based Surface Structures

844

Eukaryotic Cilia and Flagella Contain Long Doublet Microtubules Bridged by Dynein Motors	844
--	-----

Ciliary and Flagellar Beating Are Produced by Controlled Sliding of Outer Doublet Microtubules	844	Advancement of Neural Growth Cones Is Coordinated by Microfilaments and Microtubules	868
Intraflagellar Transport Moves Material Up and Down Cilia and Flagella	845		
Primary Cilia Are Sensory Organelles on Interphase Cells	847	<b>19 The Eukaryotic Cell Cycle</b>	<b>873</b>
Defects in Primary Cilia Underlie Many Diseases	848		
<b>18.6 Mitosis</b>	<b>849</b>	<b>19.1 Overview of the Cell Cycle and Its Control</b>	<b>875</b>
Centrosomes Duplicate Early in the Cell Cycle in Preparation for Mitosis	849	The Cell Cycle Is an Ordered Series of Events Leading to Cell Replication	875
Mitosis Can Be Divided into Six Stages	850	Cyclin-Dependent Kinases Control the Eukaryotic Cell Cycle	876
The Mitotic Spindle Contains Three Classes of Microtubules	851	Several Key Principles Govern the Cell Cycle	876
Microtubule Dynamics Increase Dramatically in Mitosis	852		
Mitotic Asters Are Pushed Apart by Kinesin-5 and Oriented by Dynein	853	<b>19.2 Model Organisms and Methods of Studying the Cell Cycle</b>	<b>877</b>
Chromosomes Are Captured and Oriented During Prometaphase	853	Budding and Fission Yeasts Are Powerful Systems for Genetic Analysis of the Cell Cycle	877
Duplicated Chromosomes Are Aligned by Motors and Microtubule Dynamics	854	Frog Oocytes and Early Embryos Facilitate Biochemical Characterization of the Cell Cycle Machinery	878
The Chromosomal Passenger Complex Regulates Microtubule Attachment at Kinetochores	855	Fruit Flies Reveal the Interplay Between Development and the Cell Cycle	879
Anaphase A Moves Chromosomes to Poles by Microtubule Shortening	857	The Study of Tissue Culture Cells Uncovers Cell Cycle Regulation in Mammals	880
Anaphase B Separates Poles by the Combined Action of Kinesins and Dynein	858	Researchers Use Multiple Tools to Study the Cell Cycle	881
Additional Mechanisms Contribute to Spindle Formation	858	<b>19.3 Regulation of CDK Activity</b>	<b>882</b>
Cytokinesis Splits the Duplicated Cell in Two	859	Cyclin-Dependent Kinases Are Small Protein Kinases That Require a Regulatory Cyclin Subunit for Their Activity	883
Plant Cells Reorganize Their Microtubules and Build a New Cell Wall in Mitosis	860	Cyclins Determine the Activity of CDKs	884
<b>18.7 Intermediate Filaments</b>	<b>861</b>	Cyclin Levels Are Primarily Regulated by Protein Degradation	885
Intermediate Filaments Are Assembled from Subunit Dimers	861	CDKs Are Regulated by Activating and Inhibitory Phosphorylation	886
Intermediate Filaments Are Dynamic	861	CDK Inhibitors Control Cyclin-CDK Activity	886
Cytoplasmic Intermediate Filament Proteins Are Expressed in a Tissue-Specific Manner	862	Genetically Engineered CDKs Led to the Discovery of CDK Functions	887
Lamins Line the Inner Nuclear Envelope To Provide Organization and Rigidity to the Nucleus	865	<b>19.4 Commitment to the Cell Cycle and DNA Replication</b>	<b>887</b>
Lamins Are Reversibly Disassembled by Phosphorylation During Mitosis	866	Cells Are Irreversibly Committed to Division at a Cell Cycle Point Called START or the Restriction Point	888
<b>18.8 Coordination and Cooperation Between Cytoskeletal Elements</b>	<b>867</b>	The E2F Transcription Factor and Its Regulator Rb Control the G <sub>1</sub> -S Phase Transition in Metazoans	889
Intermediate Filament-Associated Proteins Contribute to Cellular Organization	867	Extracellular Signals Govern Cell Cycle Entry	889
Microfilaments and Microtubules Cooperate to Transport Melanosomes	867	Degradation of an S Phase CDK Inhibitor Triggers DNA Replication	890
Cdc42 Coordinates Microtubules and Microfilaments During Cell Migration	867		

Replication at Each Origin Is Initiated Once and Only Once During the Cell Cycle	892
Duplicated DNA Strands Become Linked During Replication	893
<b>19.5 Entry into Mitosis</b>	<b>895</b>
Precipitous Activation of Mitotic CDKs Initiates Mitosis	896
Mitotic CDKs Promote Nuclear Envelope Breakdown	897
Mitotic CDKs Promote Mitotic Spindle Formation	897
Chromosome Condensation Facilitates Chromosome Segregation	899
<b>19.6 Completion of Mitosis: Chromosome Segregation and Exit from Mitosis</b>	<b>901</b>
Separase-Mediated Cleavage of Cohesins Initiates Chromosome Segregation	901
APC/C Activates Separase Through Securin Ubiquitinylation	901
Mitotic CDK Inactivation Triggers Exit from Mitosis	902
Cytokinesis Creates Two Daughter Cells	903
<b>19.7 Surveillance Mechanisms in Cell Cycle Regulation</b>	<b>904</b>
Checkpoint Pathways Establish Dependencies and Prevent Errors in the Cell Cycle	905
The Growth Checkpoint Pathway Ensures That Cells Enter the Cell Cycle Only After Sufficient Macromolecule Biosynthesis	905
The DNA Damage Response System Halts Cell Cycle Progression When DNA Is Compromised	905
The Spindle Assembly Checkpoint Pathway Prevents Chromosome Segregation Until Chromosomes Are Accurately Attached to the Mitotic Spindle	908
The Spindle Position Checkpoint Pathway Ensures That the Nucleus Is Accurately Partitioned Between Two Daughter Cells	909
<b>19.8 Meiosis: A Special Type of Cell Division</b>	<b>911</b>
Extracellular and Intracellular Cues Regulate Germ Cell Formation	912
Several Key Features Distinguish Meiosis from Mitosis	912
Recombination and a Meiosis-Specific Cohesin Subunit Are Necessary for the Specialized Chromosome Segregation in Meiosis I	915
Co-orienting Sister Kinetochores Is Critical for Meiosis I Chromosome Segregation	917
DNA Replication Is Inhibited Between the Two Meiotic Divisions	917

## Part IV Cell Growth and Differentiation

### 20 Integrating Cells into Tissues 921

<b>20.1 Cell-Cell and Cell–Extracellular Matrix Adhesion: An Overview</b>	<b>923</b>
Cell-Adhesion Molecules Bind to One Another and to Intracellular Proteins	923
The Extracellular Matrix Participates in Adhesion, Signaling, and Other Functions	925
The Evolution of Multifaceted Adhesion Molecules Made Possible the Evolution of Diverse Animal Tissues	928
Cell-Adhesion Molecules Mediate Mechanotransduction	929
<b>20.2 Cell-Cell and Cell–Extracellular Junctions and Their Adhesion Molecules</b>	<b>931</b>
Epithelial Cells Have Distinct Apical, Lateral, and Basal Surfaces	931
Three Types of Junctions Mediate Many Cell-Cell and Cell-ECM Interactions	932
Cadherins Mediate Cell-Cell Adhesions in Adherens Junctions and Desmosomes	933
Integrins Mediate Cell-ECM Adhesions, Including Those in Epithelial-Cell Hemidesmosomes	938
Tight Junctions Seal Off Body Cavities and Restrict Diffusion of Membrane Components	939
Gap Junctions Composed of Connexins Allow Small Molecules to Pass Directly Between the Cytosols of Adjacent Cells	942
<b>20.3 The Extracellular Matrix I: The Basal Lamina</b>	<b>945</b>
The Basal Lamina Provides a Foundation for Assembly of Cells into Tissues	945
Laminin, a Multi-adhesive Matrix Protein, Helps Cross-Link Components of the Basal Lamina	947
Sheet-Forming Type IV Collagen Is a Major Structural Component of the Basal Lamina	948
Perlecan, a Proteoglycan, Cross-Links Components of the Basal Lamina and Cell-Surface Receptors	950
<b>20.4 The Extracellular Matrix II: Connective Tissue</b>	<b>951</b>
Fibrillar Collagens Are the Major Fibrous Proteins in the ECM of Connective Tissues	951
Fibrillar Collagen Is Secreted and Assembled into Fibrils Outside the Cell	951
Type I and II Collagens Associate with Nonfibrillar Collagens to Form Diverse Structures	952

Proteoglycans and Their Constituent GAGs Play Diverse Roles in the ECM	953	Somatic Cells Can Generate iPS Cells	983
Hyaluronan Resists Compression, Facilitates Cell Migration, and Gives Cartilage Its Gel-Like Properties	956	ES and iPS Cells Can Generate Functional Differentiated Human Cells	986
Fibronectins Connect Cells and ECM, Influencing Cell Shape, Differentiation, and Movement	956	<b>21.3 Stem Cells and Niches in Multicellular Organisms</b>	<b>987</b>
Elastic Fibers Permit Many Tissues to Undergo Repeated Stretching and Recoiling	959	Adult Planaria Contain Pluripotent Stem Cells	988
Metalloproteases Remodel and Degrade the Extracellular Matrix	960	Multipotent Somatic Stem Cells Give Rise to Both Stem Cells and Differentiating Cells	988
<b>20.5 Adhesive Interactions in Motile and Nonmotile Cells</b>	<b>961</b>	Stem Cells for Different Tissues Occupy Sustaining Niches	988
Integrins Mediate Adhesion and Relay Signals Between Cells and Their Three-Dimensional Environment	961	Germ-Line Stem Cells Produce Sperm or Oocytes	990
Regulation of Integrin-Mediated Adhesion and Signaling Controls Cell Movement	962	Intestinal Stem Cells Continuously Generate All the Cells of the Intestinal Epithelium	991
Connections Between the ECM and Cytoskeleton Are Defective in Muscular Dystrophy	964	Hematopoietic Stem Cells Form All Blood Cells	994
IgCAMs Mediate Cell-Cell Adhesion in Neural and Other Tissues	965	Rare Types of Cells Constitute the Niche for Hematopoietic Stem Cells	996
Leukocyte Movement into Tissues Is Orchestrated by a Precisely Timed Sequence of Adhesive Interactions	966	Meristems Are Niches for Stem Cells in Plants	996
<b>20.6 Plant Tissues</b>	<b>968</b>	A Negative Feedback Loop Maintains the Size of the Shoot Apical Stem-Cell Population	998
The Plant Cell Wall Is a Laminate of Cellulose Fibrils in a Matrix of Glycoproteins	968	The Root Meristem Resembles the Shoot Meristem in Structure and Function	999
Loosening of the Cell Wall Permits Plant Cell Growth	969	<b>21.4 Mechanisms of Cell Polarity and Asymmetric Cell Division</b>	<b>1000</b>
Plasmodesmata Directly Connect the Cytosols of Adjacent Cells	969	The Intrinsic Polarity Program Depends on a Positive Feedback Loop Involving Cdc42	1000
Tunneling Nanotubes Resemble Plasmodesmata and Transfer Molecules and Organelles Between Animal Cells	970	Cell Polarization Before Cell Division Follows a Common Hierarchy of Steps	1002
Only a Few Adhesion Molecules Have Been Identified in Plants	971	Polarized Membrane Traffic Allows Yeast to Grow Asymmetrically During Mating	1003
		The Par Proteins Direct Cell Asymmetry in the Nematode Embryo	1003
		The Par Proteins and Other Polarity Complexes Are Involved in Epithelial-Cell Polarity	1007
		The Planar Cell Polarity Pathway Orients Cells Within an Epithelium	1008
		The Par Proteins Are Involved in Asymmetric Division of Stem Cells	1008
<b>21 Stem Cells, Cell Asymmetry, and Cell Death</b>	<b>975</b>	<b>21.5 Cell Death and Its Regulation</b>	<b>1011</b>
<b>21.1 Early Mammalian Development</b>	<b>977</b>	Most Programmed Cell Death Occurs Through Apoptosis	1012
Fertilization Unifies the Genome	977	Evolutionarily Conserved Proteins Participate in the Apoptotic Pathway	1013
Cleavage of the Mammalian Embryo Leads to the First Differentiation Events	979	Caspases Amplify the Initial Apoptotic Signal and Destroy Key Cellular Proteins	1015
<b>21.2 Embryonic Stem Cells and Induced Pluripotent Stem Cells</b>	<b>980</b>	Neurotrophins Promote Survival of Neurons	1015
The Inner Cell Mass Is the Source of ES Cells	980	Mitochondria Play a Central Role in Regulation of Apoptosis in Vertebrate Cells	1017
Multiple Factors Control the Pluripotency of ES Cells	981	The Pro-apoptotic Proteins Bax and Bak Form Pores and Holes in the Outer Mitochondrial Membrane	1018
Animal Cloning Shows That Differentiation Can Be Reversed	983		

Release of Cytochrome c and SMAC/DIABLO Proteins from Mitochondria Leads to Formation of the Apoptosome and Caspase Activation	1018
Trophic Factors Induce Inactivation of Bad, a Pro-apoptotic BH3-Only Protein	1018
Vertebrate Apoptosis Is Regulated by BH3-Only Pro-apoptotic Proteins That Are Activated by Environmental Stresses	1020
Two Types of Cell Murder Are Triggered by Tumor Necrosis Factor, Fas Ligand, and Related Death Signals	1021

## 22 Cells of the Nervous System 1025

### 22.1 Neurons and Glia: Building Blocks of the Nervous System 1026

Information Flows Through Neurons from Dendrites to Axons	1027
Information Moves Along Axons as Pulses of Ion Flow Called Action Potentials	1027
Information Flows Between Neurons via Synapses	1028
The Nervous System Uses Signaling Circuits Composed of Multiple Neurons	1028
Glial Cells Form Myelin Sheaths and Support Neurons	1029
Neural Stem Cells Form Nerve and Glial Cells in the Central Nervous System	1031

### 22.2 Voltage-Gated Ion Channels and the Propagation of Action Potentials 1034

The Magnitude of the Action Potential Is Close to $E_{Na}$ and Is Caused by $Na^+$ Influx Through Open $Na^+$ Channels	1034
Sequential Opening and Closing of Voltage-Gated $Na^+$ and $K^+$ Channels Generate Action Potentials	1035
Action Potentials Are Propagated Unidirectionally Without Diminution	1037
Nerve Cells Can Conduct Many Action Potentials in the Absence of ATP	1039
All Voltage-Gated Ion Channels Have Similar Structures	1039
Voltage-Sensing S4 $\alpha$ Helices Move in Response to Membrane Depolarization	1039
Movement of the Channel-Inactivating Segment into the Open Pore Blocks Ion Flow	1042
Myelination Increases the Velocity of Impulse Conduction	1043
Action Potentials “Jump” from Node to Node in Myelinated Axons	1043
Two Types of Glia Produce Myelin Sheaths	1044
Light-Activated Ion Channels and Optogenetics	1046

### 22.3 Communication at Synapses 1048

Formation of Synapses Requires Assembly of Presynaptic and Postsynaptic Structures	1048
Neurotransmitters Are Transported into Synaptic Vesicles by $H^+$ -Linked Antiport Proteins	1052

Three Pools of Synaptic Vesicles Loaded with Neurotransmitter Are Present in the Presynaptic Terminal	1054
Influx of $Ca^{2+}$ Triggers Release of Neurotransmitters	1054
A Calcium-Binding Protein Regulates Fusion of Synaptic Vesicles with the Plasma Membrane	1055
Fly Mutants Lacking Dynamin Cannot Recycle Synaptic Vesicles	1056
Signaling at Synapses Is Terminated by Degradation or Reuptake of Neurotransmitters	1057
Opening of Acetylcholine-Gated Cation Channels Leads to Muscle Contraction	1057
All Five Subunits in the Nicotinic Acetylcholine Receptor Contribute to the Ion Channel	1058
Nerve Cells Integrate Many Inputs to Make an All-or-None Decision to Generate an Action Potential	1059
Gap Junctions Allow Direct Communication Between Neurons and Between Glia	1060

### 22.4 Sensing the Environment: Touch, Pain, Taste, and Smell 1061

Mechanoreceptors Are Gated Cation Channels	1061
Pain Receptors Are Also Gated Cation Channels	1062
Five Primary Tastes Are Sensed by Subsets of Cells in Each Taste Bud	1064
A Plethora of Receptors Detect Odors	1066
Each Olfactory Receptor Neuron Expresses a Single Type of Odorant Receptor	1068

### 22.5 Forming and Storing Memories 1070

Memories Are Formed by Changing the Number or Strength of Synapses Between Neurons	1070
The Hippocampus Is Required for Memory Formation	1071
Multiple Molecular Mechanisms Contribute to Synaptic Plasticity	1072
Formation of Long-Term Memories Requires Gene Expression	1074

## 23 Immunology 1079

### 23.1 Overview of Host Defenses 1081

Pathogens Enter the Body Through Different Routes and Replicate at Different Sites	1081
Leukocytes Circulate Throughout the Body and Take Up Residence in Tissues and Lymph Nodes	1082
Mechanical and Chemical Boundaries Form a First Layer of Defense Against Pathogens	1083
Innate Immunity Provides a Second Line of Defense	1084
Inflammation Is a Complex Response to Injury That Encompasses Both Innate and Adaptive Immunity	1086
Adaptive Immunity, the Third Line of Defense, Exhibits Specificity	1088

<b>23.2 Immunoglobulins: Structure and Function</b>	<b>1089</b>	Many of the Variable Residues of TCRs Are Encoded in the Junctions Between V, D, and J Gene Segments	1118
Immunoglobulins Have a Conserved Structure Consisting of Heavy and Light Chains	1089	Signaling via Antigen-Specific Receptors Triggers Proliferation and Differentiation of T and B Cells	1118
Multiple Immunoglobulin Isotypes Exist, Each with Different Functions	1090	T Cells Capable of Recognizing MHC Molecules Develop Through a Process of Positive and Negative Selection	1120
Each Naive B Cell Produces a Unique Immunoglobulin	1091	T Cells Commit to the CD4 or CD8 Lineage in the Thymus	1121
Immunoglobulin Domains Have a Characteristic Fold Composed of Two $\beta$ Sheets Stabilized by a Disulfide Bond	1093	T Cells Require Two Types of Signals for Full Activation	1122
An Immunoglobulin's Constant Region Determines Its Functional Properties	1094	Cytotoxic T Cells Carry the CD8 Co-receptor and Are Specialized for Killing	1122
<b>23.3 Generation of Antibody Diversity and B-Cell Development</b>	<b>1095</b>	T Cells Produce an Array of Cytokines That Provide Signals to Other Immune-System Cells	1123
A Functional Light-Chain Gene Requires Assembly of V and J Gene Segments	1096	Helper T Cells Are Divided into Distinct Subsets Based on Their Cytokine Production and Expression of Surface Markers	1124
Rearrangement of the Heavy-Chain Locus Involves V, D, and J Gene Segments	1099	Leukocytes Move in Response to Chemotactic Cues Provided by Chemokines	1124

*Nothing in biology makes sense except in the light of evolution.*

—Theodosius Dobzhansky, 1973, essay in  
*American Biology Teacher* 35:125–129

**Biology** is a science fundamentally different from physics or chemistry, which deal with unchanging properties of matter that can be described by mathematical equations. Biological systems, of course, follow the rules of chemistry and physics, but biology is a historical science, as the forms and structures of the living world today are the results of billions of years of evolution. Through evolution, all organisms are related in a family tree extending from primitive single-celled organisms that lived in the distant past to the diverse plants, animals, and microorganisms of the present era (Figure 1-1, Table 1-1). The great insight of Charles Darwin (Figure 1-2) was the principle of natural selection: organisms vary randomly and compete within their environment for resources. Only those that survive and reproduce are able to pass down their genetic traits.

# Molecules, Cells, and Model Organisms

At first glance, the biological universe does appear amazingly diverse—from tiny ferns to tall fir trees, from single-celled bacteria and protozoans visible only under a microscope to multicellular animals of all kinds. Indeed, cells come in an astonishing variety of sizes and shapes (Figure 1-3). Some move rapidly and have fast-changing structures, as we can see in movies of amoebae and rotifers. Others are largely stationary and structurally stable. Oxygen kills some cells but is an absolute requirement for others. Most cells in multicellular organisms are intimately involved with other cells. Although some unicellular organisms live in isolation (Figure 1-3a), others form colonies or live in close association with other types of organisms (Figure 1-3b, d), such as the bacteria that help plants to extract nitrogen from the air or the bacteria that live in our intestines and help us digest food.

Yet the bewildering array of outward biological forms overlies a powerful uniformity: thanks to our common ancestry, all biological systems are composed of cells containing the same types of chemical molecules and employing similar principles of organization at the cellular level. Although the

**FIGURE 1-1 All living organisms descended from a common ancestral cell.** All organisms, from simple bacteria to complex mammals, probably evolved from a common single-celled ancestor. This family tree depicts the evolutionary relationships among the three major lineages of organisms. The structure of the tree was initially ascertained from morphological criteria: creatures that look alike were put close together. More recently, the sequences of DNA and proteins

found in organisms have provided more information-rich criteria for assigning relationships. The greater the similarities in these macromolecular sequences, the more closely related organisms are thought to be. The trees based on morphological comparisons and the fossil record generally agree well with those based on molecular data. [Data from J. R. Brown, 2005, "Universal tree of life," in *Encyclopedia of Life Sciences*, Wiley InterScience (online).]

basic kinds of biological molecules have been conserved during the billions of years of evolution, the patterns in which they are assembled to form functioning cells and organisms have undergone considerable change.

We now know that **genes**, which chemically are composed of **deoxyribonucleic acid (DNA)**, ultimately define biological structure and maintain the integration of cellular function. Many genes encode **proteins**, the primary molecules that make up cell structures and carry out cellular activities. Alterations in the structure and organization of genes, or **mutations**, provide the random variation that can alter biological structure and function. While the vast majority of random mutations have no observable effect on a gene's or protein's function, many are deleterious, and only a few confer an evolutionary advantage on the organism. In all organisms, mutations in DNA are constantly occurring, allowing over time the small alterations in cellular structures and functions that may prove to be advantageous. Entirely new cellular structures are rarely created; more often, existing cellular structures undergo changes that better adapt the organism to new circumstances. Slight changes in a protein can cause important changes in its function or abolish its function entirely.

For instance, in a particular organism, one gene may randomly become duplicated, after which one copy of the

gene and its encoded protein retain their original function while, over time, the second copy of the gene mutates such that its protein takes on a slightly different or even a totally new function. During the evolution of some organisms, the entire genome became duplicated, allowing the second copies of many genes to undergo mutations and acquire new functions. The cellular organization of organisms plays a fundamental role in this process because it allows these changes to come about by small alterations in previously evolved cells, giving them new abilities. The result is that closely related organisms have very similar genes and proteins as well as similar cellular and tissue organizations.

Multicellular organisms, including the human body, consist of such closely interrelated elements that no single element can be fully appreciated in isolation from the others. Organisms contain organs, organs are composed of tissues, tissues consist of cells, and cells are formed from molecules (Figure 1-4). The unity of living systems is coordinated by many levels of interrelationship: molecules carry messages from organ to organ and cell to cell, and tissues are delineated and integrated with other tissues by molecules secreted by cells. Generally all the levels into which we fragment biological systems interconnect.

**TABLE 1-1** Timeline for Evolution of Life on Earth, as Determined from the Fossil Record

4600 million years ago	The planet Earth forms from material revolving around the young Sun.
~3900–2500 million years ago	Cells resembling prokaryotes appear. These first organisms are chemoautotrophs: they use carbon dioxide as a carbon source and oxidize inorganic materials to extract energy.
3500 million years ago	Lifetime of the last universal ancestor; the split between Eubacteria and Archaea occurs.
3000 million years ago	Photosynthesizing cyanobacteria evolve; they use water as a reducing agent, thereby producing oxygen as a waste product.
1850 million years ago	Unicellular eukaryotes appear.
1200 million years ago	Simple multicellular organisms evolve, mostly consisting of cell colonies of limited complexity.
580–500 million years ago	Most modern phyla of animals begin to appear in the fossil record during the Cambrian explosion.
535 million years ago	Major diversification of living things in the oceans: chordates, arthropods (e.g., trilobites, crustaceans), echinoderms, mollusks, brachiopods, foraminifers, radiolarians, etc.
485 million years ago	First vertebrates with true bones (jawless fishes) evolve.
434 million years ago	First primitive plants arise on land.
225 million years ago	Earliest dinosaurs (prosauropods) and teleost fishes appear.
220 million years ago	Gymnosperm forests dominate the land; herbivores grow to huge sizes.
215 million years ago	First mammals evolve.
65.5 million years ago	The Cretaceous-Tertiary extinction event eradicates about half of all animal species, including all of the dinosaurs.
6.5 million years ago	First hominids evolve.
2 million years ago	First members of the genus <i>Homo</i> appear in the fossil record.
350 thousand years ago	Neanderthals appear.
200 thousand years ago	Anatomically modern humans appear in Africa.
30 thousand years ago	Extinction of Neanderthals.

**FIGURE 1-2 Charles Darwin (1809–1882).** Four years after his epic voyage on HMS *Beagle*, Darwin had already begun formulating in private notebooks his concept of natural selection, which would be published in his *Origin of Species* (1859). [Charles Darwin on the Galapagos Islands by Howat, Andrew (20th century)/Private Collection/© Look and Learn/Bridgeman Images.]

**FIGURE 1-3 Cells come in an astounding assortment of shapes and sizes.** Some of the morphological variety of cells is illustrated in these photographs. In addition to morphology, cells differ in their ability to move, internal organization (prokaryotic versus eukaryotic cells), and metabolic activities. (a) Eubacteria: *Lactococcus lactis*, which are used to produce cheese such as Roquefort, Brie, and Camembert. Note the dividing cells. (b) A mass of archaeans (*Methanosarcina*) that produce their energy by converting carbon dioxide and hydrogen gas to methane. Some species that live in the rumens of cattle give rise to >150 liters of methane gas each day. (c) Human blood cells, shown in false color. The red cells are oxygen-bearing erythrocytes, the white cells (leukocytes) are part of the immune system and fight infection, and the green cells are platelets that plug wounds and contain substances to initiate blood clotting. (d) A colonial single-celled green alga,

*Volvox aureus*. The large spheres are made up of many individual cells, visible as blue or green dots. The yellow masses inside are daughter colonies, each made up of many cells. (e) A single Purkinje neuron of the cerebellum, which can form more than a hundred thousand connections with other cells through its branched network of dendrites. The cell was made visible by introduction of a green fluorescent protein; the cell body is the bulb at the upper right. (f) Plant cells are fixed firmly in place in vascular plants, supported by a rigid cellulose skeleton. Spaces between the cells are joined into tubes for transport of water and food. Blau (Stanford University School of Medicine) and Dr. Clas B. Johansson (Karolinska Institutet). Part (f) Biophoto Associates/Science Source.]

To learn about biological systems, however, we must examine one small portion of a living system at a time. The biology of cells is a logical starting point because an organism can be viewed as consisting of interacting cells, which are the closest thing to autonomous biological units that exist. The last common ancestor of all life on Earth was a single cell (see Figure 1-1), and at the cellular level all life is remarkably similar. All cells use the same molecular building blocks, similar methods for the storage, maintenance, and expression of genetic information, and similar processes of energy metabolism, molecular transport, signaling, development, and structure.

In this chapter, we introduce the common features of cells. We begin with a brief discussion of the principal small

molecules and macromolecules found in biological systems. Next we discuss the fundamental aspects of cell structure and function that are conserved in present-day organisms, focusing first on prokaryotic organisms—single-celled organisms without a nucleus—and their uses in studying the basic molecules of life. Then we discuss the structure and function of eukaryotic cells—cells with a defined nucleus—focusing on their many organelles. This discussion is followed by a section describing the use of unicellular eukaryotic organisms in investigations of molecular cell biology, focusing on yeasts and the parasite that causes malaria.

We now have the complete sequences of the genomes of several thousand **metazoans** (multicellular animals), and these sequences have provided considerable insight into the

**FIGURE 1-4 Living systems such as the human body consist of closely interrelated elements.** (a) The surface of the hand is covered by a living organ, skin, that is composed of several layers of tissue. (b) An outer covering of hard, dead skin cells protects the body from injury, infection, and dehydration. This layer is constantly renewed by living epidermal cells, which also give rise to hair and fur in animals. Deeper layers of muscle and connective tissue give skin its tone and firmness. (c) Tissues are formed through subcellular adhesion

structures (desmosomes and hemidesmosomes) that join cells to one another and to an underlying layer of supporting fibers. (d) At the heart of cell-cell adhesion are its structural components: phospholipid molecules that make up the cell-surface membrane, and large protein molecules. Protein molecules that traverse the cell membrane often form strong bonds with internal and external fibers made of multiple proteins.

evolution of genes and organisms. The final section in this chapter shows us how this information can be used to refine the evolutionary relationships among organisms as well as our understanding of human development. Indeed, biologists use evolution as a research tool: if a gene and its protein have been conserved in all metazoans but are not found in unicellular organisms, the protein probably has an important function in all metazoans and thus can be studied in whatever metazoan organism is most suitable for the investigation. Because the structure and function of many types of metazoan cells is also conserved, we now understand the structure and function of many cell types in considerable detail, including muscle and liver cells and the sheets of epithelial cells that line the intestine and form our skin. But other cells—especially the multiple types that form our nervous and immune systems—still remain mysterious; much important cell biological experimentation is needed on these and other cell systems and organs that form our bodies.

## 1.1 The Molecules of Life

While large polymers are the focus of molecular cell biology, small molecules are the stage on which all cellular processes are set. Water, inorganic ions, and a wide array of relatively small organic molecules (Figure 1-5) account for 75 to 80 percent of living matter by weight, and water accounts for about 75 percent of a cell's volume. These small molecules, including water, serve as substrates for many of the reactions that take place inside the cell, including energy metabolism and cell signaling. Cells acquire these small molecules in different ways. Ions, water, and many small organic molecules are imported into the cell (see Chapter 11); other small molecules are synthesized within the cell, often by a series of chemical reactions (see Chapter 12).

Even in the structures of many small molecules, such as sugars, vitamins, and amino acids, we see the footprint of evolution. For example, all amino acids save glycine have an

**FIGURE 1-5 Some of the many small molecules found in cells.** Only the L-forms of amino acids such as serine are incorporated into proteins, not their D-mirror images; only the D-form of glucose, not its L-mirror image, can be metabolized to carbon dioxide and water.

asymmetric carbon atom, yet only the L-stereoisomer, never the D-stereoisomer, is incorporated into proteins. Similarly, only the D-stereoisomer of glucose is invariably found in cells, never the mirror-image L-stereoisomer (see Figure 1-5). At an early stage of biological evolution, our common cellular ancestor evolved the ability to catalyze reactions with one

stereoisomer instead of the other. How these selections happened is unknown, but now these choices are locked in place.

An important and universally conserved small molecule is **adenosine triphosphate (ATP)**, which stores readily available chemical energy in two of its chemical bonds (Figure 1-6). When one of these energy-rich bonds in ATP is broken, forming **ADP (adenosine diphosphate)**, the released energy can be harnessed to power energy-requiring processes such as muscle contraction or protein biosynthesis. To obtain energy for making ATP, all cells break down food molecules. For instance, when sugar is degraded to carbon dioxide and water, the energy stored in the sugar molecule's chemical bonds is released, and much of it can be "captured" in the energy-rich bonds in ATP. Bacterial, plant, and animal cells can all make ATP by this process. In addition, plants and a few other organisms can harvest energy from sunlight to form ATP in **photosynthesis**.

Other small molecules (e.g., certain hormones and growth factors) act as signals that direct the activities of cells (see Chapters 15 and 16), and neurons (nerve cells) communicate with one another by releasing and sensing certain small signaling molecules (see Chapter 22). The powerful physiological effects of a frightening event, for example, come from the instantaneous flooding of the body with the small-molecule hormone adrenaline, which mobilizes the "fight or flight" response.

Certain small molecules (**monomers**) can be joined to form **polymers** (also called **macromolecules**) through

**FIGURE 1-6 Adenosine triphosphate (ATP) is the most common molecule used by cells to capture, store, and transfer energy.** ATP is formed from adenosine diphosphate (ADP) and inorganic phosphate

( $P_i$ ) by photosynthesis in plants and by the breakdown of sugars and fats in most cells. The energy released by the splitting (hydrolysis) of  $P_i$  from ATP drives many cellular processes.

repetition of a single type of covalent chemical-linkage reaction. Cells produce three types of large macromolecules: polysaccharides, proteins, and nucleic acids. Sugars, for example, are the monomers used to form polysaccharides. Different polymers of D-glucose form cellulose, an important component of plant cell walls, and glycogen, a storage form of glucose found in liver and muscle. The cell is careful to provide the appropriate mix of small molecules needed as precursors for synthesis of macromolecules.

## Proteins Give Cells Structure and Perform Most Cellular Tasks

Proteins, the workhorses of the cell, are the most abundant and functionally versatile of the cellular macromolecules. Cells string together 20 different **amino acids** in linear chains, each with a defined sequence, to form proteins (see Figure 2-14), which commonly range in length from 100 to 1000 amino acids. During or just after its polymerization, a linear chain of amino acids folds into a complex shape, conferring a distinctive three-dimensional structure and function on the protein (Figure 1-7). Humans obtain amino acids either by synthesizing them from other molecules or by breaking down proteins that we eat.

Proteins have a variety of functions in the cell. Many proteins are **enzymes**, which accelerate (catalyze) chemical reactions involving small molecules or macromolecules (see Chapter 3). Certain proteins catalyze steps in the synthesis of all proteins; others catalyze synthesis of macromolecules such

as DNA and RNA. **Cytoskeletal proteins** serve as structural components of a cell; for example, by forming an internal skeleton. Other proteins associated with the cytoskeleton power the movement of subcellular structures such as chromosomes, and even of whole cells, by using energy stored in the chemical bonds of ATP (see Chapters 17 and 18). Still other proteins bind adjacent cells together or form parts of the extracellular matrix (see Figure 1-4). Proteins can be sensors that change shape as temperature, ion concentrations, or other properties of the cell change. Many proteins that are embedded in the cell-surface (plasma) membrane import and export a variety of small molecules and ions (see Chapter 11). Some proteins, such as insulin, are hormones; others are hormone receptors that bind their target protein or small molecule and then generate a signal that regulates a specific aspect of cell function. Other important classes of proteins bind to specific segments of DNA, turning genes on or off (see Chapter 9). In fact, much of molecular cell biology consists of studying the function of specific proteins in specific cell types.

## Nucleic Acids Carry Coded Information for Making Proteins at the Right Time and Place

The macromolecule that garners the most public attention is deoxyribonucleic acid (DNA), whose functional properties make it the cell's "master molecule." The three-dimensional structure of DNA, first proposed by James D. Watson and Francis H. C. Crick in 1953, consists of two long helical strands that are coiled around a common axis to form a

**FIGURE 1-7 Models of some representative proteins drawn to a common scale and compared with a small portion of a lipid bilayer, a DNA molecule, and an RNA molecule.** Each protein has a defined three-dimensional shape held together by numerous chemical bonds. The illustrated proteins include enzymes (glutamine synthetase and adenylate kinase), an antibody (immunoglobulin), a hormone (insulin), and the blood's oxygen carrier (hemoglobin). [Glutamine synthetase

data from H. S. Gill and D. Eisenberg, 2001, *Biochemistry* **40**:1903–1912, PDB ID 1fpy. Insulin data from E. N. Baker et al., 1988, *Phil. Trans. R. Soc. Lond. B Biol. **FIGURE 1-8 DNA consists of two complementary strands wound around each other to form a double helix.** The double helix is stabilized by weak hydrogen bonds between the A and T bases and between the C and G bases. During replication, the two strands are unwound and used as templates to produce complementary strands. The outcome is two identical copies of the original double helix, each containing one of the original strands and one new daughter (complementary) strand.

**double helix** (Figure 1-8). The double-helical structure of DNA, one of nature's most magnificent constructions, is critical to the phenomenon of **heredity**, the transfer of genetically determined characteristics from one generation to the next.

DNA strands are composed of monomers called **nucleotides**; these monomers are often referred to as **bases** because they contain cyclic organic bases (see Chapter 5). Four different nucleotides, abbreviated A, T, C, and G, are joined to form a DNA strand, with the base parts projecting inward from the backbone of the strand. Two strands bind together via the bases and twist to form a double helix. Each DNA double helix has a simple construction: wherever one strand has an A, the other strand has a T, and each C is matched with a G (see Figure 1-8). This **complementary** matching of the two strands is so strong that if complementary strands are separated under the right salt concentration and temperature conditions, they will spontaneously zip back together. This property is critical for DNA replication and inheritance, as we will learn in Chapter 5, and also underlies many of the techniques for studying DNA molecules that are detailed in Chapter 6.

The genetic information carried by DNA resides in its **sequence**, the linear order of nucleotides along a strand. Specific segments of DNA, termed **genes**, carry instructions for making specific proteins. Commonly, genes contain two parts: the coding region specifies the amino acid sequence of a protein; the regulatory region binds specific proteins and controls when and in which cells the gene's protein is made.

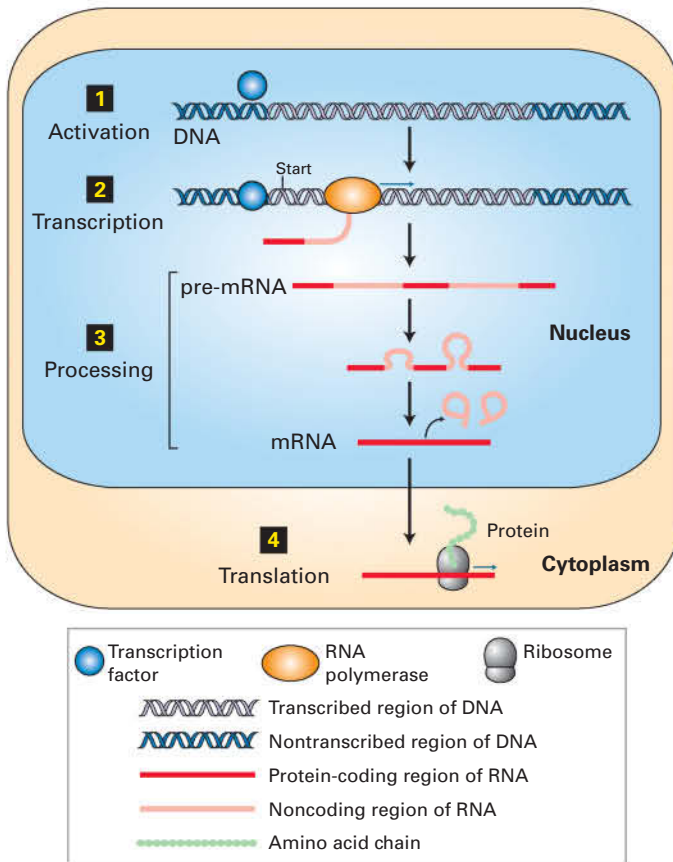

Most bacteria have a few thousand protein-coding genes; yeasts and other unicellular eukaryotes have about 5000. Humans and other metazoans have between 13,000 and 23,000, while many plants have more. As we discuss later in this chapter, many of the genes in bacteria specify the sequences of proteins that catalyze reactions that occur universally, such as the metabolism of glucose and the synthesis of nucleic acids and proteins. These genes, and the proteins encoded by them, are conserved throughout all living organisms, and thus studies on the functions of these genes and proteins in bacterial cells have yielded profound insights into these basic life processes. Similarly, many genes in unicellular eukaryotes such as yeasts encode proteins that are conserved throughout all eukaryotes; we will see how yeasts have been used in studies of processes such as cell division that have yielded profound insights into human diseases such as cancer.

How is information stored in the sequence of DNA used? Cells use two processes in series to convert the coded information in DNA into proteins (Figure 1-9). In the first process, called **transcription**, the protein-coding region of a gene is copied into a single-stranded **ribonucleic acid (RNA)** whose sequence is the same as one of the two in the double-stranded DNA. A large enzyme, **RNA polymerase**, catalyzes the linkage of nucleotides into an RNA chain using DNA as a template. In eukaryotic cells, the initial RNA product is processed into a smaller **messenger RNA (mRNA)** molecule, which moves out of the nucleus to the **cytoplasm**, the region of the cell outside of the nucleus. Here the **ribosome**, an enormously complex molecular machine composed of both RNA and proteins, carries out the second process, called **translation**. During translation, the ribosome assembles and links together amino acids in the precise order dictated by the mRNA sequence according to the nearly universal **genetic code**. We examine the cell components that carry out transcription and translation in detail in Chapter 5.

In addition to its role in transferring information from nucleus to cytoplasm, RNA can serve as a framework for building a molecular machine. The ribosome, for example, is built of four RNA chains that bind to more than 50 proteins to make a remarkably precise and efficient mRNA reader and protein synthesizer. While most chemical reactions in cells are catalyzed by proteins, a few, such as the formation by ribosomes of the peptide bonds that connect amino acids in proteins, are catalyzed by RNA molecules.

Well before the entire human genome was sequenced, it was apparent that only about 10 percent of human DNA consists of protein-coding genes, and for many years the remaining 90 percent was considered "junk DNA"! In recent years, we've learned that much of the so-called junk DNA is actually copied into thousands of RNA molecules that, though they do not encode proteins, serve equally important purposes in the cell (see Chapter 10). At present, however, we know the function of only a very few of these abundant noncoding RNAs.

Like enzymes, certain RNA molecules, termed **ribozymes**, catalyze chemical reactions, as exemplified by the RNA inside a ribosome. Many scientists support the **RNA world** hypothesis, which proposes that RNA molecules that could replicate themselves were the precursors of current life forms;

**FIGURE 1-9** The information encoded in DNA is converted into the amino acid sequences of proteins by a multistep process.

Step **1**: Transcription factors and other proteins bind to the regulatory regions of the specific genes they control to activate those genes. Step **2**: RNA polymerase begins transcription of an activated gene at a specific location, the start site. The polymerase moves along the DNA, linking nucleotides into a single-stranded pre-mRNA transcript using one of the DNA strands as a template. Step **3**: The transcript is processed to remove noncoding sequences. Step **4**: In a eukaryotic cell, the mature mRNA moves to the cytoplasm, where it is bound by ribosomes that read its sequence and assemble a protein by chemically linking amino acids into a linear chain.

billions of years ago, the RNA world gradually evolved into the DNA, RNA, and protein world of today's organisms.

All organisms must control when and where their genes are transcribed. Nearly all the cells in our bodies contain the full set of human genes, but in each cell type only some of these genes are active, or turned on, and used to make proteins. For instance, liver cells produce some proteins that are not produced by kidney cells, and vice versa. Moreover, many cells respond to external signals or changes in external conditions by turning specific genes on or off, thereby adapting their repertoire of proteins to meet current needs. Such control of gene activity depends on DNA-binding proteins called **transcription factors**, which bind to specific sequences of DNA and act as switches, either activating or repressing transcription of particular genes, as discussed in Chapter 9.

## Phospholipids Are the Conserved Building Blocks of All Cellular Membranes

In all organisms, cellular membranes are composed primarily of a bilayer (two layers) of phospholipid molecules. Each of these bipartite molecules has a “water-loving” (hydrophilic) “head” and a “water-hating” (hydrophobic) “tail.” The two phospholipid layers of a membrane are oriented with all the hydrophilic heads directed toward the inner or outer surfaces of the membrane and the hydrophobic tails buried within its interior (Figure 1-10). Smaller amounts of other lipids, such as cholesterol, are inserted into this phospholipid framework. Cellular membranes are extremely thin relative to the size of a cell. If you magnify a bacterium or yeast cell about 10,000 times to the size of a soccer ball, the plasma membrane is about as thick as a sheet of paper!

Phospholipid membranes are impermeable to water, all ions, and virtually all hydrophilic small molecules. Thus each membrane in each cell also contains groups of proteins that allow specific ions and small molecules to cross. Other membrane proteins serve to attach the cell to other cells or to polymers that surround it; still others give the cell its shape or allow its shape to change. We will learn more about membranes and how molecules cross them in Chapters 7 and 11.

New cells are always derived from parental cells by cell division. We've seen that the synthesis of new DNA molecules is templated by the two strands of the parental DNA such that each daughter DNA molecule has the same sequence as the parental one. In parallel, new membranes are made by incorporation of lipids and proteins into existing membranes in the parental cell and divided between daughter cells by fission. Thus membrane synthesis, like DNA synthesis, is templated by a parental structure.

**FIGURE 1-10** The watery interior of cells is surrounded by the plasma membrane, a two-layered shell of phospholipids.

The phospholipid molecules are oriented with their hydrophobic fatty acyl chains (black squiggly lines) facing inward and their hydrophilic head groups (white spheres) facing outward. Thus both sides of the membrane are lined by head groups, mainly charged phosphates, adjacent to the watery spaces inside and outside the cell. All biological membranes have the same basic phospholipid bilayer structure. Cholesterol (red) and various proteins are embedded in the bilayer. The interior space is actually much larger relative to the volume of the plasma membrane than is depicted here.

## 1.2 Prokaryotic Cell Structure and Function

The biological universe consists of two types of cells: prokaryotic and eukaryotic. Prokaryotic cells such as bacteria consist of a single closed compartment that is surrounded by a plasma membrane, lack a defined nucleus, and have a relatively simple internal organization (Figure 1-11). Eukaryotic cells contain a defined membrane-bounded nucleus and extensive internal membranes that enclose the organelles (see Figure 1-12).

### Prokaryotes Comprise Two Kingdoms: Archaea and Eubacteria

In recent years, detailed analysis of DNA sequences from a variety of prokaryotic organisms has revealed two distinct kingdoms: the Eubacteria, often simply called “bacteria,” and the Archaea. Eubacteria are single-celled organisms; they include the cyanobacteria, or “blue-green algae,” which can be unicellular or filamentous chains of cells. Figure 1-11 illustrates the general structure of a typical eubacterial cell; archaeal cells have a similar structure. Bacterial cells are commonly 1–2  $\mu\text{m}$  in size and consist of a single closed compartment containing the cytoplasm and bounded by the plasma membrane. The genome is composed of a single circular DNA molecule; many prokaryotes contain additional small circular DNA molecules called *plasmids*. Although bacterial cells do not have a defined nucleus, the DNA is extensively folded and condensed into the central region of the cell, called the nucleoid. In contrast, most ribosomes are found in the cytoplasm. Some bacteria also have an invagination of the cell membrane, called a mesosome, which is

associated with synthesis of DNA and secretion of proteins. Many proteins are precisely localized within the cytosol or in the plasma membrane, indicating the presence of an elaborate internal organization. Unlike those in eukaryotes (see Figure 1-9), bacterial mRNAs undergo limited if any processing. And because there is no membrane barrier between bacterial DNA and cytoplasm, ribosomes are able to bind to an mRNA as soon as part of it has been synthesized by RNA polymerase; thus in prokaryotes, transcription and translation occur contemporaneously.

Bacterial cells possess a cell wall, which lies adjacent to the external side of the plasma membrane. The cell wall is composed of layers of peptidoglycan, a complex of proteins and oligosaccharides; it helps protect the cell and maintain its shape. Some bacteria (e.g., *E. coli*) have a thin inner cell wall and an outer membrane separated from the inner cell wall by the periplasmic space. Such bacteria are not stained by the Gram technique and thus are classified as gram-negative. Other bacteria (e.g., *Bacillus polymyxa*) that have a thicker cell wall and no outer membrane take the Gram stain and thus are classified as Gram-positive.

In addition to DNA sequence distinctions that separate them from eubacteria, archaea have cell membranes that differ dramatically in composition from those of eubacteria and eukaryotes. Many archaeans grow in unusual, often extreme, environments that may resemble the ancient conditions that existed when life first appeared on Earth. For instance, halophiles (“salt lovers”) require high concentrations of salt to survive, and thermoacidophiles (“heat and acid lovers”) grow in hot (80  $^{\circ}\text{C}$ ) sulfur springs, where a pH of less than 2 is common. Still other archaeans live in oxygen-free milieus and generate methane ( $\text{CH}_4$ ) by combining water with carbon dioxide.

**FIGURE 1-11 Prokaryotic cells have a relatively simple structure.** (Left) Electron micrograph of a thin section of *Escherichia coli*, a common intestinal bacterium. The nucleoid, consisting of the bacterial DNA, is not enclosed within a membrane. *E. coli* and other gram-negative bacteria are surrounded by two membranes separated by the periplasmic space. The thin cell wall is adjacent to the inner membrane.

(Right) This artist's drawing shows the nucleoid (blue) and a magnification of the layers that surround the cytoplasm. Most of the cell is composed of water, proteins, ions, and other molecules that are too small to be depicted at the scale of this drawing. [Electron micrograph courtesy of I. D. J. Burdett and R. G. E. Murray.]

## Escherichia coli Is Widely Used in Biological Research

The bacterial lineage includes *Escherichia coli*, a favorite experimental organism, which in nature is common in soil and in animal intestines. *E. coli* and several other bacteria have a number of advantages as experimental organisms. They grow rapidly in a simple and inexpensive medium containing glucose and salts, in which they can synthesize all necessary amino acids, lipids, vitamins, and other essential small molecules. Like all bacteria, *E. coli* possesses elegant mechanisms for controlling gene activity that are now well understood

(see Chapter 9). Over time, researchers have developed powerful systems for genetic analysis of this organism. These systems are facilitated by the small size of bacterial genomes, the ease of obtaining mutants, the availability of techniques for transferring genes into bacteria, an enormous wealth of knowledge about bacterial gene control and protein functions, and the relative simplicity of mapping genes relative to one another in the bacterial genome. In Chapter 6 we see how *E. coli* is used in recombinant DNA research.

Bacteria such as *E. coli* that grow in environments as diverse as the soil and the human gut have about 4000 genes, encoding about the same number of proteins (Table 1-2).

**TABLE 1-2** Genome Sizes of Organisms Used in Molecular Cell Biology Research That Have Been Completely Sequenced

	Base Pairs (Millions)	Approximate Number of Encoded Proteins*	Chromosomes**	Reference
<b>Eubacteria</b>				
<i>Mycoplasma genitalum</i>	0.58	500	1	a
<i>Helicobacter pylori</i>	1.67	1,500	1	a

\*Numbers of encoded proteins are current estimates rounded to the nearest 100 based on genome DNA sequences. They will likely change slightly in eubacteria and archaea because of the inclusion of newly discovered genes that code for very small proteins, and modestly in eukaryotes because of newly discovered small genes and because of pseudogenes that are not expressed.

\*\*Only nuclear chromosomes are counted in eukaryotes, including distinct sex chromosomes in metazoans.

\*\*\*Predicted value.

Parasitic bacteria such as the *Mycoplasma* species acquire amino acids and other nutrients from their host cells, and they lack the genes for enzymes that catalyze reactions in the synthesis of amino acids and certain lipids. Many bacterial genes encoding proteins essential for DNA, RNA, protein synthesis, and membrane function are conserved in all organisms, and much of our knowledge of these important cellular processes was uncovered first by studies in *E. coli* and other bacteria. For example, certain *E. coli* membrane proteins that import amino acids across the plasma membrane are closely related in sequence, structure, and function to membrane proteins in certain mammalian brain cells that import small nerve-to-nerve signaling molecules called neurotransmitters (see Chapters 11 and 22).

Because many of its genes and proteins, as well as their functions, are conserved in all organisms, *E. coli* has been chosen by scientists as a favorite **model organism**: an experimental system in which the study of specific genes or proteins, or aspects of cell or organismal function or regulation, can provide an understanding of similar molecules or processes in other species. Throughout this chapter, we will encounter other model organisms that have been chosen because, like *E. coli*, they are easy to grow and study. Of course, many bacteria cause serious diseases, and research on them is often focused on understanding their unique biology and on discovering antibiotics that selectively kill them but not their human or animal hosts.

### 1.3 Eukaryotic Cell Structure and Function

**Eukaryotes** comprise all members of the plant and animal kingdoms as well as protozoans (*proto*, “primitive”; *zoan*, “animal”), which are exclusively unicellular and include fungi and amoebae. Eukaryotic cells are commonly about 10–100  $\mu\text{m}$  across, generally much larger than bacteria. A typical human fibroblast, a connective tissue cell, is about 15  $\mu\text{m}$  across, with a volume and dry weight some thousands of times those of an *E. coli* cell. An amoeba, a single-celled protozoan, can have a cell diameter of approximately 0.5 mm, more than 30 times that of a fibroblast.

Eukaryotic cells, like prokaryotic cells, are surrounded by a plasma membrane. However, unlike prokaryotic cells, most eukaryotic cells (the human red blood cell is an exception) also contain extensive internal membranes that enclose specific subcellular compartments, the **organelles**, and separate them from the cytoplasm (Figure 1-12). The **cytosol**, the organelle-free part of the cytoplasm, contains water, dissolved ions, small molecules, and proteins. Plant cells and most fungal cells are surrounded by a cell wall that gives the cell a rigid shape and also allows for rapid cell expansion.

All eukaryotic cells have many of the same organelles and other subcellular structures. Many organelles are surrounded by a single phospholipid membrane, but the

nucleus, mitochondrion, and chloroplast are enclosed by two membranes. Each organelle membrane and each space in the interior of an organelle has a unique set of proteins that enable it to carry out its specific functions, including enzymes that catalyze requisite chemical reactions. The membranes defining these subcellular compartments contain proteins that control their internal ionic composition so that it generally differs from that of the surrounding cytosol as well as that of the other organelles. Here we describe the organelles common to all eukaryotic cells as well as several that are found only in certain types of eukaryotes. We begin with the proteins that give eukaryotic cells their shapes and organize the organelles.

#### The Cytoskeleton Has Many Important Functions

The cytoplasm contains an array of fibrous proteins collectively called the **cytoskeleton** (see Chapters 17 and 18). Three classes of fibers compose the cytoskeleton: **microtubules** (20 nm in diameter), built of polymers of the protein tubulin; **microfilaments** (7 nm in diameter), built of the protein actin; and **intermediate filaments** (10 nm in diameter). All of these fibers are long chains of multiple copies of one or more small protein subunits (Figure 1-13). The cytoskeleton gives the cell strength and rigidity, thereby helping to maintain its shape; this is perhaps most obvious with neurons, in which microtubules and other fibers allow the formation of the long, slim protuberances—the axons and dendrites (see Figure 1-3e and Chapter 22)—that emanate from the cell body and allow each neuron to carry out its specialized functions. Cytoskeletal fibers also control movement of structures within the cell; for example, some cytoskeletal fibers connect to organelles or provide tracks along which organelles and chromosomes move. Other fibers play key roles in cell motility. Perhaps most important, cell division and the segregation of chromosomes and organelles into the two daughter cells could not occur without the organizational framework provided by the cytoskeleton and its associated proteins.

**Cilia** and **flagella** are similar extensions of the plasma membrane. They contain a bundle of microtubules that gives them shape and, together with motor proteins, allows them to beat rhythmically. They propel materials across epithelial surfaces (Figure 1-14), enable sperm to swim, and push eggs through the oviduct (see Chapter 18). As detailed in Chapter 16, most vertebrate cells contain at least one cilium that plays a key role in cell-cell signaling.

#### The Nucleus Contains the DNA Genome, RNA Synthetic Apparatus, and a Fibrous Matrix

The **nucleus**, the largest organelle in animal cells, is surrounded by two membranes, each one a phospholipid bilayer containing many different types of proteins

(a)

Animal cell

Plant cell

- 1** Plasma membrane controls movement of molecules in and out of the cell and functions in cell-cell signaling and cell adhesion.
- 2** Mitochondria, which are surrounded by a double membrane, generate ATP by oxidation of glucose and fatty acids.
- 3** Lysosomes, which have an acidic lumen, degrade material internalized by the cell and worn-out cellular membranes and organelles.
- 4** Nuclear envelope, a double membrane, encloses the contents of the nucleus; the outer nuclear membrane is continuous with the rough ER.
- 5** Nucleolus is a nuclear subcompartment where most of the cell's rRNA is synthesized.
- 6** Nucleus is filled with chromatin composed of DNA and proteins; site of mRNA and tRNA synthesis.
- 7** Smooth endoplasmic reticulum (ER) contains enzymes that synthesize lipids and detoxify certain hydrophobic molecules.
- 8** Rough endoplasmic reticulum (ER) functions in the synthesis, processing, and sorting of secreted proteins, lysosomal proteins, and certain membrane proteins.
- 9** Golgi complex processes and sorts secreted proteins, lysosomal proteins, and membrane proteins synthesized on the rough ER.
- 10** Secretory vesicles store secreted proteins and fuse with the plasma membrane to release their contents.
- 11** Peroxisomes contain enzymes that break down fatty acids into smaller molecules used for biosynthesis and also detoxify certain molecules.
- 12** Cytoskeletal fibers form networks and bundles that support cellular membranes, help organize organelles, and participate in cell movement.
- 13** Microvilli increase surface area for absorption of nutrients from surrounding medium.
- 14** Cell wall, composed largely of cellulose, helps maintain the cell's shape and provides protection against mechanical stress.
- 15** Vacuole stores water, ions, and nutrients, degrades macromolecules, and functions in cell elongation during growth.
- 16** Chloroplasts, which carry out photosynthesis, are surrounded by a double membrane and contain a network of internal membrane-bounded sacs.
- 17** Plasmodesmata are tubelike cell junctions that span the cell wall and connect the cytoplasms of adjacent plant cells.

(b)

**FIGURE 1-12 Subcellular organization of eukaryotic cells.** (a) Schematic overview of a “typical” animal cell (top) and plant cell (bottom) and their major substructures. Not every cell type will contain all the organelles, granules, and fibrous structures shown here, and other substructures can be present in some cell types. Cells also differ considerably in shape and in the prominence of various organelles and substructures. (b) Electron micrograph of a plasma cell, a type of white blood cell that secretes antibodies, showing some of the larger organelles. [Part (b) courtesy of I. D. J. Burdett and R. G. E. Murray.]

**FIGURE 1-13** The three types of cytoskeletal filaments have characteristic distributions within mammalian cells. Three views of the same cell. A cultured fibroblast was permeabilized and then treated with three different antibody preparations. Each antibody binds specifically to the protein monomers forming one type of filament and is chemically linked to a differently colored fluorescent

dye (green, blue, or red). Visualization of the stained cell in a fluorescence microscope reveals the locations of filaments bound to a particular dye-antibody preparation. In this case, microtubules are stained blue; microfilaments, red; and intermediate filaments, green. All three fiber systems contribute to the shape and movements of cells. [Courtesy of V. Small.]

(Figure 1-15). The *inner nuclear membrane* defines the nucleus itself. In most cells, the *outer nuclear membrane* is continuous with the endoplasmic reticulum, and the space between the inner and outer nuclear membranes is continuous with the lumen of the endoplasmic reticulum (see Figure 1-15a). The two nuclear membranes appear to fuse at **nuclear pore complexes**, ringlike structures composed of specific membrane proteins through which material moves between the nucleus and the cytosol. The structure of the nuclear pores and the regulated transport of material through them are detailed in Chapters 10 and 13. Intermediate-filament proteins called **lamins** form a two-dimensional network, called the **nuclear lamina**, along the inner surface of the inner membrane, giving it shape and rigidity. The breakdown of the lamina occurs early in cell division, as we detail in Chapter 19. In a growing or differentiating cell, the nucleus is metabolically active, as it is the site of DNA replication and the synthesis of ribosomal RNA, mRNA, and a large

variety of noncoding RNAs (see Chapters 5 and 9). Inside the nucleus one can often see a dense subcompartment, termed the **nucleolus**, where ribosomal RNA is synthesized and ribosomes are assembled (see Figure 1-15b and Chapter 10).

The total DNA in an organism is referred to as its **genome**. In most prokaryotic cells, most or all of the genetic information resides in a single circular DNA molecule about a millimeter in length; this molecule lies, folded back on itself many times, in the central region of the micrometer-sized cell (see Figure 1-11). In contrast, DNA in the nuclei of eukaryotic cells is distributed among multiple long linear structures called **chromosomes**. The length and number of chromosomes are the same in all cells of a particular species, but vary among different species (see Table 1-2). Each chromosome comprises a single DNA molecule associated with numerous histones and other proteins. In a nucleus that is not dividing, the chromosomes are dispersed and are not dense enough to be observed in the light microscope. Only during cell division are individual chromosomes visible by light microscopy. When nondividing cells are visualized in an electron microscope, the non-nucleolar regions of the nucleus, called the *nucleoplasm*, can be seen to have dark- and light-staining areas. The dark areas, which are often closely associated with the nuclear membrane, contain condensed, concentrated DNA that cannot be transcribed into RNA, called **heterochromatin** (see Figure 1-15b).

Chromosomes, which stain intensely with basic dyes, are visible in light and electron microscopes only during cell division, when the DNA becomes tightly compacted (Figure 1-16). Although the large genomic DNA molecule in prokaryotes is associated with proteins, the arrangement of DNA within a bacterial chromosome differs greatly from that within the linear chromosomes of eukaryotic cells; bacterial chromosomes are circular and are associated with different types of proteins than are eukaryotic chromosomes.

## Eukaryotic Cells Contain a Large Number of Internal Membrane Structures

We noted earlier that, unlike prokaryotic cells, most eukaryotic cells contain extensive internal membranes that enclose

**FIGURE 1-15 Structure of the nucleus.** (a) Schematic diagram of the structure of a typical cell nucleus and the connection of the outer nuclear membrane with the rough endoplasmic reticulum. The small black dots attached to the membrane of the rough endoplasmic reticulum are ribosomes that are synthesizing membrane and secreted

(b)

proteins. (b) Electron micrograph of a pancreatic acinar cell from the bat *Myotis lucifugus*. The nucleolus is a subcompartment of the nucleus and is not surrounded by a membrane; most ribosomal RNA is produced in the nucleolus. Darkly staining areas in the nucleus outside the nucleolus are regions of heterochromatin. [Part (b) Don W. Fawcett/Science Source.]

**FIGURE 1-16 Individual chromosomes can be seen in cells during cell division (mitosis).** (a) During the S phase of the cell cycle (see Figure 1-21) chromosomes are duplicated, and the daughter "sister chromatids," each with a complete copy of the chromosomal DNA, remain attached at the centromere. (b) During the actual cell division process (mitosis), the chromosomal DNA becomes highly compacted, and the pairs of sister chromatids can be seen in the electron micro-

(c)

scope, as depicted here. (c) Light-microscope image of a chromosomal spread from a cultured human male lymphoid cell arrested in the metaphase stage of mitosis by treatment with the microtubule-depolymerizing drug colcemid. There is a single copy of the duplicated X and Y chromosomes and two copies of each of the others. [Part (b) Medical RF/The Medical File/Peter Arnold Inc. Part (c) courtesy of Tatyana Pyntikova.]

specific subcellular compartments, termed organelles. Here we review the organelles and their functions.

**Endoplasmic Reticulum and Golgi Complex** Generally the largest membrane in a eukaryotic cell encloses the organelle termed the **endoplasmic reticulum (ER)**—an extensive network of closed, flattened membrane-bounded sacs called **cisternae** (Figure 1-17; see also Figure 1-15a). The endoplasmic reticulum has a number of functions in the cell but is particularly important in the synthesis of lipids, secreted proteins, and many types of membrane proteins. The **smooth endoplasmic reticulum** is smooth because it lacks ribosomes; it is the site of synthesis of fatty acids and phospholipids.

In contrast, the cytosolic side of the **rough endoplasmic reticulum** is studded with ribosomes; these ribosomes synthesize certain membrane and organelle proteins and virtually all proteins that are to be secreted from the cell (see Chapter 13). As a growing polypeptide emerges from a ribosome, it passes through the rough ER membrane with the help of specific transport proteins that are embedded in the membrane. Newly made membrane proteins remain associated with the rough ER membrane, and proteins to be secreted accumulate in the **lumen**, the aqueous interior of the organelle. Several minutes after proteins are synthesized in the rough ER, most of them leave the organelle within small membrane-bounded transport vesicles. These vesicles, which bud from regions of the rough ER not coated with ribosomes, carry the proteins to another membrane-bounded organelle, the **Golgi complex** (see Figure 1-17). As detailed in Chapter 14, secreted and membrane proteins undergo a series of enzyme-catalyzed chemical modifications in the Golgi complex that are essential for these proteins to function normally.

After proteins to be secreted and membrane proteins are modified in the Golgi complex, they are transported out of the complex by a second set of vesicles, which bud from one side of the Golgi complex. Some vesicles carry membrane

proteins destined for the plasma membrane or soluble proteins to be released from the cell into the extracellular space; others carry soluble or membrane proteins to lysosomes or other organelles. How intracellular transport vesicles “know” with which membranes to fuse and where to deliver their contents is also discussed in Chapter 14.

**Endosomes** Although transport proteins in the plasma membrane mediate the movement of ions and small molecules into the cell across the lipid bilayer, proteins and some other soluble macromolecules in the extracellular milieu are internalized by **endocytosis**. In this process, a segment of the plasma membrane invaginates into a **coated pit**, whose cytosolic face is lined by a specific set of proteins that cause vesicles to form. The pit pinches from the membrane into a small membrane-bounded vesicle that contains the extracellular material. The vesicle is delivered to and fuses with an **endosome**, a sorting station of membrane-limited tubules and vesicles (Figure 1-18). From this compartment, some membrane proteins are recycled back to the plasma membrane; other membrane proteins are transported in vesicles that eventually fuse with **lysosomes** for degradation. The entire endocytic pathway is described in detail in Chapter 14.

**Lysosomes** Lysosomes provide an excellent example of the ability of intracellular membranes to form closed compartments in which the composition of the lumen (the aqueous interior of the compartment) differs substantially from that of the surrounding cytosol. Found exclusively in animal cells, lysosomes are responsible for degrading many components that have become obsolete for the cell or organism. The process by which an aged organelle is degraded in a lysosome is called **autophagy** (“eating oneself”). Materials taken into a cell by endocytosis or phagocytosis may also be degraded in lysosomes (see Figure 1-18). In **phagocytosis**, large, insoluble particles (e.g., bacteria) are enveloped by the plasma membrane and internalized.

**FIGURE 1-17 The Golgi complex and rough endoplasmic reticulum.** An electron micrograph of a section of a human liver cell shows the abundant ribosome-studded rough endoplasmic reticulum and the Golgi complex, as well as many ribosomes free in the cytosol. [Courtesy George E. Palade EM Slide Collection, University of California, San Diego.]

**FIGURE 1-18 Endosomes and other cellular structures deliver materials to lysosomes.** Schematic overview of three pathways by which materials are moved to lysosomes. Soluble macromolecules and molecules bound to proteins on the cell surface are taken into the cell by invagination of segments of the plasma membrane and delivered to lysosomes through the endocytic pathway **1**. Whole cells and other large, insoluble particles move from the cell surface to lysosomes through the phagocytic pathway **2**. Worn-out organelles and bulk cytoplasm are delivered to lysosomes through the autophagic pathway **3**. Within the acidic lumen of a lysosome, hydrolytic enzymes degrade proteins, nucleic acids, lipids, and other large molecules.

Lysosomes contain a group of enzymes that degrade polymers into their monomeric subunits. For example, nucleases degrade RNA and DNA into their mononucleotide building blocks; proteases degrade a variety of proteins and peptides; phosphatases remove phosphate groups from mononucleotides, phospholipids, and other compounds; still other enzymes degrade complex polysaccharides and glycolipids into smaller units. All of these lysosomal enzymes, collectively termed *acid hydrolases*, work most efficiently at acidic pH values. The acidic pH helps to denature proteins, making them accessible to the action of the lysosomal hydrolases. These enzymes are less active at the neutral pH of cells and most extracellular fluids. Thus if a lysosome releases its enzymes into the cytosol, where the pH is between 7.0 and 7.3, they cause little degradation of cytosolic components. Cytosolic and nuclear proteins generally are not degraded in lysosomes, but rather in proteasomes, large multiprotein complexes in the cytosol (see Chapter 3).

**Peroxisomes** All animal cells (except erythrocytes) and many plant and fungal cells contain **peroxisomes**, a class of roughly spherical organelles 0.2–1.0  $\mu\text{m}$  in diameter. Peroxisomes contain several *oxidases*: enzymes that use molecular oxygen to oxidize organic substances and in the process form hydrogen peroxide ( $\text{H}_2\text{O}_2$ ), a corrosive substance. Peroxisomes also contain copious amounts of the enzyme *catalase*, which degrades hydrogen peroxide to yield water and oxygen (see Chapter 12). Plant seeds contain *glyoxisomes*, small organelles that oxidize stored lipids as a source of carbon and energy for growth. They are similar to peroxisomes and contain many of the same types of enzymes as well as additional ones used to convert fatty acids into glucose precursors.

**Plant Vacuoles** Most plant cells contain at least one membrane-limited **vacuole** that accumulates and stores water, ions, and small-molecule nutrients such as sugars and amino acids. A variety of membrane proteins in the vacuolar membrane allow the transport of these molecules from the cyto-

sol and their retention in the vacuole lumen. The number and size of vacuoles depend on both the type of cell and its stage of development; a single vacuole may occupy as much as 80 percent of a mature plant cell (Figure 1-19). Like that of a lysosome, the lumen of a vacuole contains a battery of degradative enzymes and has an acidic pH, which is maintained by similar transport proteins in the vacuolar membrane. Thus plant vacuoles may also have a degradative function similar to that of lysosomes in animal cells. Similar

**FIGURE 1-19 Electron micrograph of a thin section of a leaf cell.** In this cell, a single large vacuole occupies much of the cell volume. Parts of five chloroplasts and the cell wall are also visible. Note the internal subcompartments in the chloroplasts. [Biophoto Associates/Science Source.]

storage vacuoles are found in green algae and in many microorganisms such as fungi.

## Mitochondria Are the Principal Sites of ATP Production in Aerobic Cells

Most eukaryotic cells contain many **mitochondria** (Figure 1-20), which occupy up to 25 percent of the volume of the cytoplasm. These complex organelles, which are the main sites of ATP production during aerobic metabolism, are generally exceeded in size only by the nucleus, vacuoles, and chloroplasts. The two membranes that bound a mitochondrion differ in composition and function. The **outer mitochondrial membrane** contains proteins that allow many molecules to move from the cytosol to the **intermembrane space** between the inner and outer membrane. The **inner mitochondrial membrane**, which is much less permeable, is about 20 percent lipid and 80 percent protein—a proportion of protein that is higher than those in other cellular membranes. The surface area of the inner membrane is greatly increased by a large number of infoldings, or **cristae**, that protrude into the **matrix**, or central aqueous space.

In non-photosynthetic cells, the principal fuels for ATP synthesis are fatty acids and glucose. The complete aerobic degradation of 1 molecule of glucose to carbon dioxide and water is coupled to the synthesis of as many as 30 molecules of ATP from ADP and inorganic phosphate (see Figure 1-6). In eukaryotic cells, the initial stages of glucose degradation take place in the cytosol, where 2 ATP molecules per glucose molecule are generated. The terminal stages of oxidation and

ATP synthesis are carried out by enzymes in the mitochondrial matrix and inner membrane (see Chapter 12); as many as 28 ATP molecules per glucose molecule are generated in mitochondria. Similarly, virtually all the ATP formed in the oxidation of fatty acids to carbon dioxide is generated in mitochondria. Thus mitochondria can be regarded as the “power plants” of the cell.

Mitochondria contain small DNA molecules that encode a small number of mitochondrial proteins; the majority of mitochondrial proteins are encoded by nuclear DNA. As discussed in Chapter 12, the popular *endosymbiont hypothesis* postulates that mitochondria originated by endocytosis of an ancient bacterium by the precursor of a eukaryotic cell; the bacterial plasma membrane evolved to become the inner mitochondrial membrane.

## Chloroplasts Contain Internal Compartments in Which Photosynthesis Takes Place

Except for vacuoles, **chloroplasts** are the largest and the most characteristic organelles in the cells of plants and green algae (see Figure 1-19). The endosymbiont hypothesis (see Chapter 12) posits that these organelles originated by endocytosis of a primitive photosynthetic bacterium. Chloroplasts can be as long as 10  $\mu\text{m}$  and are typically 0.5–2  $\mu\text{m}$  thick, but they vary in size and shape in different cells, especially among the algae. In addition to the inner and outer membranes that bound a chloroplast, this organelle also contains an extensive internal system of interconnected membrane-limited vesicles called **thylakoids**, which are flattened to form disks. Thylakoids often form stacks called *grana* and are embedded in an aqueous matrix termed the *stroma*. The thylakoid membranes contain green pigments (chlorophylls) and other pigments that absorb light, as well as enzymes that generate ATP during photosynthesis. Some of the ATP is used to convert carbon dioxide into three-carbon intermediates by enzymes located in the stroma; the intermediates are then exported to the cytosol and converted into sugars.

The molecular mechanisms by which ATP is formed in mitochondria and chloroplasts are very similar, as explained in Chapter 12. Besides being surrounded by two membranes, chloroplasts and mitochondria have other features in common: both often migrate from place to place within cells, and both contain their own DNA, which encodes some of the key organelle proteins (see Chapter 12). The proteins encoded by mitochondrial or chloroplast DNA are synthesized on ribosomes within the organelles. However, most of the proteins in each organelle are encoded in nuclear DNA and are synthesized in the cytosol; these proteins are then incorporated into the organelles by processes described in Chapter 13.

## All Eukaryotic Cells Use a Similar Cycle to Regulate Their Division

Unicellular eukaryotes, animals, and plants all use essentially the same **cell cycle**, the series of events that prepares a cell to

**FIGURE 1-20 Electron micrograph of a mitochondrion in a pancreas cell.** The smooth outer membrane forms the outside boundary of the mitochondrion. The inner membrane is distinct from the outer membrane and is highly invaginated to form sheets and tubes called cristae; ATP is produced by proteins embedded in the membranes of the cristae. The aqueous space between the inner and outer membranes (the intermembrane space) and the space inside the inner membrane (the matrix) each contain specific proteins important for the metabolism of sugars, lipids, and other molecules. [Keith R. Porter/Science Source.]

**FIGURE 1-21 During growth, all eukaryotic cells continually progress through the four phases of the cell cycle.** In proliferating cells, the four phases of the cell cycle proceed successively. In humans, the cycle takes from 10 to 20 hours depending on cell type and developmental state. Yeasts divide much faster. During interphase, which consists of the  $G_1$ ,  $S$ , and  $G_2$  phases, the cell roughly doubles its mass. Replication of DNA during the  $S$  phase leaves the cell with four copies of each type of chromosome. In the mitotic ( $M$ ) phase, the chromosomes are evenly partitioned into two daughter cells, and in most cases the cytoplasm divides roughly in half. Under certain conditions, such as starvation or when a tissue has reached its final size, cells will stop cycling and remain in a waiting state called  $G_0$ . Some types of cells in  $G_0$  can reenter the cell cycle if conditions change.

divide, and the same actual division process, called **mitosis**. The eukaryotic cell cycle is commonly divided into four phases (Figure 1-21). The chromosomes and the DNA they carry are duplicated during the **S (synthesis) phase**. The replicated chromosomes separate during the **M (mitotic) phase**, in which the cell divides, and each daughter cell gets a copy of each chromosome. The  $M$  and  $S$  phases are separated by two gap phases, the  **$G_1$  phase** and the  **$G_2$  phase**, during which mRNAs, proteins, lipids, and other cell constituents are made and the cell increases in size.

Under optimal conditions, some bacteria, such as *E. coli*, can divide to form two daughter cells once every 30 minutes. Most eukaryotic cells take considerably longer to grow and divide, generally several hours. Moreover, the cell cycle in eukaryotes is normally highly regulated (see Chapter 19). This tight control prevents imbalanced, excessive growth of cells and tissues if essential nutrients or certain hormonal signals are lacking. Some highly specialized cells in adult animals, such as neurons and striated muscle cells, divide rarely, if at all. However, an organism usually replaces worn-out cells or makes more cells in response to a new need, as exemplified by the generation of new muscle cells from undifferentiated stem cells in response to exercise or damage. Another example is the formation of additional red blood cells when a person ascends to a higher altitude and needs more capacity to capture oxygen. The fundamental defect in cancer is loss of the ability to control the growth and

division of cells. In Chapter 24 we examine the molecular and cellular events that lead to inappropriate, uncontrolled proliferation of cells.

## 1.4 Unicellular Eukaryotic Model Organisms

Our current understanding of the molecular functioning of eukaryotic cells largely rests on studies of just a few types of organisms, termed model organisms (Figure 1-22). Because of the evolutionary conservation of genes, proteins, organelles, cell types, and so forth, discoveries about biological structures and functions obtained with one experimental organism often apply to others. Thus researchers generally conduct studies with the organism that is most suitable for rapidly and completely answering the question being posed, knowing that the results obtained in one organism are likely to be broadly applicable. Indeed, many organisms, particularly rats, frogs, sea urchins, chickens, and slime molds, have been and continue to be immensely valuable for cell biology research. As more and more organisms have their entire genomes sequenced, a wide variety of other species are increasingly being used for investigations, especially for studies of the evolution of genes, cells, and organisms and of how organisms become adapted to diverse ecological niches.

As we have seen, bacteria are excellent models for studies of several cellular functions, but they lack the organelles found in eukaryotes. Unicellular eukaryotes such as yeasts are used to study many fundamental aspects of eukaryotic cell structure and function. Metazoan models such as the roundworm, fruit fly, and mouse are required to study more complex tissue and organ systems and development. As we will see in this section and the next, several eukaryotic model organisms are widely used to understand complex cell systems and mechanisms.

### Yeasts Are Used to Study Fundamental Aspects of Eukaryotic Cell Structure and Function

One group of single-celled eukaryotes, the yeasts, has proven exceptionally useful in molecular and genetic analysis of eukaryotic cell formation and function. Yeasts and their multicellular cousins, the molds, which collectively constitute the fungi, have an important ecological role in breaking down plant and animal remains for reuse. They also make numerous antibiotics and are used in the manufacture of bread, beer, and wine.

The common yeast used to make bread and beer, *Saccharomyces cerevisiae*, appears frequently in this book because it has proved to be an extremely useful experimental organism. Homologs of many of the approximately 6000 different proteins expressed in an *S. cerevisiae* cell (see Table 1-2) are found in most, if not all, eukaryotes and are important for cell division or for the functioning of individual eukaryotic organelles. Much of what we know of the proteins in the endoplasmic reticulum and Golgi complex

**FIGURE 1-22 Each eukaryotic organism used in cell biology has advantages for certain types of studies.** The yeast *Saccharomyces cerevisiae* (a) has the cellular organization of a eukaryote but is a relatively simple single-celled organism that is easy to grow and to manipulate genetically. The green alga *Chlamydomonas reinhardtii* (b) is widely used to study photosynthesis and the structure and function of flagella. In the roundworm *Caenorhabditis elegans* (c), which has a small number of cells arranged in a nearly identical way in every worm, the formation of each individual cell can be traced. The fruit fly *Drosophila melanogaster* (d), first used to discover the properties of chromosomes, has been especially valuable in identifying genes that control embryonic development. Many of these genes are evolutionarily conserved in humans. Planaria (e) are flatworms that can regenerate any part of

the body that is cut off, including the head and the photoreceptors. The stem cells that give rise to their new cells and tissues are widely studied. The zebrafish *Danio rerio* (f) is used for rapid genetic screens to identify genes that control vertebrate development and organogenesis. Of the experimental animal systems, mice (*Mus musculus*) (g) are evolutionarily the closest to humans and have thus provided models for studying numerous human genetic and infectious diseases. The mustard-family weed *Arabidopsis thaliana* (h) has been used for genetic screens to identify genes involved in nearly every aspect of plant life. [Part (a) Sci-mat/Photo Researchers, Inc. Part (b) William Dentler University of Kansas. Part (c) Science Source. Part (d) Darwin Dale/Science Source. Part (e) Peter Reddien, MIT Whitehead Institute. Part (f) blickwinkel/Hartl/Alamy. Part (g) J. M. Labat/Jacana/Photo Researchers, Inc. Part (h) Darwin Dale/Science Source.]

that promote protein secretion was elucidated first in yeasts (see Chapter 14). Yeasts were also essential for the identification of many proteins that regulate the cell cycle and catalyze DNA replication and transcription. *S. cerevisiae* (Figure 1-23a; see also Figure 1-22a) and other yeasts offer many advantages to molecular and cellular biologists:

- Vast numbers of yeast cells can be grown easily and cheaply in culture from a single cell; the cells in such **clones** are genetically identical and have the same biochemical properties. Individual proteins or multiprotein complexes can be purified from large amounts of cells and then studied in detail.
- Yeast cells may be either haploid (containing one copy of each chromosome) or diploid (containing two copies of each chromosome), and both forms can divide by mitosis; this ability makes isolating and characterizing mutations in genes encoding essential yeast cell proteins relatively straightforward.
- Yeasts, like many organisms, have a sexual cycle that allows exchange of genes between cells. Under starvation conditions, diploid cells undergo meiosis (see Chapter 19) to form haploid daughter cells, which are of two types, **a** and  $\alpha$  cells. If haploid **a** and  $\alpha$  cells encounter each other, they can fuse, forming an **a**/ $\alpha$  diploid cell that contains two copies of each chromosome, one from each parent cell (Figure 1-23b).

With the use of a single species such as *S. cerevisiae* as a model organism, results from studies carried out by tens of thousands of scientists worldwide, using multiple experimental techniques, can be combined to yield a deeper level of understanding of a single type of cell. As we will see many times in this book, conclusions based on studies of *S. cerevisiae* have often proved true for all eukaryotes and have formed the basis for exploring the evolution of more complex processes in multicellular animals and plants.

## Mutations in Yeast Led to the Identification of Key Cell Cycle Proteins

Biochemical studies can tell us much about an individual protein, but they cannot prove that it is required for cell division or any other cell process. The importance of a protein is demonstrated most firmly if a mutation that prevents its synthesis or makes it nonfunctional adversely affects the process under study.

In a classical genetics approach, scientists isolate and characterize mutants that lack the ability to do something a normal organism can do. Often large genetic “screens” are done to look for many different mutant individuals (e.g., fruit flies, yeast cells) that are unable to complete a certain process, such as cell division or muscle formation. Mutations are usually produced by treatment with a *mutagen*, a chemical or physical agent that promotes mutations in a largely random fashion. But how can we isolate and maintain mutant organisms or cells that are defective in some process, such as cell division or protein secretion, that is essential for survival?

**FIGURE 1-23 The yeast *Saccharomyces cerevisiae* can be haploid or diploid and can reproduce sexually or asexually.** (a) Scanning electron micrograph of the budding yeast *Saccharomyces cerevisiae*. These cells grow by an unusual type of mitosis termed mitotic budding. One daughter nucleus remains in the “mother” cell; the other daughter nucleus is transported into the bud, which grows in size and soon is released as a new cell. After each bud cell breaks free, a scar is left at the budding site, so the number of previous buds on the parent cell can be counted. The orange-colored cells are bacteria. (b) Haploid yeast cells can have different mating types, called **a** (blue) and  $\alpha$  (orange). Both types contain a single copy of each yeast chromosome, half the usual number, and grow by mitotic budding. Two haploid cells that differ in mating type, one **a** and one  $\alpha$ , can fuse together to form an **a**/ $\alpha$  diploid cell that contains two copies of each chromosome; diploid cells can multiply by mitotic budding. Under starvation conditions, a diploid cell can undergo meiosis, a special type of cell division, to form four haploid ascospores. Rupture of an ascus releases four haploid spores, which can germinate into haploid **a** and  $\alpha$  cells. These cells can also multiply asexually. [Part (a) SCIMAT/Science Source.]

One way is to isolate organisms with a **temperature-sensitive mutation**. These mutants are able to grow at the *permissive temperature*, but not at another, usually higher temperature, the *nonpermissive temperature*. Normal cells can grow at either temperature. In most cases, a temperature-sensitive mutant produces an altered protein that works at the permissive temperature but unfolds and is nonfunctional at the nonpermissive temperature. Screens for temperature-sensitive mutations are most readily done with haploid

organisms such as yeasts because they have only one copy of each gene, and thus a mutation in it will immediately have a consequence.

By analyzing the effects of numerous different temperature-sensitive mutations that altered the division of haploid yeast cells, geneticists discovered most of the genes necessary for cell division without knowing anything, initially, about which proteins they encode or how these proteins participate in the process. In general, the great power of genetics is to reveal the existence and relevance of all proteins required for a particular cell function without prior knowledge of their biochemical identity or molecular function. These “mutation-defined” genes can be isolated and replicated (cloned) with recombinant DNA techniques discussed in Chapter 6. With the isolated genes in hand, the encoded proteins can be produced in a test tube or in engineered bacteria or cultured cells. In this way, biochemists can investigate whether the genes necessary for cell division encode proteins that associate with other proteins or DNA or catalyze particular chemical reactions during cell division (see Chapter 19).

Most of these yeast cell cycle genes are found in human cells as well, and the encoded proteins have similar amino acid sequences. Proteins from different organisms, but with similar amino acid sequences, are said to be **homologous**; such proteins may have the same or similar functions. Remarkably, it has been shown that a human cell cycle protein, when expressed in a mutant yeast defective in the homologous yeast protein, is able to “rescue the defect” of the mutant yeast (that is, to allow the cell to grow normally), thus demonstrating the protein’s ability to function in a very different type of eukaryotic cell. This experimental result, which garnered a Nobel Prize for Paul Nurse, was especially notable because the common ancestor of present-day yeasts, plants, and humans is thought to have lived over a billion years ago. Clearly the eukaryotic cell cycle and many of the genes and proteins that catalyze and regulate it evolved early in biological evolution and have remained quite constant over a very long period of evolutionary time. Subsequent studies showed that mutations in many yeast cell cycle proteins that allow uncontrolled cell growth also frequently occur in human cancers (see Chapter 24), again attesting to the important conserved functions of these proteins in all eukaryotes.

### Studies in the Alga *Chlamydomonas reinhardtii* Led to the Development of a Powerful Technique to Study Brain Function

The green unicellular alga *Chlamydomonas reinhardtii* (Figure 1-22b), which swims using its two long flagella, is widely used in studies of the structure, function, and assembly of this organelle. In part because of the powerful genetic techniques now available, *Chlamydomonas* is also used in studies of chloroplast formation and photosynthesis. The *Chlamydomonas* genome (see Table 1-2) encodes many more proteins than do those of yeasts, including flagellar proteins and proteins needed to build a chloroplast, organelles not found in yeasts.

One important outcome of the use of this experimental organism came from studies of phototaxis, the behavior in which an organism moves toward or away from a source of light. *Chlamydomonas* needs to move toward light to undergo photosynthesis and thus generate the energy it needs to grow and divide, but light that is too intense repels it, as it causes damage to the chloroplast. Studies of *Chlamydomonas* phototaxis led to the discovery of two proteins in its plasma membrane that, when they absorb light, open a “channel” in the membrane that allows ions such as  $\text{Ca}^{2+}$  to flow from the extracellular medium into the cytosol, triggering phototactic responses. As detailed in Chapter 22, recombinant DNA techniques have been used to express one such protein in specific neurons in the mouse brain, allowing investigators to activate just one or a few cells in the brain using a point source of light. Thus studies on this humble alga have led to the development of an important experimental system—optogenetics—for the study of brain function.

### The Parasite That Causes Malaria Has Novel Organelles That Allow It to Undergo a Remarkable Life Cycle

Whereas yeasts are used in the manufacture of bread, beer, wine, and cheese, some unicellular eukaryotes cause major human diseases and are widely studied in an attempt to develop drugs that will kill them but not injure their human host. *Entamoeba histolytica* causes dysentery; *Trichomonas vaginalis*, vaginitis; and *Trypanosoma brucei*, sleeping sickness. Each year the worst of these protozoans, *Plasmodium falciparum* and related species, cause more than 300 million new cases of malaria, a disease that kills 1.5 million to 3 million people annually. These protozoans inhabit mammals and mosquitoes alternately, changing their morphology and behavior in response to signals in each of these environments.

The complex life cycle of *Plasmodium* dramatically illustrates how a single cell can adapt to multiple challenges (Figure 1-24a). Additionally, the *merozoite* form that infects human red blood cells contains several organelles, not found in most eukaryotes, that enable the parasite to invade a red blood cell, including the rhoptry, polar ring, and microneme, as well as a fuzzy surface coat on the outside of the cell (Figure 1-24b, c). Entry of the parasite into a red blood cell is initiated by binding of certain parasite cell-surface proteins to proteins on the red blood cell surface, followed by the formation of a tight junction between the two plasma membranes, the loss of the “fuzzy coat,” and secretion of proteins stored in the microneme and rhoptry.

All the transformations in cell type that occur during the *Plasmodium* life cycle are governed by instructions encoded in the genetic material of this parasite (see Table 1-2). The *Plasmodium* genome has about the same number of protein-coding genes as the yeast *Saccharomyces cerevisiae*, but about two-thirds of the *Plasmodium* genes appear to be unique to this and related parasites, attesting to the great evolutionary distance between these parasites, the

**FIGURE 1-24 *Plasmodium* species, the parasites that cause malaria, are single-celled protozoans with a remarkable life cycle.** Many *Plasmodium* species are known, and they can infect a variety of animals, cycling between insect and vertebrate hosts. The four species that cause malaria in humans undergo several dramatic transformations within their human and mosquito hosts. (a) Diagram of the life cycle. Step **1**: Sporozoites enter a human host when an infected *Anopheles* mosquito bites a person. Step **2**: They migrate to the liver, where they develop into merozoites, which are released into the blood. Merozoites differ substantially from sporozoites, so this transformation is a metamorphosis (Greek, “to transform” or “many shapes”). Step **3**: Circulating merozoites invade red blood cells (RBCs) and reproduce within them. Proteins produced by some *Plasmodium* species move to the surface of infected RBCs, causing the cells to adhere to the walls of blood vessels. This prevents infected RBCs from circulating to the spleen, where cells of the immune system would destroy the RBCs and the *Plasmodium* organisms they harbor. Step **4**: After growing and reproducing in RBCs for a period of time characteristic of each *Plasmodium* species, the merozoites suddenly burst forth in synchrony from large numbers of infected cells. It is this event that brings on the fevers and shaking chills that are the well-known symptoms of malaria. Some of the released merozoites infect additional RBCs, creating a cycle of production and infection. Step **5**: Eventually, some merozoites undergo meiosis and develop into male and female gametocytes, another metamorphosis. These cells, which contain half the usual number of

chromosomes, cannot survive for long unless they are transferred in blood to an *Anopheles* mosquito. Step **6**: In the mosquito’s stomach, the gametocytes are transformed into sperm or eggs (gametes), yet another metamorphosis marked by development of long hairlike flagella on the sperm. Step **7**: Fusion of sperm and eggs generates zygotes, which implant into the cells of the stomach wall and grow into oocysts, essentially factories for producing sporozoites. Step **8**: Rupture of an oocyst releases thousands of sporozoites, which migrate to the salivary glands, setting the stage for infection of another human host. (b) Organelles of the *Plasmodium vivax* merozoite. Some of these organelles are found only in *Plasmodium* and related eukaryotic parasitic microorganisms. (c) Section of a *Plasmodium vivax* merozoite invading a human red blood cell. See A. Cowman and B. Crabb, 2006, *Cell* **124**:755–766. [Part (c) Masamichi Aikawa.]

Apicomplexa (see Figure 1-1), and most other eukaryotes as well as the presence of unusual organelles required for their complex life cycles.

## 1.5 Metazoan Structure, Differentiation, and Model Organisms

The evolution of multicellular organisms most likely began when cells remained associated in small colonies after division instead of separating into individual cells. A few prokaryotes and several unicellular eukaryotes, such as *Volvox* (see Figure 1-3d), as well as many fungi and slime molds, exhibit such rudimentary social behavior. The full flowering of multicellularity, however, occurred in eukaryotic organisms whose cells became differentiated and organized into groups, or tissues, in which the different cells performed specialized functions.

### Multicellularity Requires Cell-Cell and Cell-Matrix Adhesions

The cells of higher plants are encased in a network of chambers formed by the interlocking cell walls surrounding the cells and are connected by cytoplasmic bridges called **plasmodesmata** (see Figure 1-12a). Animal cells are often “glued” together into a chain, a ball, or a sheet by cell-adhesion proteins on their surfaces, often called **cell-adhesion molecules**, or **CAMs** (see Figure 1-4d). Some CAMs bind cells to one another; other types bind cells to the extracellular matrix, forming a cohesive unit. In animals, the matrix cushions cells and allows nutrients to diffuse toward them and waste products to diffuse away. A specialized, especially tough matrix called the **basal lamina**, made up of polysaccharides and multiple proteins such as collagen, forms a supporting layer underlying cell sheets and prevents the cell aggregates from ripping apart (see Figure 1-4). Many CAMs and extracellular-matrix proteins found in humans also occur in invertebrates, indicating their importance during metazoan evolution. Similarly, many of the proteins and small molecules used by metazoans as signaling molecules are conserved in humans and many invertebrates, as are their **receptors**, the cellular proteins that bind to these signaling molecules and trigger an effect in the receiving cell. As one example, the signaling protein Wnt, discussed in Chapter 16, was discovered simultaneously as the gene mutated in the *Drosophila* Wingless mutation and as the site of integration of a cancer-causing virus in mice.

### Epithelia Originated Early in Evolution

Metazoans, which are thought to have evolved in an ocean-like, saline environment, had to solve a fundamental problem: separating the inside of the organism from the outside. The external surfaces of all metazoan animals, as well as the surfaces of their internal organs, are covered by a sheet-like layer of tissue called an **epithelium**. Epithelia commonly serve

as barriers and protective surfaces, as exemplified by the sheets of epidermal cells that form the skin (see Figure 1-4). Other epithelia are one cell layer thick and line internal organs such as the small intestine, where they are crucial for transport of the products of digestion (e.g., glucose and amino acids) into the blood (see Chapter 11). As discussed in Chapter 20, epithelia in different body locations have characteristic morphologies and functions.

Cells that form epithelial tissues are said to be *polarized* because their plasma membranes are organized into at least two discrete regions. Typically, the distinct surfaces of a polarized epithelial cell are the **apical** surface—the “top” of the cell facing the external world—and the **basal** and **lateral** (collectively, **basolateral**) surfaces that face the organism’s interior. As shown in Figure 1-4, the basal surface usually contacts an underlying extracellular matrix, the basal lamina. Specialized junction proteins in the basolateral plasma membrane link adjacent cells together and also bind the cells to the basal lamina.

### Tissues Are Organized into Organs

Cells in metazoans do not work in isolation; specialized groups of differentiated cells often form tissues, which are themselves the major components of organs. For example, the lumen of a small blood vessel is lined with a sheet-like layer of endothelial cells, or **endothelium**, which prevents blood cells from leaking out (Figure 1-25). A layer of smooth muscle tissue encircles the endothelium and basal lamina and contracts to limit blood flow. During times of fright, constriction of smaller peripheral vessels forces more blood to the vital organs. The muscle layer of a blood vessel is wrapped in an outer layer of connective tissue, a network of fibers and cells that encases the vessel walls and protects them from stretching and rupture.

This hierarchy of tissues is copied in other blood vessels, which differ mainly in the thickness of the layers. The wall of a major artery must withstand much stress and is therefore thicker than that of a minor vessel. The strategy of grouping and layering different tissues is used to build other complex organs as well. In each case, the function of the organ is determined by the specific functions of its component tissues, and each type of cell in a tissue produces the specific groups of proteins that enable the tissue to carry out its functions.

### Genomics Has Revealed Important Aspects of Metazoan Evolution and Cell Function

Metazoans—be they invertebrates such as the fruit fly *Drosophila melanogaster* and the roundworm *Caenorhabditis elegans*, or vertebrates such as mice and humans—contain between 13,000 and 23,000 protein-coding genes, about three to four times as many as a yeast (see Table 1-2). Sequencing of entire genomes has shown that many of these genes are conserved among the metazoans, and genetic

**FIGURE 1-25 All organs are organized arrangements of various tissues, as illustrated in this cross section of a small artery (arteriole).** Blood flows through the vessel lumen, which is lined by a thin sheet of endothelial cells forming the endothelium and by the underlying basal lamina. This tissue adheres to the overlying layer of smooth muscle tissue; contraction of the muscle layer controls blood flow through the vessel. A fibrillar layer of connective tissue surrounds the vessel and connects it to other tissues. [SPL/Science Source.]

studies have shown that many of them are essential for the formation and function of specific tissues and organs. Thus many of the organisms listed in Table 1-2 are used to study the roles of these conserved proteins in cell development and function.

While the human and mouse genomes encode about the same number of proteins as those of the roundworm *Caenorhabditis elegans*, frogs, and fish, mammalian cells contain about 30 times the DNA of a roundworm and two to three times the DNA of frogs and fish. Only about 10 percent of human DNA encodes proteins. We know now that much of the remaining 90 percent has important functions. Many DNA segments bind proteins that regulate expression of nearby genes, allowing each mammalian gene to make the precise amount of mRNA and protein needed in each of many types of cells.

Other segments of DNA are used to synthesize thousands of RNA molecules whose function in regulating gene expression is only now being uncovered. As an example, hundreds of different micro-RNAs, 20 to 25 nucleotides long, are abundant in metazoan cells, where they bind to and repress the activity of target mRNAs. These small RNAs may indirectly regulate the activity of most or all genes, either by inhibiting the ability of mRNAs to be translated into proteins or by triggering the degradation of target mRNAs (see Chapter 10).

Some of this non-protein-coding DNA probably regulates expression of genes that make us uniquely human. Indeed, fish and humans have about the same number of protein-coding genes—about 20,000—yet as noted above, the human genome is over twice the size of that in fish (see Table 1-2). The human brain can perform complex mental processes such as reading and writing a textbook. Somehow these 20,000 human genes are exquisitely regulated such that humans produce a brain with about 100,000,000,000 neurons, which communicate with one another at about 100,000,000,000,000 interaction sites termed *synapses*.

**Genomics**—the study of the entire DNA sequences of organisms—has shown us how close humans really are to our nearest relatives, the great apes (Figure 1-26). Human DNA is 99 percent identical in sequence to that of chimpanzees and bonobos; the 1 percent difference is about 3,000,000 base pairs, but it somehow explains the obvious differences between our species, such as the evolution of human brains during the past 5,000,000 years since we last shared a common ancestor.

Genomics coupled with paleontological findings indicates that humans and mice descended from a common mammalian ancestor that probably lived about 75 million years ago. Nonetheless, both organisms contain about the same number of genes, and about 99 percent of mouse protein-coding genes have homologs in humans, and vice versa. Over 90 percent of mouse and human genomes can be partitioned into regions of **synteny**—that is, DNA segments that have the same order of unique DNA sequences and genes along a segment of a chromosome. This observation suggests that much of the gene order in the most recent common ancestor of humans and mice has been conserved in both species (Figure 1-27). Of course, mice are not people; relative to humans, mice have expanded families of genes related to immunity, reproduction, and olfaction, probably reflecting the differences between the human and mouse lifestyles.

It's not only human evolution that interests us! Polar bears live in the Arctic and eat a high-fat diet, mostly composed of seals. Recent genome sequencing allowed researchers to conclude that the most recent common ancestor of polar bears and their brown bear relatives, which live in temperate climates, was present about 500,000 years—or only about 20,000 bear generations—ago. But during that rather short evolutionary period the polar bear genome acquired changes in many genes regulating cardiovascular function, fat metabolism, and heart development, allowing it to consume a diet very rich in fats.

## Embryonic Development Uses a Conserved Set of Master Transcription Factors

The astute reader will note a paradox in the previous discussion: if indeed most human protein-coding genes are shared with apes and mice, and many with flies and worms, how is it that these organisms look and function so differently?

**FIGURE 1-26 Evolutionary tree connecting monkeys, apes, and humans.** The evolutionary tree of humans, great apes, a small ape, and an Old World monkey was estimated from the divergence among their genomic DNA sequences. Whole-genome DNA sequences were aligned, and the average nucleotide divergence in unique DNA

sequences was estimated. Estimates of the times the different species diverged from each other, indicated at each node, were calculated in millions of years (Myr) based on DNA sequence identity; ~1 Myr implies approximately 1 Myr or less. [Data from D. P. Locke et al., 2011, *Nature* **469**:529–533.]

The answer to this question resides in the way genes are regulated during the development of all metazoans from a single cell, the fertilized egg. As we learn in Chapters 8 and 9, each protein-coding gene is associated with regulatory DNA sequences that differ in different organisms. Many of these regulatory sequences bind proteins that direct the expression of the gene, and thus the amount of a protein it makes, in specific types of cells. Some of these proteins are termed *master transcription factors*; these proteins bind to regulatory DNA sequences, are conserved throughout evolution, and control the development of specific types of cells by activating or repressing groups of genes, often at different stages of development.

The early stages in the development of a human embryo are similar to those in the mouse. They are characterized by rapid cell divisions (Figure 1-28) followed by the

**FIGURE 1-27 Conservation of synteny between human and mouse.** Shown is a 510,000-base-pair (bp) segment of mouse chromosome 12 that shares common ancestry with a 600,000-bp section of human chromosome 14. Pink lines connect the reciprocal unique DNA sequences in the two genomes. Mb, 1 million base pairs. [Data from Mouse Genome Sequencing Consortium, 2002, *Nature* **420**:520.]

differentiation of cells into tissues. In all organisms, the embryonic body plan—the spatial pattern of cell types (tissues) and body parts—emerges from two influences: a program of genes that specifies the pattern of the body, and local cell interactions that induce different parts of the program.

With only a few exceptions, animals display axial symmetry; that is, their left and right sides mirror each other. This most basic of patterns is encoded in the genome. Developmental biologists have divided bilaterally symmetric animal phyla into two large groups depending on where the mouth and anus form in the early embryo. **Protostomes** develop a mouth close to a transient opening in the early embryo (the **blastopore**) and have a ventral nerve cord; protostomes include all worms, insects, and mollusks. **Deuterostomes** develop an anus close to this transient opening in the embryo and have a dorsal central nervous system; they include echinoderms (such as sea stars and sea urchins) and vertebrates. The bodies of both protostomes and deuterostomes are divided into discrete segments that form early in embryonic development. Protostomes and deuterostomes probably evolved from a common ancestor, termed **Urbilateria**, that lived approximately 600 million years ago (Figure 1-29a).

Many **patterning genes** encode master transcription factors that control expression of other genes and specify the general organization of an organism, beginning with the major body axes—anterior-posterior (head-to-tail), dorsal-ventral (back-to-belly), and left-right—and ending with body segments such as the head, chest, abdomen, and tail. The conservation of axial symmetry from the simplest worms to mammals is explained by the presence of conserved

**FIGURE 1-28** The first few cell divisions of a fertilized egg set the stage for all subsequent development. A developing mouse embryo is shown at the (a) two-cell, (b) four-cell, and (c) eight-cell stages. The embryo is surrounded by supporting membranes. The corresponding steps in human development occur during the first few days after fertilization. [Claude Edelman/Science Source.]

**FIGURE 1-29** Similar master transcription factors, conserved during evolution, regulate early developmental processes in diverse animals. (a) Urbilateria is the presumed ancestor of all protostomes and deuterostomes that existed about 600 million years ago. The positions of its nerve cord (violet), surface ectoderm (mainly skin; white), and endoderm (mainly digestive tract and organs; light green) are shown. (b) Highly conserved master transcription factors called Hox proteins, which determine the identity of body segments during embryonic development, are found in both protostomes and deuterostomes. Hox genes are found in clusters on the chromosomes of most or all animals, and they encode related master transcription factors that control the activities of other genes. In many animals, different Hox genes direct the development of different segments along the head-to-tail axis, as indicated by corresponding colors. Each gene is activated (transcriptionally) in a specific region along the head-to-tail axis and controls the growth and development of tissues there. For example, in the mouse, a deuterostome, the Hox genes are responsible for the distinctive shapes of vertebrae. Mutations affecting Hox genes in the fruit fly, a protostome, cause body parts to form in the wrong locations, such as legs in lieu of antennae on the head. In both organisms, these genes provide a head-to-tail “address” and serve to direct the formation of structures in the appropriate places.

patterning genes in their genomes. Other patterning genes encode proteins that are important in cell adhesion or in cell signaling. This broad repertoire of patterning genes permits the integration and coordination of events in different parts of the developing embryo and gives each segment in the body its unique identity.

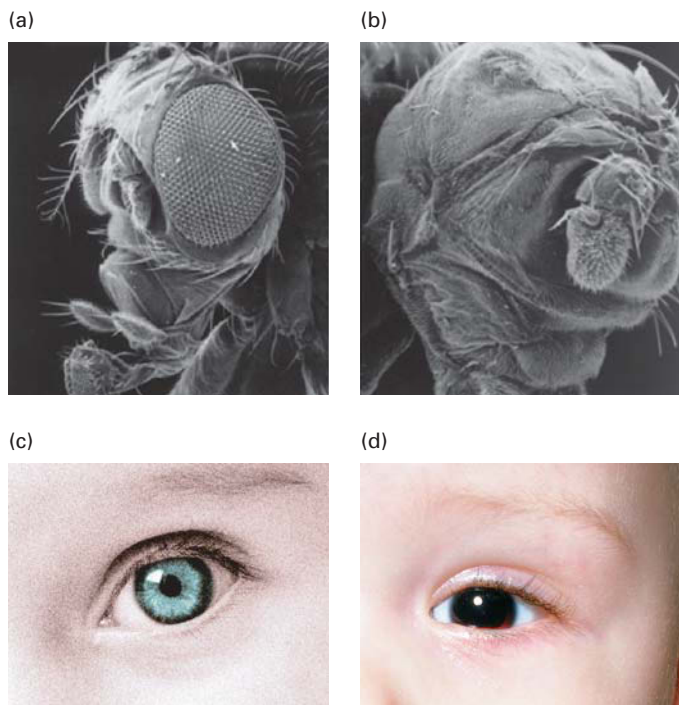

Remarkably, many patterning genes encoding master transcription factors are highly conserved in both protostomes and deuterostomes (Figure 1-29b). This conservation of body plan reflects evolutionary pressure to preserve the commonalities in the molecular and cellular mechanisms controlling development in different organisms. For instance, fly eyes and human eyes are very different in their structure, function, and nerve connections. Nonetheless, the master transcription factors that initiate eye development—*eyeless* in the fly and *Pax6* in the human—are highly related proteins that regulate the activities of other genes and are descended from the same ancestral gene. Mutations in the *eyeless* or *Pax6* genes cause major defects in eye formation (Figure 1-30).

## Planaria Are Used to Study Stem Cells and Tissue Regeneration

In single-celled organisms, both daughter cells usually (though not always) resemble the parent cell. Similarly, in multicellular organisms, when many types of cells divide, the daughter cells look a lot like the parent cell—liver cells, for instance, divide to generate liver cells with the same characteristics and functions as their parent, as do insulin-producing cells in the pancreas. In contrast, **stem cells** and certain other undifferentiated cells can generate multiple types of differentiated descendant cells; these cells often divide in such a way that the two daughter cells are different. Such **asymmetric cell division** is characteristic of stem cells and is critical to the generation of different cell types in the body (see Chapter 21). Often one daughter cell resembles its parent in that it remains undifferentiated and retains its ability to give rise to multiple types of differentiated cells. The other daughter cell divides many times, and each of its daughter cells differentiates into a specific type of cell.

The planarian *Schmidtea mediterranea* is best known for its capacity to regenerate complete individuals—with a normal head—from minuscule body parts formed by dissection (see Figure 1-22e). Planaria contain stem cells that

**FIGURE 1-30 Homologous genes regulate eye development in diverse animals.** (a) Development of the large compound eyes in fruit flies requires a gene called *eyeless* (named for the mutant phenotype). (b) Flies with inactivated *eyeless* genes lack eyes. (c) Normal human eyes require the gene *Pax6*, the homolog of *eyeless*. (d) People lacking adequate *Pax6* function have the genetic disease aniridia, a lack of irises in the eyes. *Pax6* and *eyeless*, which encode highly related master transcription factors that regulate the activities of other genes, are homologs and presumably descended from the same ancestral gene. [Parts (a) and (b) Courtesy Andreas Hefti, Interdepartmental Electron Microscopy (IEM), Biocenter of the University of Basel. Part (c) © Simon Fraser/Science Source. Part (d) © Mediscan/Alamy.]

replace cells lost to normal turnover. In portions of a dissected animal, they will, after several cell divisions, generate any cell type needed during regeneration. These stem cells have served as a potent experimental system to discover how heads and tails, each built of many types of cells, are formed (see Chapters 16 and 21). The hormones that instruct stem cells in different parts of the body to generate specific types of cells are similar to those used in mammals, including humans, in development (see Chapter 16), and thus future studies on planarian regeneration may inform scientists how to regenerate human body parts such as a hand or an eye.

## Invertebrates, Fish, Mice, and Other Organisms Serve as Experimental Systems for Study of Human Development and Disease

Organisms with large-celled embryos that develop outside the mother's body (e.g., frogs, sea urchins, fish, and chickens) are extremely useful for tracing the fates of cells as they form different tissues, as well as for making extracts for biochemical studies. For instance, a key protein in regulating

cell division in all eukaryotes, including humans, was first identified in studies with sea stars and sea urchin embryos and subsequently purified from extracts prepared from these embryos (see Chapter 19).

Studies of cells in specialized tissues make use of animal and plant model organisms. Neurons and muscle cells, for instance, were traditionally studied in mammals or in creatures with especially large or accessible cells, such as the giant neural cells of the squid and sea hare or cells in the flight muscles of birds. More recently, muscle and nerve development have been extensively studied in fruit flies (*Drosophila melanogaster*), roundworms (*Caenorhabditis elegans*), and zebrafish (*Danio rerio*), in which mutations in genes required for muscle and nerve formation or function can be readily isolated (see Figure 1-22).

Mice have one enormous advantage over other experimental organisms: they are the most closely related to humans of any animal for which powerful genetic approaches have been available for many years. Mice and humans have shared living structures for millennia, have similar nervous systems, have similar immune systems, and are subject to infection by many of the same pathogens. As noted, both organisms contain about the same number of genes, and about 99 percent of mouse protein-coding genes have homologs in the human genome, and vice versa.

Using recombinant DNA techniques developed in the past few years, researchers can inactivate any desired gene, and thus abolish production of its encoded protein. Such specific mutations can be introduced into the genomes of worms, flies, frogs, sea urchins, chickens, mice, a variety of plants, and other organisms, permitting the effects of these mutations to be assessed. Using the Cas9 experimental system described in Chapter 6, this approach is being used extensively to produce animal versions of human genetic diseases, in mice as well as in other animals. As an example, people with autism spectrum disorder often have mutations in specific protein-coding genes. To understand the role of these mutations, these genes have been inactivated in mice; in many cases, the mice exhibit symptoms of the human disease, including repetitive actions such as excessive grooming, strongly suggesting that the human mutation indeed has a role in triggering the disorder. Within the past year, similar techniques have been used to produce monkeys in which the targeted gene has been inactivated. Such approaches can be useful in uncovering the role of specific genes in higher-order brain tasks such as learning and memory, or in studies of viruses that infect only humans and nonhuman primates. Once animal models of a human disease are available, further studies on the molecular defects causing the disease can be done and new treatments can be tested, thereby minimizing the testing of new drugs on humans.

## Genetic Diseases Elucidate Important Aspects of Cell Function

Many genetic diseases are caused by mutations in a single protein; studies on people with these diseases have shed light on the normal function of those proteins. As an example,

**FIGURE 1-31 The dystrophin glycoprotein complex (DGC) in skeletal muscle cells.**

Dystrophin—the protein that is defective in Duchenne muscular dystrophy—links the actin cytoskeleton to the multiprotein sarcoglycan complex in the plasma membrane. Other proteins in the complex bind to components of the basal lamina, such as laminin, which in turn bind to the collagen fibers that give the basal lamina strength and rigidity. Thus dystrophin is an important member of a group of proteins that links the muscle cell and its internal actin cytoskeleton with the surrounding basal lamina. See D. E. Michele and K. P. Campbell, 2003, *J. Biol. Chem.* **278**:15457.

consider Duchenne muscular dystrophy (DMD), the most common among the hereditary muscle-wasting diseases, collectively called muscular dystrophies. DMD, an X chromosome-linked disorder that affects 1 in 3300 boys, results in cardiac or respiratory failure and death, usually in the late teens or early twenties. The first clue to understanding the molecular basis of this disease came from the discovery that people with DMD carry mutations in the gene encoding a protein named dystrophin. As detailed in Chapter 17, this very large protein was later found to be a cytosolic adapter protein that binds to actin filaments that are part of the cytoskeleton (see Figure 1-13) and to a complex of muscle plasma-membrane proteins termed the sarcoglycan complex (Figure 1-31). The resulting large multiprotein assemblage, the dystrophin glycoprotein complex (DGC), links the extracellular matrix protein laminin to the cytoskeleton within muscle cells. Mutations in dystrophin, other DGC components, or laminin can disrupt the DGC-mediated link between the exterior and interior of muscle cells and cause muscle weakness and eventual death. The first step in identifying the entire dystrophin glycoprotein complex involved cloning the dystrophin-encoding gene using DNA from normal individuals and from patients with Duchenne muscular dystrophy.

### The Following Chapters Present Much Experimental Data That Explains How We Know What We Know About Cell Structure and Function

In subsequent chapters of this book, we discuss cellular processes in much greater detail. We begin (in Chapter 2) with a discussion of the chemical nature of the building blocks

of cells and the basic chemical processes required to understand the macromolecular processes discussed in subsequent chapters. We go on to discuss the structure and function of proteins (in Chapter 3). Chapter 4 discusses many of the techniques biologists use to culture and fractionate cells and to visualize specific proteins and structures within cells. Chapter 5 describes how DNA is replicated, how segments of DNA are copied into RNA, and how proteins are synthesized on ribosomes. Chapter 6 describes many of the techniques used to study genes, gene expression, and protein function, including the generation of animals with specific genetic mutations. Biomembrane structure is the topic of Chapter 7. Gene and chromosome structure and the regulation of gene expression are covered in Chapters 8, 9, and 10. The transport of ions and small molecules across membranes is covered in Chapter 11, and Chapter 12 discusses cellular energetics and the functions of mitochondria and chloroplasts. Membrane biogenesis, protein secretion, and protein trafficking—the directing of proteins to their correct subcellular destinations—are the topics of Chapters 13 and 14. Chapters 15 and 16 discuss the many types of signals and signal receptors used by cells to communicate and regulate their activities. The cytoskeleton and cell movements are discussed in Chapters 17 and 18. Chapter 19 discusses the cell cycle and how cell division is regulated. The interactions among cells, and between cells and the extracellular matrix, that enable formation of tissues and organs are detailed in Chapter 20. Later chapters of the book discuss important types of specialized cells—stem cells (Chapter 21), neurons (Chapter 22), and cells of the immune system (Chapter 23). Chapter 24 discusses cancer and the multiple ways in which cell growth and differentiation can be altered by mutations.

# Chemical Foundations

“Star of David” catenane. Two triply entwined rings composed of carbon, hydrogen, and nitrogen are linked together with bridging iron atoms via a complex chemical synthetic pathway to cross each other six times and form a hexagram (six-pointed star). The chemical structure is indicated on the left, where the two independent rings are colored blue and orange. On the right is the three-dimensional structure determined by x-ray crystallography with the carbon atoms of one ring in blue and the other light gray; irons are pink and nitrogens purple. In the center is a noncovalently bound, negatively charged phosphorus hexafluoride (cyan and green). See D. A. Leigh, R. G. Pritchard, and A. J. Stephens, 2014, *Nature Chem.* **6**:978–982.

**The life** of a cell depends on thousands of chemical interactions and reactions exquisitely coordinated with one another in time and space, influenced by the cell’s genetic instructions and its environment. By understanding these interactions and reactions at a molecular level, we can begin to answer fundamental questions about cellular life: How does a cell extract nutrients and information from its environment? How does a cell convert the energy stored in nutrients into the work of movement or metabolism? How does a cell transform nutrients into the cellular components required for its survival? How does a cell link itself to other cells to form a tissue? How do cells communicate with one another so that a complex, efficiently functioning organism can develop

and thrive? One of the goals of *Molecular Cell Biology* is to answer these and other questions about the structure and function of cells and organisms in terms of the properties of individual molecules and ions.

For example, the properties of one such molecule, water, control the evolution, structure, and function of all cells. An understanding of biology is not possible without appreciating how the properties of water control the chemistry of life. Life first arose in a watery environment. Constituting 70–80 percent of most cells by weight, water is the most abundant molecule in biological systems. It is within this aqueous milieu that small molecules and ions, which make up about 7 percent of the weight of living matter, combine into the

### 2.3 Chemical Reactions and Chemical Equilibrium

### 2.4 Biochemical Energetics

**(a) Molecular complementarity**

### (b) Chemical building blocks

**(c) Chemical equilibrium**

**(d) Chemical bond energy**

**FIGURE 2-1 Chemistry of life: four key concepts.** (a) Molecular complementarity lies at the heart of all biomolecular interactions (see Section 2.1), as when two proteins with complementary shapes and chemical properties come together to form a tightly bound complex. (b) Small molecules serve as building blocks for larger structures (see Section 2.2). For example, to generate the information-carrying macromolecule DNA, four small nucleotide building blocks are covalently linked into long strings (polymers), which then wrap around each other to form the double helix. (c) Chemical reactions are reversible, and the distribution of the chemicals

between starting reactants (*left*) and the products of the reactions (*right*) depends on the rate constants of the forward ( $k_f$ , upper arrow) and reverse ( $k_r$ , lower arrow) reactions. The ratio of these,  $K_{eq}$ , provides an informative measure of the relative amounts of products and reactants that will be present at equilibrium (see Section 2.3). (d) In many cases, the source of energy for chemical reactions in cells is the hydrolysis of the molecule ATP (see Section 2.4). This energy is released when a high-energy phosphoanhydride bond linking the b and g phosphates in the ATP molecule (red) is broken by the addition of a water molecule, forming ADP and  $P_i$ .

larger macromolecules and macromolecular assemblies that make up a cell's machinery and architecture and thus the remaining mass of organisms. These small molecules include amino acids (the building blocks of proteins), nucleotides (the building blocks of DNA and RNA), lipids (the building blocks of biomembranes), and sugars (the building blocks of complex carbohydrates).

Many of the cell's biomolecules (such as sugars) readily dissolve in water; these molecules are referred to as **hydrophilic** ("water liking"). Others (such as cholesterol) are oily, fatlike substances that shun water; these molecules are said to be **hydrophobic** ("water fearing"). Still other biomolecules (such as phospholipids) contain both hydrophilic and hydrophobic regions; these molecules are said to be **amphipathic** or **amphiphilic** ("both liking"). The smooth functioning of cells, tissues, and organisms depends on all these molecules, from the smallest to the largest. Indeed, the chemistry of the simple proton ( $\text{H}^+$ ) can be as important to the survival of a human cell as that of each gigantic DNA molecule (the

mass of the DNA molecule in human chromosome 1 is  $8.6 \times 10^{10}$  times that of a proton!). The chemical interactions of all these molecules, large and small, with water and with one another define the nature of life.

Luckily, although many types of biomolecules interact and react in numerous and complex pathways to form functional cells and organisms, a relatively small number of chemical principles are necessary to understand cellular processes at the molecular level (Figure 2-1). In this chapter, we review these key principles, some of which you already know well. We begin with the covalent bonds that connect atoms into molecules and the noncovalent interactions that stabilize groups of atoms within and between molecules. We then consider the basic chemical building blocks of macromolecules and macromolecular assemblies. After reviewing those aspects of chemical equilibrium that are most relevant to biological systems, we end the chapter with the basic principles of biochemical energetics, including the central role of ATP (adenosine triphosphate) in capturing and transferring energy in cellular metabolism.

## 2.1 Covalent Bonds and Noncovalent Interactions

Strong and weak attractive forces between atoms are the “glue” that holds individual molecules together and permits interactions between different molecules. When two atoms share a single pair of electrons, the result is a **covalent bond**—a type of strong force that holds atoms together in molecules. Sharing of multiple pairs of electrons results in multiple covalent bonds (e.g., “double” or “triple” bonds). The weak attractive forces of **noncovalent interactions** are equally important in determining the properties and functions of biomolecules such as proteins, nucleic acids, carbohydrates, and lipids. In this section, we first review covalent bonds and then discuss the four major types of noncovalent interactions: ionic bonds, hydrogen bonds, van der Waals interactions, and the hydrophobic effect.

### The Electronic Structure of an Atom Determines the Number and Geometry of the Covalent Bonds It Can Make

Hydrogen, oxygen, carbon, nitrogen, phosphorus, and sulfur are the most abundant elements in biological molecules. These atoms, which rarely exist as isolated entities, readily form covalent bonds, using electrons in the outermost electron orbitals surrounding their nuclei (Figure 2-2). As a rule, each type of atom forms a characteristic number of covalent bonds with other atoms. These bonds have a well-defined geometry determined by the atom’s size and by both the distribution of electrons around the nucleus and the number of electrons that it can share. In some cases, the number of stable covalent bonds an atom can make is fixed; carbon, for example, always forms four covalent bonds. In other cases, different numbers of stable covalent bonds are possible; for example, sulfur can form two, four, or six stable covalent bonds.

All the biological building blocks are organized around the carbon atom, which forms four covalent bonds. In these

**FIGURE 2-2 Covalent bonds form by the sharing of electrons.** Covalent bonds, the strong forces that hold atoms together in molecules, form when atoms share electrons from their outermost electron orbitals. Each atom forms a defined number and geometry of covalent bonds.

organic biomolecules, each carbon usually bonds to three or four other atoms. [Carbon can also bond to two other atoms, as in the linear molecule carbon dioxide,  $\text{CO}_2$ , which has two carbon-oxygen double bonds ( $\text{O}=\text{C}=\text{O}$ ); however, such bond arrangements of carbon are not found in biological building blocks.] As illustrated in Figure 2-3a for formaldehyde, carbon can bond to three atoms, all in a common plane. The carbon atom forms two single bonds with two atoms and one double bond (two shared electron pairs) with the third atom. In the absence of other constraints, atoms joined by a single bond generally can rotate freely about the bond axis, whereas those connected by a double bond cannot. The rigid planarity imposed by double bonds has enormous significance for the shapes and flexibility of biomolecules such as phospholipids, proteins, and nucleic acids.

Carbon can also bond to four rather than three atoms. As illustrated by methane ( $\text{CH}_4$ ), when carbon is bonded to four other atoms, the angle between any two bonds is  $109.5^\circ$ , and the positions of bonded atoms define the four points of a tetrahedron (Figure 2-3b). This geometry defines the structures of many biomolecules. A carbon (or any other) atom bonded to four dissimilar atoms or groups in a nonplanar

(a) Formaldehyde

(b) Methane

**FIGURE 2-3 Geometry of bonds when carbon is covalently linked to three or four other atoms.** (a) A carbon atom can be bonded to three atoms, as in formaldehyde ( $\text{CH}_2\text{O}$ ). In this case, the carbon-bonding electrons participate in two single bonds and one double bond, which all lie in the same plane. Unlike atoms connected by a single bond, which usually can rotate freely about the bond axis, those connected by a double bond cannot. (b) When a carbon atom forms four single bonds, as in methane ( $\text{CH}_4$ ), the bonded atoms (all H in this case) are oriented in space in the form of a tetrahedron. The letter representations on the left clearly indicate the atomic composition of each molecule and its bonding pattern. The ball-and-stick models in the center illustrate the geometric arrangement of the atoms and bonds, but the diameters of the balls representing the atoms and their nonbonding electrons are unrealistically small compared with the bond lengths. The sizes of the electron clouds in the space-filling models on the right more accurately represent the structure in three dimensions.

**FIGURE 2-4 Stereoisomers.** Many molecules in cells contain at least one asymmetric carbon atom. The tetrahedral orientation of bonds formed by an asymmetric carbon atom can be arranged in three-dimensional space in two different ways, producing molecules that are mirror images, or stereoisomers, of each other. Shown here is the common structure of an amino acid, with its central asymmetric carbon and four attached groups, including the R group, discussed in Section 2.2. Amino acids can exist in two mirror-image forms, designated L and D. Although the chemical properties of such stereoisomers are identical, their biological activities are distinct. Only L amino acids are found in proteins.

configuration is said to be asymmetric. The tetrahedral orientation of bonds formed by an **asymmetric carbon atom** can be arranged in three-dimensional space in two different ways, producing molecules that are mirror images of each other, a property called *chirality* (“handedness,” from the Greek word *cheir*, meaning “hand”) (Figure 2-4). Such molecules are called *optical isomers*, or **stereoisomers**. Many molecules in cells contain at least one asymmetric carbon atom, often called a *chiral carbon* atom. The different stereoisomers of a molecule usually have completely different biological activities because the arrangement of atoms within their structures, and thus their ability to interact with other molecules, differs.

 Some drugs are mixtures of the stereoisomers of small molecules in which only one stereoisomer has the biological activity of interest. The use of a pure single stereoisomer of the chemical in place of the mixture may result in a more potent drug with reduced side effects. For example, one stereoisomer of the antidepressant drug citalopram (Celexa) is 170 times more potent than the other. Some stereoisomers have very different activities. Darvon is a pain reliever, whereas its stereoisomer, Novrad (*Darvon* spelled backward), is a cough suppressant. One stereoisomer of ketamine is an anesthetic, whereas the other causes hallucinations. ■

The typical numbers of covalent bonds formed by other atoms common in biomolecules are shown in Table 2-1. A hydrogen atom forms only one covalent bond. An atom of oxygen usually forms only two covalent bonds but has two additional pairs of electrons that can participate in

**TABLE 2-1 Bonding Properties of Atoms Most Abundant in Biomolecules**

·C·	4	

noncovalent interactions. Sulfur forms two covalent bonds in hydrogen sulfide (H<sub>2</sub>S) but can accommodate six covalent bonds, as in sulfuric acid (H<sub>2</sub>SO<sub>4</sub>) and its sulfate derivatives. Nitrogen and phosphorus each have five electrons to share. In ammonia (NH<sub>3</sub>), the nitrogen atom forms three covalent bonds; the pair of electrons around the atom not involved in a covalent bond can take part in noncovalent interactions. In the ammonium ion (NH<sub>4</sub><sup>+</sup>), nitrogen forms four covalent bonds, which have a tetrahedral geometry. Phosphorus commonly forms five covalent bonds, as in phosphoric acid (H<sub>3</sub>PO<sub>4</sub>) and its phosphate derivatives, which form the backbone of nucleic acids. Phosphate groups covalently attached to proteins play a key role in regulating the activity of many proteins, and the central molecule in cellular energetics, ATP, contains three phosphate groups (see Section 2.4). A summary of common covalent linkages and functional groups, which confer distinctive chemical properties on the molecules of which they are a part, is provided in Table 2-2.

## Electrons May Be Shared Equally or Unequally in Covalent Bonds

The extent of an atom’s ability to attract an electron is called its *electronegativity*. In a bond between atoms with identical or similar electronegativities, the bonding electrons are essentially shared equally between the two atoms, as is the case for most carbon-carbon single bonds (C—C) and carbon-hydrogen single bonds (C—H). Such bonds are called **nonpolar**. In many molecules, however, the bonded atoms have different electronegativities, resulting in unequal sharing of electrons. The bond between them is said to be **polar**.

One end of a polar bond has a partial negative charge (δ<sup>−</sup>), and the other end has a partial positive charge (δ<sup>+</sup>). In an O—H bond, for example, the greater electronegativity of the oxygen atom relative to the hydrogen atom results in the electrons spending more time around the oxygen atom than around the hydrogen. Thus the O—H bond possesses an

**TABLE 2-2 Common Functional Groups and Linkages in Biomolecules**

electric **dipole**, a positive charge separated from an equal but opposite negative charge. The amount of  $\delta^+$  charge on the oxygen atom of an O—H dipole is approximately 25 percent that of an electron, and there is an equivalent and opposite  $\delta^+$  charge on the H atom. A common quantitative measure of the extent of charge separation, or strength, of a dipole is called the **dipole moment**,  $\mu$ , which for a chemical bond is the product of the partial charge on each atom and the distance between the two atoms. For a molecule with multiple dipoles, the amount of charge separation for the molecule as a whole depends in part on the dipole moments of all of its individual chemical bonds and in part on the geometry of the molecule (the relative orientations of the individual dipole moments).

Consider the example of water ( $\text{H}_2\text{O}$ ), which has two O—H bonds and thus two individual bond dipole moments. If water were a linear molecule with the two bonds on exact opposite sides of the O atom, the two dipoles on each end of the molecule would be identical in strength but would be oriented in opposite directions. The two dipole moments would cancel each other, and the dipole moment of molecule as a whole would be zero. However, because water is a V-shaped molecule, with the individual dipoles of its two O—H bonds both pointing toward the oxygen, one end of the water molecule (the end with the oxygen atom) has a partial negative charge and the other end (the one with the two hydrogen atoms) has a partial positive charge. As a consequence, the molecule as a whole is a dipole with a well-defined dipole moment (Figure 2-5). This dipole moment and the electronic properties of the oxygen and hydrogen atoms allow water to form electrostatic, noncovalent interactions with other

**FIGURE 2-5 The dipole nature of a water molecule.** The symbol  $\delta$  represents a partial charge (a weaker charge than the one on an electron or a proton). Because of the difference in the electronegativities of H and O, each of the polar H—O bonds in water is a dipole. The sizes and directions of the dipoles of each of the bonds determine the net distance and amount of charge separation, or dipole moment, of the molecule.

water molecules and with molecules of other types. These interactions play a critical role in almost every biochemical interaction in cells and organisms, as we will see shortly.

Another important example of polarity is the O=P double bond in  $\text{H}_3\text{PO}_4$ . In the structure of  $\text{H}_3\text{PO}_4$  shown on the left below, lines represent single and double bonds and nonbonding electrons are shown as pairs of dots (each dot represents one electron):

**FIGURE 2-6 Relative energies of covalent bonds and noncovalent interactions.** Bond energies are defined as the energy required to break a particular type of linkage. Shown here are the energies required to break a variety of linkages, arranged on a log scale. Covalent bonds, including single (C—C) and double (C=C) carbon-carbon bonds, are one to two powers of 10 stronger than noncovalent interactions. Noncovalent interactions have energies somewhat greater than the thermal energy of the environment at normal room temperature (25 °C). Many biological processes are coupled to the energy released during hydrolysis of a phosphoanhydride bond in ATP.

Because of the polarity of the O=P double bond,  $\text{H}_3\text{PO}_4$  can also be represented by the structure on the right, in which one of the electrons from the P=O double bond has accumulated around the O atom, giving it a negative charge and leaving the P atom with a positive charge. These charges are important in noncovalent interactions. Neither of these two models precisely describes the electronic state of  $\text{H}_3\text{PO}_4$ . The actual structure can be considered to be an intermediate, or hybrid, between these two representations, as indicated by the double-headed arrow between them. Such intermediate structures are called *resonance hybrids*.

### Covalent Bonds Are Much Stronger and More Stable Than Noncovalent Interactions

Covalent bonds are considered to be strong because the energies required to break them are much greater than the thermal energy available at room temperature (25 °C) or body temperature (37 °C). As a consequence, they are stable at these temperatures. For example, the thermal energy available at 25 °C is approximately 0.6 kilocalorie per mole (kcal/mol), whereas the energy required to break the C—C bond in ethane is about 140 times larger (Figure 2-6). Consequently, at room temperature (25 °C), fewer than 1 in  $10^{12}$  ethane molecules is broken into a pair of  $\cdot\text{CH}_3$  molecules, each containing an unpaired, nonbonding electron (called a radical).

Covalent single bonds in biological molecules have energies similar to the energy of the C—C bond in ethane. Because more electrons are shared between atoms in double bonds, they require more energy to break than single bonds. For instance, it takes 84 kcal/mol to break a single C—O bond but 170 kcal/mol to break a C=O double bond. The most common double bonds in biological molecules are C=O, C=N, C=C, and P=O.

In contrast, the energy required to break noncovalent interactions is only 1–5 kcal/mol, much less than the bond energies of covalent bonds (see Figure 2-6). Indeed, noncovalent interactions are weak enough that they are constantly being formed and broken at room temperature. Although these interactions are weak and have a transient existence

at physiological temperatures (25–37 °C), multiple noncovalent interactions can, as we will see, act together to produce highly stable and specific associations between different parts of a large molecule or between different macromolecules. Protein-protein and protein-nucleic acid interactions are good examples of such noncovalent interactions. Below, we review the four main types of noncovalent interactions and then consider their roles in the binding of biomolecules to one another and to other molecules.

### Ionic Interactions Are Attractions Between Oppositely Charged Ions

**Ionic interactions** result from the attraction between a positively charged ion—a **cation**—and a negatively charged ion—an **anion**. In sodium chloride (NaCl), for example, the bonding electron contributed by the sodium atom is completely transferred to the chlorine atom (Figure 2-7a). Unlike covalent bonds, ionic interactions do not have fixed or specific geometric orientations because the electrostatic field around an ion—its attraction for an opposite charge—is uniform in all directions. In solid NaCl, oppositely charged ions pack tightly together in an alternating pattern, forming the highly ordered crystalline array, or lattice, that is typical of salt crystals (Figure 2-7b). The energy required to break an ionic interaction depends on the distance between the ions and the electrical properties of the environment of the ions.

When solid salts dissolve in water, the ions separate from one another and are stabilized by their interactions with water molecules. In aqueous solutions, simple ions of biological significance, such as  $\text{Na}^+$ ,  $\text{K}^+$ ,  $\text{Ca}^{2+}$ ,  $\text{Mg}^{2+}$ , and  $\text{Cl}^-$ , are *hydrated*, surrounded by a stable shell of water molecules held in place by ionic interactions between the ion at the center and the oppositely charged ends of the water molecules, which are dipoles (Figure 2-7c). Most ionic compounds dissolve readily in water because the energy of hydration—the energy released when ions tightly bind water molecules and spread out in an aqueous solution—is greater than the lattice energy that stabilizes the crystal structure. Parts or all of the aqueous *hydration shell* must be removed from ions in solution when they interact directly with proteins. For example,

**FIGURE 2-7 Electrostatic interactions of the oppositely charged ions of salt (NaCl) in crystals and in aqueous solution.** (a) In crystal-line table salt, sodium atoms are positively charged ions (Na<sup>+</sup>) due to the loss of one electron each, whereas chloride atoms are correspondingly negatively charged (Cl<sup>-</sup>) by gaining one electron each. (b) In solid form, ionic compounds form neatly ordered arrays, or crystals, of tightly packed ions in which the positive and negatively charged ions

counterbalance each other. (c) When the crystals are dissolved in water, the ions separate, and their charges, no longer balanced by immediately adjacent ions of opposite charge, are stabilized by interactions with polar water. The water molecules and the ions are held together by electrostatic interactions between the charges on the ion and the partial charges on the water's oxygen and hydrogen atoms. In aqueous solutions, all ions are surrounded by a hydration shell of water molecules.

water of hydration is lost when ions pass through protein pores in the cell membrane during nerve conduction.

The relative strength of the interaction between two oppositely charged ions, A<sup>-</sup> and C<sup>+</sup>, depends on the concentration of other ions in a solution. The higher the concentration of other ions (e.g., Na<sup>+</sup> and Cl<sup>-</sup>), the more opportunities A<sup>-</sup> and C<sup>+</sup> have to interact ionically with those other ions, and thus the lower the energy required to break the interaction between A<sup>-</sup> and C<sup>+</sup>. As a result, increasing the concentrations of salts such as NaCl in a solution of biological molecules can weaken and even disrupt the ionic interactions holding the biomolecules together. This principle can be exploited to separate complex mixtures of interacting molecules such as proteins into their individual, pure components.

## Hydrogen Bonds Are Noncovalent Interactions That Determine the Water Solubility of Uncharged Molecules

A **hydrogen bond** is the interaction of a partially positively charged hydrogen atom in a dipole, such as water, with unpaired electrons from another atom, either in the same or in a different molecule. Normally, a hydrogen atom forms a covalent bond with only one other atom. However, a hydrogen atom covalently bonded to an electronegative donor atom D may form an additional weak association, the hydrogen bond, with an acceptor atom A, which must have a nonbonding pair of electrons available for the interaction:

The length of the covalent D—H bond is a bit longer than it would be if there were no hydrogen bond because the acceptor “pulls” the hydrogen away from the donor. An important feature of all hydrogen bonds is directionality. In the strongest hydrogen bonds, the donor atom, the hydrogen atom, and the acceptor atom all lie in a straight line. Nonlinear hydrogen bonds are weaker than linear ones; still, multiple nonlinear hydrogen bonds help to stabilize the three-dimensional structures of many proteins.

Hydrogen bonds are both longer and weaker than covalent bonds between the same atoms. In water, for example, the distance between the nuclei of the hydrogen and oxygen atoms of adjacent, hydrogen-bonded water molecules is about 0.27 nm, about twice the length of the covalent O—H bonds within a single water molecule (Figure 2-8a). A hydrogen bond between water molecules (approximately 5 kcal/mol) is much weaker than a covalent O—H bond (roughly 110 kcal/mol), although it is stronger than many other hydrogen bonds in biological molecules (1–2 kcal/mol). Extensive intermolecular hydrogen bonding between water molecules accounts for many of water's key properties, including its unusually high melting and boiling points and its ability to dissolve many other molecules.

The solubility of uncharged substances in an aqueous environment depends largely on their ability to form hydrogen bonds with water. For instance, the hydroxyl group (—OH) in alcohols (—CH<sub>2</sub>OH) and the amino group (—NH<sub>2</sub>) in amines (—CH<sub>2</sub>NH<sub>2</sub>) can form several hydrogen bonds with water, which allows these molecules to dissolve in water at high concentrations (Figure 2-8b). In general, molecules with polar bonds that easily form hydrogen bonds with water, as well as charged molecules and ions

**FIGURE 2-8 Hydrogen bonding of water with itself and with other compounds.** Each pair of nonbonding outer electrons in an oxygen or a nitrogen atom can accept a hydrogen atom in a hydrogen bond. The hydroxyl and the amino groups can also form hydrogen bonds with water. (a) In liquid water, each water molecule forms transient hydrogen bonds with several others, creating a dynamic network

that interact with the dipole in water, can readily dissolve in water; that is, they are hydrophilic. Many biological molecules contain, in addition to hydroxyl and amino groups, peptide and ester groups, which form hydrogen bonds with water via otherwise nonbonded electrons on their carbonyl oxygens (Figure 2-8c). X-ray crystallography combined with computational analysis permits an accurate depiction of the distribution of the outermost unbonded electrons of atoms that can participate in hydrogen bonds as well as the electrons in covalent bonds, as illustrated in Figure 2-9.

### Van der Waals Interactions Are Weak Attractive Interactions Caused by Transient Dipoles

When any two atoms approach each other closely, they create a weak, nonspecific attractive force called a **van der Waals interaction**. These nonspecific interactions result

of hydrogen-bonded molecules. (b) Water can also form hydrogen bonds with alcohols and amines, which accounts for the high solubility of these compounds. (c) The peptide group and the ester group, which are present in many biomolecules, commonly participate in hydrogen bonds with water or polar groups in other molecules.

from the momentary random fluctuations in the distribution of the electrons of any atom, which give rise to a transient unequal distribution of electrons. If two noncovalently bonded atoms are close enough, electrons of one atom will perturb the electrons of the other. This perturbation generates a transient dipole in the second atom, and the two dipoles attract each other weakly (Figure 2-10). Similarly, a polar covalent bond in one molecule attracts an oppositely oriented dipole in another.

Van der Waals interactions, involving either transient or permanent dipoles, occur in all types of molecules, both polar and nonpolar. In particular, van der Waals interactions are responsible for the cohesion between nonpolar molecules such as heptane,  $\text{CH}_3-(\text{CH}_2)_5-\text{CH}_3$ , that cannot form hydrogen bonds or ionic interactions with each other. The strength of van der Waals interactions decreases rapidly with increasing distance; thus these noncovalent interactions

**FIGURE 2-9 Distribution of bonding and outer nonbonding electrons in the peptide group.** Shown here is a peptide bond linking two amino acids within a protein called crambin. No protein has been structurally characterized at higher resolution than crambin. The black lines represent the covalent bonds between atoms. The red (negative) and blue (positive) lines represent contours of charge determined using x-ray crystallography and computational methods. The greater the number of contour lines, the higher the charge. The high density of red contour lines between atoms represents the covalent bonds (shared electron pairs). The two sets of red contour lines emanating from the oxygen (O) and not falling on a covalent bond (black line) represent the two pairs of nonbonding electrons on the oxygen that are available to participate in hydrogen bonding. The high density of blue contour lines near the hydrogen (H) bonded to nitrogen (N) represents a partial positive charge, indicating that this H can act as a donor in hydrogen bonding. [From *Proc. Natl. Acad. Sci. USA*, 2000, **97**(7):3171–3176, Fig. 3A. Accurate protein crystallography at ultra-high resolution: Valence electron distribution in crambin, by Christian Jelsch et al., Copyright (2000) National Academy of Sciences, USA.]

**FIGURE 2-10 Two oxygen molecules in van der Waals contact.**

In this model, red indicates negative charge and blue indicates positive charge. Transient dipoles in the electron clouds of all atoms give rise to weak attractive forces, called van der Waals interactions. Each type of atom has a characteristic van der Waals radius at which van der Waals interactions with other atoms are optimal. Because atoms repel one another if they are close enough together for their outer electrons to overlap without being shared in a covalent bond, the van der Waals radius is a measure of the size of the electron cloud surrounding an atom. The covalent radius indicated here is for the double bond of  $\text{O}=\text{O}$ ; the single-bond covalent radius of oxygen is slightly longer.

can form only when atoms are quite close to one another. However, if atoms get too close together, the negative charges of their electrons create a repulsive force. When the van der Waals attraction between two atoms exactly balances the repulsion between their two electron clouds, the atoms are said to be in van der Waals contact. The strength of the van der Waals interaction is about 1 kcal/mol, so it is weaker than typical hydrogen bonds, and its energy is only slightly higher than the average thermal energy of molecules at 25 °C. Thus multiple van der Waals interactions, a van der Waals interaction together with other noncovalent interactions, or both are required to form van der Waals-mediated stable attractions within and between molecules.

## The Hydrophobic Effect Causes Nonpolar Molecules to Adhere to One Another

Because nonpolar molecules do not contain charged groups, do not possess a dipole moment, and do not become hydrated, they are insoluble, or almost insoluble, in water; that is, they are hydrophobic. The covalent bonds between two carbon atoms and between carbon and hydrogen atoms are the most common nonpolar bonds in biological systems. **Hydrocarbons**—molecules made up only of carbon and hydrogen—are virtually insoluble in water. Large triacylglycerols (also known as triglycerides), which make up animal fats and vegetable oils, also essentially are insoluble in water. As we will see later, the major part of these molecules consists of long hydrocarbon chains. After being shaken in water, triacylglycerols form a separate phase. A familiar example is the separation of oil from the water-based vinegar in an oil-and-vinegar salad dressing.

Nonpolar molecules or nonpolar parts of molecules tend to aggregate in water owing to a phenomenon called the **hydrophobic effect**. Because water molecules cannot form hydrogen bonds with nonpolar substances, they tend to form “cages” of relatively rigid hydrogen-bonded pentagons and hexagons around nonpolar molecules (Figure 2-11, *left*). This state is energetically unfavorable because it decreases the entropy, or randomness, of the population of water molecules. (The role of entropy in chemical systems is discussed in Section 2.4.) If nonpolar molecules in an aqueous environment aggregate with their hydrophobic surfaces facing each other, the net hydrophobic surface area exposed to water is reduced (Figure 2-11, *right*). As a consequence, less water is needed to form the cages surrounding the nonpolar molecules, entropy increases relative to the unaggregated state, and an energetically more favorable state is reached. In a sense, then, water squeezes the nonpolar molecules into aggregates. Rather than constituting an attractive force, as in hydrogen bonds, the hydrophobic effect results from an avoidance of an unstable state—that is, extensive water cages around individual nonpolar molecules.

Nonpolar molecules can also associate, albeit weakly, through van der Waals interactions. The net result of the hydrophobic effect and van der Waals interactions is a very powerful tendency for hydrophobic molecules to interact with one another, not with water. Simply put, *like dissolves like*. Polar molecules dissolve in polar solvents such as water; nonpolar molecules dissolve in nonpolar solvents such as hexane.

 One well-known hydrophobic molecule is cholesterol (see the structure in Section 2.2). Cholesterol, triglycerides, and other poorly water-soluble molecules are called lipids. Unlike hydrophilic molecules such as glucose or

**FIGURE 2-11 Schematic depiction of the hydrophobic effect.**

Cages of water molecules that form around nonpolar molecules in solution are more ordered than water molecules in the surrounding bulk liquid. Aggregation of nonpolar molecules reduces the number of water molecules involved in forming highly ordered cages, resulting in a higher-entropy, more energetically favorable state (*right*) compared with the unaggregated state (*left*).

amino acids, lipids cannot readily dissolve in the blood, the aqueous circulatory system that transports molecules and cells throughout the body. Instead, lipids such as cholesterol must be packaged into special hydrophilic carriers, called lipoproteins, that can themselves dissolve in the blood and be transported throughout the body. There can be hundreds to thousands of lipid molecules packed into the center, or core, of each lipoprotein. The hydrophobic core is surrounded by amphipathic molecules that have hydrophilic parts that interact with water and hydrophobic parts that interact with one another and the core. The packaging of lipids into lipoproteins (discussed in Chapter 14) permits their efficient transport in blood and is reminiscent of the containerization of cargo for efficient long-distance transport via cargo ships, trains, and trucks.

High-density lipoprotein (HDL) and low-density lipoprotein (LDL) are two such lipoprotein carriers that are associated with either reduced or increased heart disease, respectively, and are therefore often referred to as “good” and “bad” cholesterol. Actually, the cholesterol molecules and their derivatives that are carried by both HDL and LDL are essentially identical and in themselves are neither “good” nor “bad.” However, HDL and LDL have different effects on cells, and as a consequence, LDL contributes to and HDL appears to protect from clogging of the arteries (known as *atherosclerosis*) and consequent heart disease and stroke. Thus LDL is known as “bad” cholesterol. ■

## Molecular Complementarity Due to Noncovalent Interactions Leads to a Lock-and-Key Fit Between Biomolecules

Both inside and outside cells, ions and molecules constantly collide. The higher the concentration of any two types of molecules, the more likely they are to encounter each other. When two molecules encounter each other, they are most likely to simply bounce apart because the noncovalent interactions that would bind them together are weak and have a transient existence at physiological temperatures. However, molecules that exhibit **molecular complementarity**, a lock-and-key kind of fit between their shapes, charges, or other physical properties, can form multiple noncovalent interactions at close range. When two such structurally complementary molecules bump into each other, these multiple interactions cause them to stick together, or bind.

Figure 2-12 illustrates how multiple, different weak interactions can cause two hypothetical proteins to bind together tightly. Numerous examples of such protein-to-protein molecular complementarity may be found throughout this book (see, for example, Figures 16-8, 16-9, and 16-11). Almost any other arrangement of the same groups of molecules on the two surfaces would not allow the molecules to bind so tightly. Such molecular complementarity between regions within a protein molecule allow it to fold into a unique three-dimensional shape (see Chapter 3); it is also what holds the two chains of DNA together in a double helix (see Chapter 5). Similar interactions underlie the association

**FIGURE 2-12 Molecular complementarity permits tight protein bonding via multiple noncovalent interactions.** The complementary shapes, charges, polarity, and hydrophobicity of two protein surfaces permit multiple weak interactions, which in combination produce a strong interaction and tight binding. Because deviations from molecular complementarity substantially weaken binding, a particular surface region of any given biomolecule usually can bind tightly to only one or a very limited number of other molecules. The complementarity of the two protein molecules on the left permits them to bind much more tightly than the two noncomplementary proteins on the right.

of groups of molecules into multimolecular assemblies, or complexes, leading, for example, to the formation of muscle fibers, to the glue-like associations between cells in solid tissues, and to numerous other cellular structures. The antibodies that help neutralize pathogens (see Chapter 23) bind to them using similar principles of complementary molecular shapes.

Depending on the number and strength of the noncovalent interactions between the two molecules and on their environment, their binding may be tight or loose and, as a consequence, either lasting or transient. The higher the *affinity* of two molecules for each other, the better the molecular “fit” between them, the more noncovalent interactions can form, and the more tightly they can bind together. An important quantitative measure of affinity is the binding dissociation constant  $K_d$ , described in Section 2.3. It is important to note that many large biological molecules are not hard, rigid structures, but rather can be somewhat malleable. Thus the binding of a molecule to another has the potential to induce a change in the shape of its binding partner. When the molecular complementarity increases after such interactions, the process is called *induced fit*.

As we discuss in Chapter 3, nearly all the chemical reactions that occur in cells also depend on the binding properties of enzymes. These proteins not only speed up, or catalyze, reactions, but do so with a high degree of *specificity*, which is a reflection of their ability to bind tightly to only one or a few related molecules. The specificity of intermolecular interactions and reactions, which depends on molecular complementarity, is essential for many processes critical to life.

## KEY CONCEPTS OF SECTION 2.1

### Covalent Bonds and Noncovalent Interactions

- The terms hydrophilic, hydrophobic, and amphipathic/amphiphilic refer to the tendency of molecules to be water-loving, incapable of interacting with water, and having features of or being tolerant of both, respectively. Hydrophilic molecules typically dissolve readily in water, whereas hydrophobic molecules are poorly soluble or insoluble in water.
- Covalent bonds consist of pairs of electrons shared by two atoms. Covalent bonds arrange the atoms of a molecule into a specific geometry.
- Many molecules in cells contain at least one asymmetric carbon atom, which is bonded to four dissimilar atoms. Such molecules can exist as stereoisomers (mirror images), designated D and L (see Figure 2-4), which have different biological activities. Nearly all amino acids are L isomers.
- Electrons may be shared equally or unequally in covalent bonds. Atoms that differ in electronegativity form polar covalent bonds, in which the bonding electrons are distributed unequally. One end of a polar bond has a partial positive charge and the other end has a partial negative charge (see Figure 2-5).
- Covalent bonds are stable in biological systems because the relatively high energies required to break them (50–200 kcal/mol) are much larger than the thermal kinetic energy available at room (25 °C) or body (37 °C) temperatures.
- Noncovalent interactions between atoms are considerably weaker than covalent bonds, with energies ranging from about 1–5 kcal/mol (see Figure 2-6).
- Four main types of noncovalent interactions occur in biological systems: ionic bonds, hydrogen bonds, van der Waals interactions, and interactions due to the hydrophobic effect.
- Ionic bonds result from the electrostatic attraction between the positive and negative charges of ions. In aqueous solutions, all cations and anions are surrounded by a shell of bound water molecules (see Figure 2-7c). Increasing the salt (e.g., NaCl) concentration of a solution can weaken the relative strength of and even break the ionic bonds between biomolecules.
- In a hydrogen bond, a hydrogen atom covalently bonded to an electronegative atom associates with an acceptor atom whose nonbonding electrons attract the hydrogen (see Figure 2-8).
- Weak and relatively nonspecific van der Waals interactions result from the attraction between transient dipoles associated with all molecules. They can form when two atoms approach each other closely (see Figure 2-10).
- In an aqueous environment, nonpolar molecules or nonpolar parts of larger molecules are driven together by the

hydrophobic effect, thereby reducing the extent of their direct contact with water molecules (see Figure 2-11).

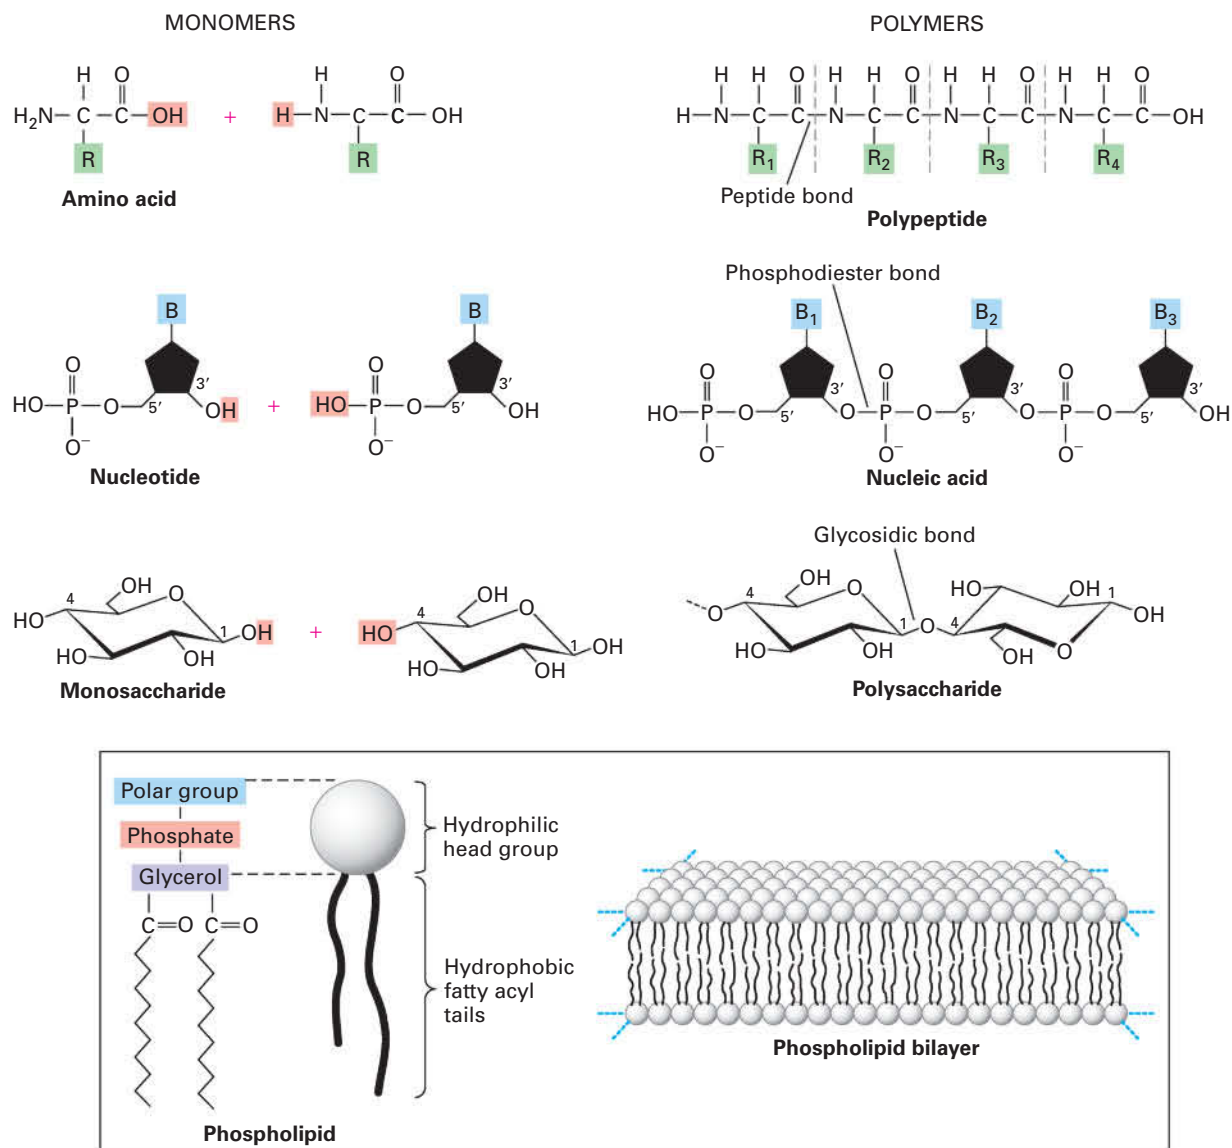

- Molecular complementarity is the lock-and-key fit between molecules whose shapes, charges, and other physical properties are complementary. Multiple noncovalent interactions can form between complementary molecules, causing them to bind tightly (see Figure 2-12), but not between molecules that are not complementary.
- The high degree of binding specificity that results from molecular complementarity is one of the features that underlies intermolecular interactions in biology and thus is essential for many processes critical to life.

## 2.2 Chemical Building Blocks of Cells

A common theme in biology is the construction of large **macromolecules** and macromolecular structures out of smaller molecular subunits, which can be thought of as building blocks. Often these subunits are similar or identical. The three main types of biological macromolecules—proteins, nucleic acids, and polysaccharides—are all **polymers** composed of multiple covalently linked small molecules, or **monomers** (Figure 2-13). **Proteins** are linear polymers containing up to several thousand amino acids linked by **peptide bonds**. **Nucleic acids** are linear polymers containing hundreds to millions of nucleotides linked by **phosphodiester bonds**. **Polysaccharides** are linear or branched polymers of monosaccharides (sugars) such as glucose linked by **glycosidic bonds**.

Although the actual mechanisms of covalent bond formation between monomers are complex, as we will see, the formation of a covalent bond between two monomers usually involves the net loss of a hydrogen (H) from one monomer and a hydroxyl (OH) from the other monomer—or the net loss of one water molecule—and can therefore be thought of as a *dehydration reaction*. The breakdown, or cleavage, of a covalent bond in a polymer that releases a monomeric subunit involves the reverse reaction, or the addition of water, called *hydrolysis*. The covalent bonds that link monomers together are normally stable under normal biological conditions (e.g., 37 °C, neutral pH), so these biopolymers are stable and can perform a wide variety of jobs in cells, such as storing information, catalyzing chemical reactions, serving as structural elements that define cell shape and movement, and many others. Macromolecular structures can also be assembled using noncovalent interactions. The two-ply, or “bilayer,” structure of cellular membranes is built up by the noncovalent assembly of many thousands of small molecules called phospholipids (see Figure 2-13).

In this chapter, we focus on the chemical building blocks making up cells—amino acids, nucleotides, sugars, and phospholipids. The structure, function, and assembly of

**FIGURE 2-13 Overview of the cell's principal chemical building blocks.** (Top) The three major types of biological macromolecules are each assembled by the polymerization of multiple small molecules (monomers) of a particular type: proteins from amino acids (see Chapter 3), nucleic acids from nucleotides (see Chapter 5), and

polysaccharides from monosaccharides (sugars). Each monomer is covalently linked into the polymer by a reaction whose net result is loss of a water molecule (dehydration). (Bottom) In contrast, phospholipid monomers noncovalently assemble into a bilayer structure, which forms the basis of all cellular membranes (see Chapter 7).

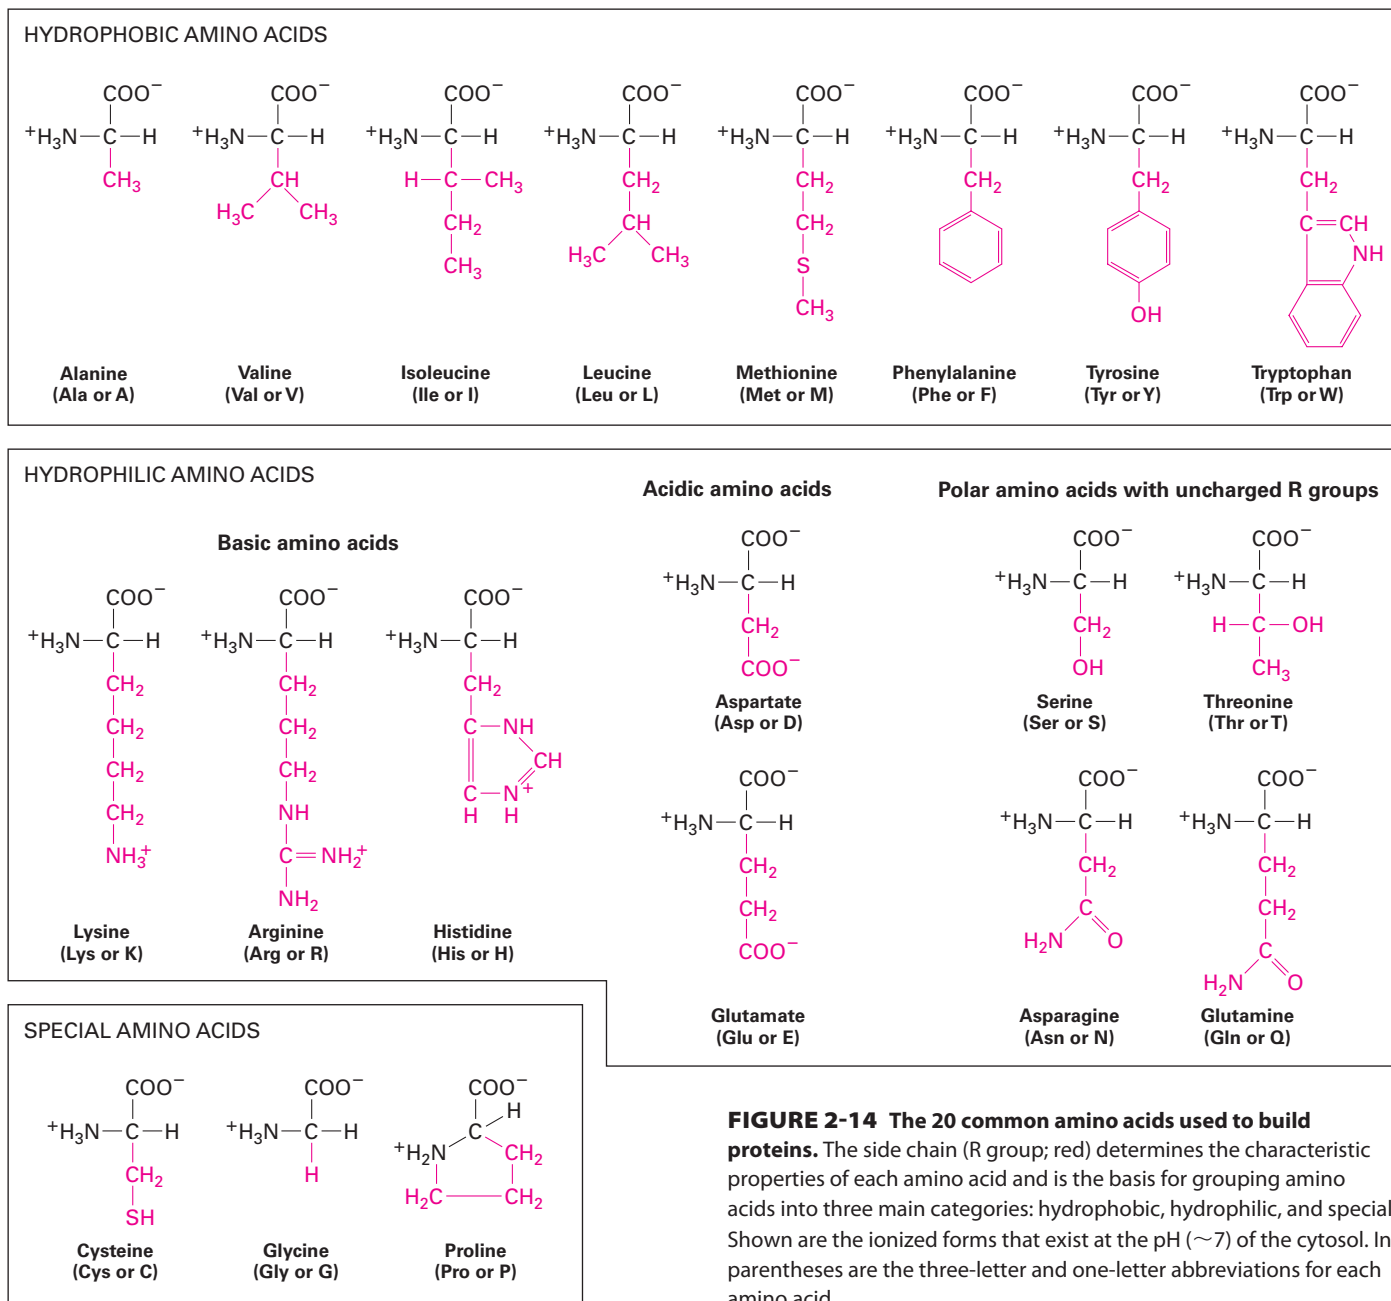

proteins, nucleic acids, polysaccharides, and biomembranes are discussed in subsequent chapters.

### Amino Acids Differing Only in Their Side Chains Compose Proteins

The monomeric building blocks of proteins are 20 **amino acids**, which—when incorporated into a protein polymer—are sometimes called **residues**. All amino acids have a characteristic structure consisting of a central **alpha carbon atom** ( $\text{C}_\alpha$ ) bonded to four different chemical groups: an amino ( $-\text{NH}_2$ ) group, a carboxyl or carboxylic acid ( $-\text{COOH}$ ) group (hence the name *amino acid*), a hydrogen (H) atom, and one variable group, called a *side chain* or *R*

*group*. Because the  $\alpha$  carbon in all amino acids except glycine is asymmetric, these molecules can exist in two mirror-image forms, called by convention the **D** (dextro) and the **L** (levo) isomers (see Figure 2-4). The two isomers cannot be interconverted (one made identical to the other) without breaking and then re-forming a chemical bond in one of them. With rare exceptions, only the **L** forms of amino acids are found in proteins. However, **D** amino acids are prevalent in bacterial cell walls and other microbial products.

To understand the three-dimensional structures and functions of proteins, discussed in detail in Chapter 3, you must be familiar with some of the distinctive properties of amino acids, which are determined in part by their side chains. You need not memorize the detailed structure of each type of side chain

**FIGURE 2-14 The 20 common amino acids used to build proteins.** The side chain (R group; red) determines the characteristic properties of each amino acid and is the basis for grouping amino acids into three main categories: hydrophobic, hydrophilic, and special. Shown are the ionized forms that exist at the pH (~7) of the cytosol. In parentheses are the three-letter and one-letter abbreviations for each amino acid.

to understand how proteins work because amino acids can be classified into several broad categories based on the size, shape, charge, hydrophobicity (a measure of water solubility), and chemical reactivity of their side chains (Figure 2-14).

Amino acids with nonpolar side chains, called hydrophobic amino acids, are poorly soluble in water. The larger the nonpolar side chain, the more hydrophobic the amino acid. The side chains of *alanine*, *valine*, *leucine*, and *isoleucine* are linear or branched hydrocarbons that do not form a ring, and they are therefore called aliphatic amino acids. These amino acids are all nonpolar, as is *methionine*, which is similar to them except that it contains one sulfur atom. *Phenylalanine*, *tyrosine*, and *tryptophan* have large, hydrophobic,

aromatic rings in their side chains. In later chapters, we will see in detail how hydrophobic side chains under the influence of the hydrophobic effect often pack into the interior of proteins or line the surfaces of proteins that are embedded within hydrophobic regions of biomembranes.

Amino acids with polar side chains are called hydrophilic amino acids; the most hydrophilic of these amino acids is the subset with side chains that are charged (ionized) at the pH typical of biological fluids (~7) both inside and outside the cell (see Section 2.3). *Arginine* and *lysine* have positively charged side chains and are called basic amino acids; *aspartic acid* and *glutamic acid* have negatively charged side chains due to the carboxylic acid groups in their side chains

(their charged forms are called *aspartate* and *glutamate*) and are called acidic amino acids. A fifth amino acid, *histidine*, has a side chain containing a ring with two nitrogens, called imidazole, which can shift from being positively charged to uncharged in response to small changes in the acidity of its environment:

The activities of many proteins are modulated by shifts in environmental acidity (pH) through protonation or deprotonation of histidine side chains. *Asparagine* and *glutamine* are uncharged but have polar side chains containing amide groups with extensive hydrogen-bonding capacities. Similarly, *serine* and *threonine* are uncharged but have polar hydroxyl groups, which also participate in hydrogen bonds with other polar molecules.

Finally, cysteine, glycine, and proline play special roles in proteins because of the unique properties of their side chains. The side chain of *cysteine* contains a reactive *sulfhydryl group* ( $-\text{SH}$ ). On release of a proton ( $\text{H}^+$ ), a sulfhydryl group is converted into a thiolate anion ( $\text{S}^-$ ). Thiolate anions can play important roles in catalysis, notably in certain enzymes that destroy proteins (proteases). In proteins, each of two adjacent sulfhydryl groups can be oxidized, each releasing a proton and an electron, to form a covalent *disulfide bond* ( $-\text{S}-\text{S}-$ ):

Disulfide bonds serve to “cross-link” regions within a single polypeptide chain (intramolecular cross-linking) or between two separate chains (intermolecular cross-linking). Disulfide bonds stabilize the folded structure of some proteins. The smallest amino acid, *glycine*, has a single hydrogen atom as its R group. Its small size allows it to fit into tight spaces. Unlike those of the other common amino acids, the side chain of *proline* (pronounced pro-leen) bends around to form a ring by covalently bonding to the nitrogen atom in the amino group attached to the  $\text{C}_\alpha$ . As a result, proline is very rigid, and its amino group is not available for typical

hydrogen bonding. The presence of proline in a protein creates a fixed kink in the polymer chain, limiting how it can fold in the vicinity of the proline residue.

Some amino acids are more abundant in proteins than others. Cysteine, tryptophan, and methionine are not common amino acids: together, they constitute approximately 5 percent of the amino acids in a typical protein. Four amino acids—leucine, serine, lysine, and glutamic acid—are the most abundant amino acids, constituting 32 percent of all the residues in a typical protein. However, the amino acid compositions of particular proteins may vary widely from these values.

Humans and other mammals can synthesize 11 of the 20 amino acids. The other nine are called *essential amino acids* and must be included in the diet to permit normal protein production. These essential amino acids are phenylalanine, valine, threonine, tryptophan, isoleucine, methionine, leucine, lysine, and histidine. Adequate provision of these essential amino acids in feed is key to the livestock industry. Indeed, a genetically engineered variety of corn with a high lysine content is now in use as an “enhanced” feed to promote the growth of animals. ■

Although cells use the 20 amino acids shown in Figure 2-14 in the *initial* synthesis of proteins, analysis of cellular proteins reveals that they contain over 100 different amino acids. The difference is due to the chemical modification of some amino acids after they are incorporated into proteins by the addition of a variety of chemical groups (Figure 2-15). One important modification is the addition of acetyl groups ( $\text{CH}_3\text{CO}$ ) to amino acids, a process known as acetylation. Another is the addition of a phosphate ( $\text{PO}_4$ ) to hydroxyl groups in serine, threonine, and tyrosine residues, a process known as phosphorylation. We will encounter numerous examples of proteins whose activity is regulated by reversible phosphorylation and dephosphorylation. Phosphorylation of nitrogen in the side chain of histidine is well known in bacteria, fungi, and plants, but less studied—perhaps because of the relative instability of phosphorylated histidine—and apparently rare in mammals. Methylation of arginine and lysine side chains on proteins called histones is an important regulator of gene expression in eukaryotes (see Chapter 9). Like phosphorylation and dephosphorylation, controlled methylation and demethylation are important regulatory processes. The side chains of asparagine, serine, and threonine are sites for glycosylation, the attachment of linear and branched carbohydrate chains. Many secreted proteins and membrane proteins contain glycosylated residues, and the reversible modification of hydroxyl groups on specific serines and threonines by a sugar called N-acetylglucosamine also regulates protein activities. Other amino acid modifications found in selected proteins include the hydroxylation of proline and lysine residues in collagen (see Chapter 19), the methylation of histidine residues in membrane receptors, and the  $\gamma$ -carboxylation of glutamate in blood-clotting factors such as prothrombin. Deamidation of asparagine and

**FIGURE 2-15 Common modifications of amino acid side chains in proteins.** These modified residues and numerous others are formed by addition of various chemical groups (red) to the amino acid side chains during or after synthesis of a polypeptide chain.

glutamine to form the corresponding acidic amino acids, aspartate and glutamate, is also a common occurrence.

Acetylation of the amino group of the N-terminal residue is the most common form of amino acid chemical modification, affecting an estimated 80 percent of all proteins:

This modification may play an important role in controlling the life span of proteins within cells because many nonacetylated proteins are rapidly degraded.

## Five Different Nucleotides Are Used to Build Nucleic Acids

Two types of chemically similar nucleic acids, DNA (**deoxyribonucleic acid**) and RNA (**ribonucleic acid**), are the cell's principal molecules that carry genetic information. The monomers from which DNA and RNA polymers are built, called **nucleotides**, all have a common structure: a phosphate group linked by a phosphoester bond to a pentose (five-carbon) sugar, which in turn is linked to a nitrogen- and carbon-containing ring structure commonly referred to as a *base* (Figure 2-16a). In RNA, the pentose is ribose; in DNA, it is deoxyribose, which has a proton, rather than a hydroxyl group, at position 2' (Figure 2-16b). (We describe the structures of sugars in more detail below.) The bases *adenine*, *guanine*, and *cytosine* (Figure 2-17) are found in both DNA and RNA; *thymine* is found only in DNA, and *uracil* is found only in RNA.

Adenine and guanine are **purines**, which contain a pair of fused rings; cytosine, thymine, and uracil are **pyrimidines**, which contain a single ring (see Figure 2-17). The bases are often abbreviated A, G, C, T, and U, respectively; these same single-letter abbreviations are also commonly used to denote the entire nucleotides in nucleic acid polymers. In nucleotides, the 1' carbon atom of the sugar (ribose or deoxyribose) is attached to the nitrogen at position 9 of a purine (N<sub>9</sub>) or at position 1 of a pyrimidine (N<sub>1</sub>). The acidic character of nucleotides is due to the phosphate group, which under normal intracellular conditions releases hydrogen

**FIGURE 2-16 Common structure of nucleotides.** (a) Adenosine 5'-monophosphate (AMP), a nucleotide present in RNA. By convention, the carbon atoms of the pentose sugar in nucleotides are numbered with primes. In natural nucleotides, the 1' carbon is joined by a  $\beta$  linkage to the base (in this case, adenine); both the base (blue) and the phosphate on the 5' hydroxyl (red) extend above the plane of the sugar ring. (b) Ribose and deoxyribose, the pentoses in RNA and DNA, respectively.

**FIGURE 2-17 Chemical structures of the principal bases in nucleic acids.** In nucleic acids and nucleotides, nitrogen 9 of purines and nitrogen 1 of pyrimidines (red) are bonded to the 1' carbon of ribose or deoxyribose. U is found only in RNA, and T is found only in DNA. Both RNA and DNA contain A, G, and C.

ions ( $\text{H}^+$ ), leaving the phosphate negatively charged (see Figure 2-16a). Most nucleic acids in cells are associated with proteins, which form ionic interactions with the negatively charged phosphates.

Cells and extracellular fluids in organisms contain small concentrations of **nucleosides**, combinations of a base and a sugar without a phosphate. Nucleotides are nucleosides that have one, two, or three phosphate groups esterified at the 5' hydroxyl. *Esterification*—the formation of an

ester—involves the covalent linking of an acid, such as a carboxylic acid or a phosphoric acid, with an alcohol accompanied by the release of an hydroxyl ( $\text{—OH}$ ) group from the acid and an H from the hydroxyl group on the other molecule, which together form a water molecule. Here, a phosphoric acid is esterified with the 5' hydroxyl group of the ribose. Nucleoside monophosphates have a single esterified phosphate (see Figure 2-16a); nucleoside diphosphates contain a pyrophosphate group:

and nucleoside triphosphates have a third phosphate. Table 2-3 lists the names of the nucleosides and nucleotides in nucleic acids and the various forms of nucleoside phosphates. The nucleoside triphosphates are used in the synthesis of nucleic acids, which we cover in Chapter 5. Among their other functions in the cell, GTP participates in intracellular signaling and acts as an energy reservoir, particularly in protein synthesis, and ATP, discussed later in this chapter, is the most widely used biological energy carrier.

## Monosaccharides Covalently Assemble into Linear and Branched Polysaccharides

The building blocks of the polysaccharides are the simple sugars, or **monosaccharides**. Monosaccharides are **carbohydrates**, which are literally covalently bonded combinations of carbon and water in a one-to-one ratio  $(\text{CH}_2\text{O})_n$ , where  $n$  equals 3, 4, 5, 6, or 7. **Hexoses** ( $n = 6$ ) and **pentoses** ( $n = 5$ ) are the most common monosaccharides. All monosaccharides

**TABLE 2-3 Terminology of Nucleosides and Nucleotides**

Bases	Purines		Pyrimidines		
	Adenine (A)	Guanine (G)	Cytosine (C)	Uracil (U) Thymine (T)	
Nucleosides	in RNA	Adenosine	Guanosine	Cytidine	Uridine
	in DNA	Deoxyadenosine	Deoxyguanosine	Deoxycytidine	Deoxythymidine
Nucleotides	in RNA	Adenylylate	Guanylylate	Cytidylylate	Uridylylate
	in DNA	Deoxyadenylylate	Deoxyguanylylate	Deoxycytidylylate	Deoxythymidylylate
Nucleoside monophosphates		AMP	GMP	CMP	UMP
Nucleoside diphosphates		ADP	GDP	CDP	UDP
Nucleoside triphosphates		ATP	GTP	CTP	UTP
Deoxynucleoside mono-, di-, and triphosphates		dAMP, etc.	dGMP, etc.	dCMP, etc.	dTMP, etc.

contain hydroxyl (—OH) groups and either an aldehyde or a keto group:

Many biologically important sugars are hexoses, including glucose, mannose, and galactose (Figure 2-18). Mannose is identical to glucose except that the orientation of the groups bonded to carbon 2 is reversed. Similarly, galactose, another hexose, differs from glucose only in the orientation of the groups attached to carbon 4. Interconversion of glucose and mannose or galactose requires the breaking and making of covalent bonds; such reactions are carried out by enzymes called *epimerases*.

D-Glucose ( $\text{C}_6\text{H}_{12}\text{O}_6$ ) is the principal external source of energy for most cells in complex multicellular organisms. It can exist in three different forms: a linear structure and two different hemiacetal ring structures (Figure 2-18a). If the aldehyde group on carbon 1 combines with the hydroxyl group on carbon 5, the resulting hemiacetal, D-glucopyranose, contains a six-member ring. In the  $\alpha$  anomer of D-glucopyranose, the hydroxyl group attached

to carbon 1 points “downward” from the ring, as shown in Figure 2-18a; in the  $\beta$  anomer, this hydroxyl points “upward.” In aqueous solution, the  $\alpha$  and  $\beta$  anomers readily interconvert spontaneously; at equilibrium there is about one-third  $\alpha$  anomer and two-thirds  $\beta$ , with very little of the open-chain form. Because enzymes can distinguish between the  $\alpha$  and  $\beta$  anomers of D-glucose, these forms have distinct biological roles. Condensation of the hydroxyl group on carbon 4 of the linear glucose with its aldehyde group results in the formation of D-glucofuranose, a hemiacetal containing a five-member ring. Although all three forms of D-glucose exist in biological systems, the pyranose (six-member ring) form is by far the most abundant.

The pyranose ring in Figure 2-18a is depicted as planar. In fact, because of the tetrahedral geometry around carbon atoms, the most stable conformation of a pyranose ring has a nonplanar, chairlike shape. In this conformation, each bond from a ring carbon to a nonring atom (e.g., H or O) is either nearly perpendicular to the ring, referred to as axial (a), or nearly in the plane of the ring, referred to as equatorial (e):

**FIGURE 2-18 Chemical structures of hexoses.** All hexoses have the same chemical formula ( $\text{C}_6\text{H}_{12}\text{O}_6$ ) and contain an aldehyde or a keto group. (a) The ring forms of D-glucose are generated from the linear molecule by reaction of the aldehyde at carbon 1 with the hydroxyl on carbon 5 or carbon 4. The three forms are readily interconvertible, although the pyranose form (right) predominates in biological systems. (b) In D-mannose and D-galactose, the configuration of the H (green) and OH (blue) bound to one carbon atom differs from that in glucose. These sugars, like glucose, exist primarily as pyranoses (six-member rings).

**Disaccharides**, formed from two monosaccharides, are the simplest polysaccharides. The disaccharide lactose, composed of galactose and glucose, is the major sugar in milk; the disaccharide sucrose, composed of glucose and fructose, is a principal product of plant photosynthesis and is refined into common table sugar (Figure 2-19).

Larger polysaccharides, containing dozens to hundreds of monosaccharide units, can function as reservoirs for glucose, as structural components, or as adhesives that help hold cells together in tissues. The most common storage carbohydrate in animal cells is **glycogen**, a very long, highly branched polymer of glucose. As much as 10 percent of the liver by weight can be glycogen. The primary storage carbohydrate in plant cells, **starch**, is also a glucose polymer. It occurs in an unbranched form (amylose) and a lightly branched form (amylopectin). Both glycogen and starch are composed of the  $\alpha$  anomer of glucose. In contrast, **cellulose**, the major constituent of plant cell walls, which confers stiffness to many plant structures (see Chapter 19), is an unbranched polymer of the  $\beta$  anomer of glucose. Human digestive enzymes can hydrolyze the  $\alpha$  glycosidic bonds in starch but not the  $\beta$  glycosidic bonds in cellulose. Many species of plants, bacteria, and molds produce cellulose-degrading enzymes. Cows and termites can break down cellulose because they harbor cellulose-degrading bacteria in their gut. Bacterial cell walls consist of **peptidoglycan**, a polysaccharide chain cross-linked by peptide cross-bridges, which confers rigidity and cell shape. Human tears and gastrointestinal fluids contains lysozyme, an enzyme capable of hydrolyzing peptidoglycan in the bacterial cell wall.

**FIGURE 2-19 Formation of the disaccharides lactose and sucrose.** In any glycosidic linkage, the anomeric carbon of one sugar molecule (in either the  $\alpha$  or  $\beta$  conformation) is linked to a hydroxyl oxygen on another sugar molecule. The linkages are named accordingly; thus lactose contains a  $\beta(1 \rightarrow 4)$  bond, and sucrose contains an  $\alpha(1 \rightarrow 2)$  bond.

The enzymes that make the glycosidic bonds linking monosaccharides into polysaccharides are specific for the  $\alpha$  or  $\beta$  anomer of one sugar and a particular hydroxyl group on the other. In principle, any two sugar molecules can be linked in a variety of ways because each monosaccharide has multiple hydroxyl groups that can participate in the formation of glycosidic bonds. Furthermore, any one monosaccharide has the potential to be linked to more than two other monosaccharides, thus generating a branch point and nonlinear polymers. Glycosidic bonds are usually formed between the growing polysaccharide chain and a covalently modified form of a monosaccharide. Such modifications include the addition of a phosphate (e.g., glucose-6-phosphate) or a nucleotide (e.g., UDP-galactose):

The epimerase enzymes that interconvert different monosaccharides often do so using the nucleotide sugars rather than the unmodified, or “free,” sugars.

Many complex polysaccharides contain modified sugars that are covalently linked to various small groups, particularly amino, sulfate, and acetyl groups. Such modifications are abundant in **glycosaminoglycans**, major polysaccharide components of the extracellular matrix that we describe in Chapter 19.

## Phospholipids Associate Noncovalently to Form the Basic Bilayer Structure of Biomembranes

Biomembranes are large, flexible sheets with a two-ply, or bilayer, structure. They serve as the boundaries of cells and

their intracellular organelles and form the outer surfaces of some viruses. Membranes literally define what is a cell (the outer membrane and the contents within the membrane) and what is not (the extracellular space outside the membrane). Unlike proteins, nucleic acids, and polysaccharides, membranes are assembled by the *noncovalent* association of their component building blocks. The primary building blocks of all biomembranes are **phospholipids**, whose physical properties are responsible for the formation of the sheet-like bilayer structure of membranes. In addition to phospholipids, biomembranes can contain a variety of other molecules, including cholesterol, glycolipids, and proteins. The structure and functions of biomembranes will be described in detail in Chapter 7. Here we will focus on the phospholipids in biomembranes.

To understand the structure a phospholipid molecule, we have to understand each of its component parts and how it is assembled. As we will see shortly, a phospholipid molecule consists of two long-chain, nonpolar fatty acid groups linked (usually by an ester bond) to small, highly polar groups, including a short organic molecule such as glycerol (trihydroxy propane), a phosphate, and typically, a small organic molecule (Figure 2-20).

**Fatty acids** consist of a hydrocarbon chain attached to a carboxyl group ( $-\text{COOH}$ ). Like glucose, fatty acids are an important energy source for many cells (see Chapter 12). They differ in length, although the predominant fatty acids in cells have an even number of carbon atoms, usually 14, 16, 18, or 20. The major fatty acids in phospholipids are listed in Table 2-4. Fatty acids are often designated by the abbreviation  $\text{Cx:y}$ , where  $x$  is the number of carbons in the chain and  $y$  is the number of double bonds. Fatty acids containing 12 or more carbon atoms are nearly insoluble in aqueous solutions because of their long hydrophobic hydrocarbon chains.

Fatty acids in which all the carbon-carbon bonds are single bonds—that is, the fatty acids have no carbon-carbon double bonds—are said to be **saturated**; those with at least one carbon-carbon double bond are called **unsaturated**.

**FIGURE 2-20 Phosphatidylcholine, a typical phosphoglyceride.**

All phosphoglycerides are amphipathic phospholipids, having a hydrophobic tail (yellow) and a hydrophilic head (blue) in which glycerol is linked via a phosphate group to an alcohol. Either or both

of the fatty acyl side chains in a phosphoglyceride may be saturated or unsaturated. In phosphatidic acid (red), the simplest phospholipid, the phosphate is not linked to an alcohol.

Unsaturated fatty acids with more than one carbon-carbon double bond are referred to as **polyunsaturated**. Two “essential” polyunsaturated fatty acids, linoleic acid (C18:2) and linolenic acid (C18:3), cannot be synthesized by mammals and must be supplied in their diet. Mammals can synthesize other common fatty acids.

In phospholipids, fatty acids are covalently attached to another molecule by esterification. In the combined molecule formed by this reaction, the part derived from the fatty acid is called an *acyl group*, or *fatty acyl group*. This structure is illustrated by the most common forms of phospholipids: **phosphoglycerides**, which contain two acyl groups attached to two of the three hydroxyl groups of glycerol (see Figure 2-20).

In phosphoglycerides, one hydroxyl group of the glycerol is esterified to phosphate while the other two are normally esterified to fatty acids. The simplest phospholipid, phosphatidic acid, contains only these components. Phospholipids such as phosphatidic acids are not only membrane building blocks but also important signaling molecules. Lyso-phosphatidic acid, in which the acyl chain at the 2 position (attached to the hydroxyl group on the central carbon of the glycerol) has been removed, is relatively water soluble and can be a potent inducer of cell division (called a mitogen). In most phospholipids found in membranes, the phosphate group is also esterified to a hydroxyl group on another hydrophilic compound. In phosphatidylcholine, for example,

choline is attached to the phosphate (see Figure 2-20). The negatively charged phosphate, as well as the charged or polar groups esterified to it, can interact strongly with water. The phosphate and its associated esterified group constitute the “head” group of a phospholipid, which is hydrophilic, whereas the fatty acyl chains, the “tails,” are hydrophobic. Other common phosphoglycerides and associated head groups are shown in Table 2-5. Molecules such as phospholipids that have both hydrophobic and hydrophilic regions are called amphipathic. In Chapter 7, we will see how the amphipathic properties of phospholipids allow their assembly into sheet-like bilayers in which the fatty acyl tails point into the center of the sheet and the head groups point outward toward the aqueous environment (see Figure 2-13).

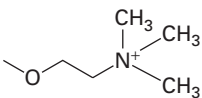

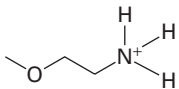

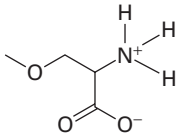

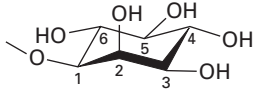

Fatty acyl groups also can be covalently linked in other fatty molecules, including **triacylglycerols**, or **triglycerides**, which contain three acyl groups esterified to glycerol:

**TABLE 2-4 Fatty Acids That Predominate in Phospholipids**

Common Name of Acid (ionized form in parentheses)	Abbreviation	Chemical Formula
<b>Saturated Fatty Acids</b>		
Myristic (myristate)	C14:0	$\text{CH}_3(\text{CH}_2)_{12}\text{COOH}$
Palmitic (palmitate)	C16:0	$\text{CH}_3(\text{CH}_2)_{14}\text{COOH}$
Stearic (stearate)	C18:0	$\text{CH}_3(\text{CH}_2)_{16}\text{COOH}$
<b>Unsaturated Fatty Acids</b>		
Oleic (oleate)	C18:1	$\text{CH}_3(\text{CH}_2)_7\text{CH}=\text{CH}(\text{CH}_2)_7\text{COOH}$
Linoleic (linoleate)	C18:2	$\text{CH}_3(\text{CH}_2)_4\text{CH}=\text{CHCH}_2\text{CH}=\text{CH}(\text{CH}_2)_7\text{COOH}$
Arachidonic (arachidonate)	C20:4	$\text{CH}_3(\text{CH}_2)_4(\text{CH}=\text{CHCH}_2)_3\text{CH}=\text{CH}(\text{CH}_2)_3\text{COOH}$

**TABLE 2-5 Common Phosphoglycerides and Head Groups**

Common Phosphoglycerides	Head Group
Phosphatidylcholine	 <p><b>Choline</b></p>
Phosphatidylethanolamine	 <p><b>Ethanolamine</b></p>
Phosphatidylserine	 <p><b>Serine</b></p>
Phosphatidylinositol	 <p><b>Inositol</b></p>

They also can be covalently attached to the very hydrophobic molecule cholesterol, an alcohol, to form cholesteryl esters:

Triglycerides and cholesteryl esters are extremely water-insoluble molecules in which fatty acids and cholesterol are either stored or transported. Triglycerides are the storage form of fatty acids in the fat cells of adipose tissue and are the principal components of dietary fats. Cholesteryl esters and triglycerides are transported between tissues through the bloodstream in specialized carriers called lipoproteins (see Chapter 14).

We saw above that the fatty acids, which are key components of both phospholipids and triglycerides, can be either saturated or unsaturated. An important consequence of the carbon-carbon double bond ( $C=C$ ) in an unsaturated fatty acid is that two stereoisomeric configurations, *cis* and *trans*, are possible around each of these bonds:

A *cis* double bond introduces a rigid kink in the otherwise flexible straight acyl chain of a saturated fatty acid (Figure 2-21). In general, the unsaturated fatty acids in biological systems contain only *cis* double bonds. Saturated fatty acids without the kink can pack together tightly and so have higher melting points than unsaturated fatty acids. The main fatty molecules in butter are triglycerides with saturated fatty acyl chains, which is why butter is usually solid at room temperature. Unsaturated fatty acids or fatty acyl chains with the *cis* double bond kink cannot pack as closely together as saturated fatty acyl chains. Thus vegetable oils, composed of triglycerides with unsaturated fatty acyl groups, usually are liquid at room temperature. Vegetable and similar oils may be partially hydrogenated to convert some of their unsaturated fatty acyl chains to saturated fatty acyl chains. As a consequence, the hydrogenated vegetable oil can be molded into solid sticks of margarine. A by-product of the hydrogenation reaction is the conversion of some of the fatty acyl chains into *trans* fatty acids, popularly called “*trans* fats.” These “*trans* fats,” found in partially hydrogenated margarine and other food products, are not natural. Saturated and *trans* fatty acids have similar physical properties; for example, they tend to be solids at room temperature. Their consumption, relative to the consumption of unsaturated fats, is associated with increased plasma cholesterol levels and is discouraged by some nutritionists. ■

**FIGURE 2-21 The effect of a double bond on the shape of fatty acids.** Shown are chemical structures of the ionized form of palmitic acid, a saturated fatty acid with 16 C atoms, and oleic acid,

an unsaturated one with 18 C atoms. In saturated fatty acids, the hydrocarbon chain is often linear; the *cis* double bond in oleate creates a rigid kink in the hydrocarbon chain.

## KEY CONCEPTS OF SECTION 2.2

### Chemical Building Blocks of Cells

- Macromolecules are polymers of monomer subunits linked together by covalent bonds via dehydration reactions. Three major types of macromolecules are found in cells: proteins, composed of amino acids linked by peptide bonds; nucleic acids, composed of nucleotides linked by phosphodiester bonds; and polysaccharides, composed of monosaccharides (sugars) linked by glycosidic bonds (see Figure 2-13). Phospholipids, the fourth major chemical building block, assemble noncovalently into biomembranes.

- Differences in the size, shape, charge, hydrophobicity, and reactivity of the side chains of the 20 common amino acids determine the chemical and structural properties of proteins (see Figure 2-14). The three general categories into which the side chains fall are hydrophobic, hydrophilic (basic, acidic, polar), and special (see Figure 2-14). It is helpful to remember which amino acids fall into each of these categories.

- The bases in the nucleotides composing DNA and RNA are carbon- and nitrogen-containing rings attached to a pentose sugar. They form two groups: the purines, with two rings—adenine (A) and guanine (G)—and the pyrimidines, with one ring—cytosine (C), thymine (T), and uracil (U) (see Figure 2-17). A, G, T, and C are found in DNA, and A, G, U, and C are found in RNA.

- Glucose and other hexoses can exist in three forms: an open-chain linear structure, a six-member (pyranose) ring, and a five-member (furanose) ring (see Figure 2-18). In biological systems, the pyranose form of D-glucose predominates.

- Glycosidic bonds are formed between either the  $\alpha$  or the  $\beta$  anomer of one sugar and a hydroxyl group on another

sugar, leading to formation of disaccharides and other polysaccharides (see Figure 2-19).

- Phospholipids are amphipathic molecules with a hydrophobic tail (often two fatty acyl chains) connected by a small organic molecule (often glycerol) to a hydrophilic head (see Figure 2-20).

- The long hydrocarbon chain of a fatty acid may be saturated (containing no carbon-carbon double bonds) or unsaturated (containing one or more double bonds). Fatty substances such as butter that have primarily saturated fatty acyl chains tend to be solid at room temperature, whereas unsaturated fats with *cis* double bonds have kinked chains that cannot pack closely together and so tend to be liquids at room temperature.

## 2.3 Chemical Reactions and Chemical Equilibrium

We now shift our discussion to chemical reactions in which bonds, primarily covalent bonds in *reactant* chemicals, are broken and new bonds are formed to generate reaction *products*. At any one time, several hundred different kinds of chemical reactions are occurring simultaneously in every cell, and many chemicals can, in principle, undergo multiple chemical reactions. Both the *extent* to which reactions can proceed and the *rate* at which they take place determine the chemical composition of cells. In this section, we discuss the concepts of equilibrium and steady state as well as dissociation constants and pH. These concepts will arise again and again throughout this text, so it is important for you to be familiar with them. In Section 2.4, we discuss how energy influences the extents and rates of chemical reactions.

## A Chemical Reaction Is in Equilibrium When the Rates of the Forward and Reverse Reactions Are Equal

When reactants first mix together—before any products have been formed—the rate of the forward reaction to form products is determined in part by the reactants' initial concentrations, which determine the likelihood of reactants bumping into one another and reacting (Figure 2-22). As the reaction products accumulate, the concentration of each reactant decreases, and so does the forward reaction rate. Meanwhile, some of the product molecules begin to participate in the reverse reaction, which re-forms the reactants. The ability of a reaction to go “backward” is called *microscopic reversibility*. The reverse reaction is slow at first but speeds up as the concentration of product increases. Eventually, the rates of the forward and reverse reactions become equal, so that the concentrations of reactants and products stop changing. The system is then said to be in **chemical equilibrium** (plural, *equilibria*).

The ratio of the concentrations of the products to the concentrations of the reactants when they reach equilibrium, called the **equilibrium constant** ( $K_{eq}$ ), is a fixed value. Thus  $K_{eq}$  provides a measure of the extent to which a reaction occurs by the time it reaches equilibrium. The rate of a chemical reaction can be increased by a **catalyst**, but a catalyst does not change the equilibrium constant (see Section 2.4). A catalyst accelerates the making and breaking of covalent bonds but itself is not permanently changed during a reaction.

**FIGURE 2-22 Time dependence of the rates of a chemical reaction.** The forward and reverse rates of a reaction depend in part on the initial concentrations of reactants and products. The net forward reaction rate slows as the concentration of reactants decreases, whereas the net reverse reaction rate increases as the concentration of products increases. At equilibrium, the rates of the forward and reverse reactions are equal, and the concentrations of reactants and products remain constant.

## The Equilibrium Constant Reflects the Extent of a Chemical Reaction

For any chemical reaction,  $K_{eq}$  depends on the chemical nature of the reactants and products, the temperature, and the pressure (particularly in reactions involving gases). Under standard physical conditions (25 °C and 1 atm pressure for biological systems),  $K_{eq}$  is always the same for a given reaction, whether or not a catalyst is present.

For the general reaction with three reactants and three products,

where capital letters represent particular molecules or atoms and lowercase letters represent the number of each in the reaction, the formula for the equilibrium constant is given by

$$K_{eq} = \frac{[X]^x[Y]^y[Z]^z}{[A]^a[B]^b[C]^c} \quad (2-2)$$

where brackets denote the concentrations of the molecules. In Equation 2-2, the concentrations of reactants and products are those present at equilibrium. The rate of the forward reaction (left to right in Equation 2-1) is

$$\text{Rate}_{\text{forward}} = k_f[A]^a[B]^b[C]^c$$

where  $k_f$  is the **rate constant** for the forward reaction. Similarly, the rate of the reverse reaction (right to left in Equation 2-1) is

$$\text{Rate}_{\text{reverse}} = k_r[X]^x[Y]^y[Z]^z$$

where  $k_r$  is the rate constant for the reverse reaction. These reaction rate equations apply whether or not the reaction has reached equilibrium. It is important to remember that the forward and reverse rates of a reaction can change because of changes in reactant or product concentrations, yet at the same time the forward and reverse rate *constants* do not change; hence the name “constant.” Confusing rates and rate constants is a common error. At equilibrium the forward and reverse rates are equal, so  $\text{Rate}_{\text{forward}}/\text{Rate}_{\text{reverse}} = 1$ . By rearranging these equations, we can express the equilibrium constant as the ratio of the rate constants:

$$K_{eq} = \frac{k_f}{k_r} \quad (2-3)$$

The concept of  $K_{eq}$  is particularly helpful when we want to think about the energy that is released or absorbed when a chemical reaction occurs. We will discuss this concept in considerable detail in Section 2.4.

## Chemical Reactions in Cells Are at Steady State

Under appropriate conditions and given sufficient time, a single biochemical reaction carried out in a test tube eventually reaches equilibrium, at which the concentrations of reactants and products do not change with time because the

(a) Test tube equilibrium concentrations

(b) Intracellular steady-state concentrations

**FIGURE 2-23 Comparison of reactions at equilibrium and at steady state.** (a) In the test tube, a biochemical reaction ( $A \rightarrow B$ ) eventually reaches equilibrium, at which the rates of the forward and reverse reactions are equal (as indicated by the reaction arrows of equal length). (b) In metabolic pathways within cells, the product B is commonly consumed—in this example, by conversion to C. A pathway of linked reactions is at steady state when the rate of formation of the intermediates (e.g., B) equals their rate of consumption. As indicated by the unequal length of the arrows, the individual reversible reactions constituting a metabolic pathway do not reach equilibrium. Moreover, the concentrations of the intermediates at steady state can differ from what they would be at equilibrium.

rates of the forward and reverse reactions are equal. Within cells, however, many reactions are linked in pathways in which a product of one reaction is not simply reconverted via a reverse reaction to the reactants. For example, the product of one reaction might serve as a reactant in another, or it might be pumped out of the cell. In this more complex situation, the original reaction can never reach equilibrium because some of the products do not have a chance to be converted back to reactants. Nevertheless, in such non-equilibrium conditions, the rate of formation of a substance can be equal to the rate of its consumption, and as a consequence, the concentration of the substance remains constant over time. In such circumstances, the system of linked reactions for producing and consuming that substance is said to be in a **steady state** (Figure 2-23). One consequence of such linked reactions is that they prevent the accumulation of excess intermediates, protecting cells from the harmful effects of intermediates that are toxic at high concentrations. When the concentration of a product of an ongoing reaction is not changing over time, it might be a consequence of a state of equilibrium, or it might be a consequence of a steady state. In biological systems, when metabolite concentrations, such as blood glucose levels, are not changing with time—a condition called *homeostasis*—it is a consequence of a steady state rather than equilibrium.

## Dissociation Constants of Binding Reactions Reflect the Affinity of Interacting Molecules

The concept of equilibrium also applies to the binding of one molecule to another without covalent changes to either molecule. Many important cellular processes depend on such binding “reactions,” which involve the making and breaking of various noncovalent interactions rather than covalent bonds, as discussed above. A common example is the binding

of a **ligand** (e.g., the hormone insulin or adrenaline) to its **receptor** on the surface of a cell, which triggers an intracellular signaling pathway (see Chapter 15). Another example is the binding of a protein to a specific sequence of bases in a molecule of DNA, which frequently causes the expression of a nearby gene to increase or decrease (see Chapter 9). If the equilibrium constant for a binding reaction is known, the stability of the resulting complex can be predicted.

To illustrate the general approach for determining the concentration of noncovalently associated complexes, let’s calculate the extent to which a protein (P) is bound to DNA (D), forming a protein-DNA complex (PD):

Most commonly, binding reactions are described in terms of the **dissociation constant** ( $K_d$ ), which is the reciprocal of the equilibrium constant. For this binding reaction, the dissociation constant is calculated from the concentrations of the three components when they are at equilibrium by

$$K_d = \frac{[P][D]}{[PD]} \quad (2-4)$$

It is worth noting that in such a binding reaction, when half of the DNA is bound to the protein ( $[PD] = [D]$ ), the concentration of P is equal to  $K_d$ . The lower the  $K_d$ , the lower the concentration of P needed to bind to half of D. In other words, the lower the  $K_d$ , the tighter the binding (the higher the affinity) of P for D.

Typically, a protein’s binding to a specific DNA sequence exhibits a  $K_d$  of  $10^{-10}$  M, where M symbolizes molarity, or moles per liter (mol/L). To relate the magnitude of this dissociation constant to the intracellular ratio of bound to unbound DNA, let’s consider the simple example of a bacterial cell having a volume of  $1.5 \times 10^{-15}$  L and containing 1 molecule of DNA and 10 molecules of the DNA-binding protein P. In this case, given a  $K_d$  of  $10^{-10}$  M and the total concentration of the P in the cell ( $\sim 111 \times 10^{-10}$  M, about a hundredfold higher than the  $K_d$ ), 99 percent of the time this specific DNA sequence will have a molecule of protein bound to it and 1 percent of the time it will not, even though the cell contains only 10 molecules of the protein! Clearly P and D have a high affinity for each other and bind tightly, as reflected by the low value of the dissociation constant for their binding reaction. For protein-protein and protein-DNA binding,  $K_d$  values of  $\sim 10^{-9}$  M (nanomolar) are considered to be tight,  $\sim 10^{-6}$  M (micromolar) modestly tight, and  $\sim 10^{-3}$  M (millimolar) relatively weak.

A large biological macromolecule, such as a protein, can have multiple binding surfaces for binding several molecules simultaneously (Figure 2-24). In some cases, these binding reactions are independent, with their own distinct  $K_d$  values that are independent of each other. In other cases, binding of a molecule at one site on a macromolecule can change the three-dimensional shape, or conformation, of a distant site, thus altering the binding interactions of that distant site with some other molecule. The modifications

**FIGURE 2-24 Macromolecules can have distinct binding sites for multiple ligands.** A large macromolecule (e.g., a protein, blue) with three distinct binding sites (A–C) is shown; each of the three binding sites exhibit molecular complementarity to three different binding partners (ligands A–C) with distinct dissociation constants ( $K_{dA-C}$ ).

of amino acid side chains—mentioned above—often contribute to the molecular shapes required for such binding interactions. These covalent and noncovalent binding reactions are important mechanisms by which one molecule can alter, and thus regulate, the structure and binding activity of another. We examine this regulatory mechanism in more detail in Chapter 3.

## Biological Fluids Have Characteristic pH Values

The solvent inside cells and in all extracellular fluids is water. An important characteristic of any aqueous solution is the concentration of positively charged hydrogen ions ( $H^+$ ) and negatively charged hydroxyl ions ( $OH^-$ ). Because these ions are the dissociation products of  $H_2O$ , they are constituents of all living systems, and they are liberated by many reactions that take place between molecules within cells. These ions can also be transported into or out of cells, as when highly acidic gastric juice is secreted by cells lining the walls of the stomach.

When a water molecule dissociates, one of its polar  $H-O$  bonds breaks. The resulting hydrogen ion, referred to as a *proton*, has a short lifetime as a free ion and quickly combines with a water molecule to form a hydronium ion ( $H_3O^+$ ). For convenience, we refer to the concentration of hydrogen ions in a solution,  $[H^+]$ , even though this quantity really represents the concentration of hydronium ions,  $[H_3O^+]$ . Dissociation of  $H_2O$  generates one  $OH^-$  ion along with each  $H^+$ . The dissociation of water is a reversible reaction:

At 25 °C,  $[H^+][OH^-] = 10^{-14} M^2$ , so that in pure water,  $[H^+] = [OH^-] = 10^{-7} M$ .

The concentration of hydrogen ions in a solution is expressed conventionally as its **pH**, defined as the negative log of the hydrogen ion concentration. The pH of pure water at 25 °C is 7:

$$pH = -\log[H^+] = \log \frac{1}{[H^+]} = \log \frac{1}{10^{-7}} = 7$$

It is important to keep in mind that a one-unit difference in pH represents a tenfold difference in the concentration of protons. On the pH scale, 7.0 is considered neutral: pH values below 7.0 indicate acidic solutions (higher  $[H^+]$ ), and values above 7.0 indicate basic, or alkaline, solutions (Figure 2-25). For instance, gastric juice, which is rich in hydrochloric acid (HCl), has a pH of about 1. Its  $[H^+]$  is roughly 1-million-fold greater than that of cytoplasm, which has a pH of about 7.2–7.4.

Although the cytosol of cells normally has a pH of about 7.2, the interior of certain organelles in eukaryotic cells (see Chapter 1) can have a much lower pH. The internal (luminal) fluid in lysosomes, for example, has a pH of about 4.5.

**FIGURE 2-25 Some pH values for common solutions.** The pH of an aqueous solution is the negative log of the hydrogen ion concentration. The pH values for most intracellular and extracellular biological fluids are near 7 and are carefully regulated to permit the proper functioning of cells, organelles, and cellular secretions. The pH values for solutions of ammonia and hydrochloric acid are for one normal (1 N) solutions.

The many degradative enzymes within lysosomes function optimally in an acidic environment, whereas their action is inhibited in the near neutral pH environment of the cytoplasm. As this example illustrates, maintenance of a particular pH is essential for the proper functioning of some cellular structures. On the other hand, dramatic shifts in cellular pH may play an important role in controlling cellular activity. For example, the pH of the cytoplasm of an unfertilized egg of the sea urchin, an aquatic animal, is 6.6. Within 1 minute of fertilization, however, the pH rises to 7.2; that is, the  $[H^+]$  decreases to about one-fourth its original value, a change that is necessary for subsequent growth and division of the egg.

## Hydrogen Ions Are Released by Acids and Taken Up by Bases

In general, an **acid** is any molecule, ion, or chemical group that tends to release a hydrogen ion ( $H^+$ ), such as the carboxyl group ( $-COOH$ ), which tends to dissociate to form the negatively charged carboxylate ion ( $-COO^-$ ); or hydrochloric acid ( $HCl$ ). Conversely, a **base** is any molecule, ion, or chemical group that readily combines with an  $H^+$ , such as the hydroxyl ion ( $OH^-$ ); ammonia ( $NH_3$ ), which forms an ammonium ion ( $NH_4^+$ ); or the amino group ( $-NH_2$ ).

When an acid is added to an aqueous solution, the  $[H^+]$  increases, and the pH goes down. Conversely, when a base is added to a solution, the  $[H^+]$  decreases, and the pH goes up. Because  $[H^+][OH^-] = 10^{-14} M^2$ , any increase in  $[H^+]$  is coupled with a commensurate decrease in  $[OH^-]$ , and vice versa.

Many biological molecules contain both acidic and basic groups. For example, in neutral solutions ( $pH = 7.0$ ), many amino acids exist predominantly in the doubly ionized form, in which the carboxyl group has lost a proton and the amino group has accepted one:

where R represents the uncharged side chain. Such a molecule, containing an equal number of positive and negative ions, is called a *zwitterion*. Zwitterions, having no net charge, are neutral. At extreme pH values, only one of these two ionizable groups of an amino acid is charged: the  $-NH_2^+$  at low pH and the  $-COO^-$  at high pH.

The dissociation reaction for an acid (or acid group in a larger molecule) HA can be written as  $HA \rightleftharpoons H^+ + A^-$ . The equilibrium constant for this reaction, denoted  $K_a$  (the subscript *a* stands for “acid”), is defined as  $K_a = [H^+][A^-]/[HA]$ . Taking the logarithm of both sides and rearranging the result yields a very useful relation between the equilibrium constant and pH:

$$pH = pK_a + \log \frac{[A^-]}{[HA]} \quad (2-5)$$

where  $pK_a$  equals  $-\log K_a$ .

**FIGURE 2-26** The relationship between pH,  $pK_a$ , and the dissociation of an acid. As the pH of a solution of carbonic acid rises from 0 to 8.5, the percentage of the compound in the undissociated, or un-ionized, form ( $H_2CO_3$ ) decreases from 100 percent and that of the ionized form increases from 0 percent. When the pH (6.4) is equal to the acid's  $pK_a$ , half of the carbonic acid has ionized. When the pH rises to above 8, virtually all of the acid has ionized to the bicarbonate form ( $HCO_3^-$ ).

From this expression, commonly known as the *Henderson-Hasselbalch equation*, it can be seen that the  $pK_a$  of any acid is equal to the pH at which half the molecules are dissociated and half are neutral (undissociated). This is because when  $[A^-] = [HA]$ , then  $\log([A^-]/[HA]) = 0$ , and thus  $pK_a = pH$ . The Henderson-Hasselbalch equation allows us to calculate the degree of dissociation of an acid—that is, the ratio of dissociated and undissociated forms—if both the pH of the solution and the  $pK_a$  of the acid are known. Experimentally, by measuring the  $[A^-]$  and  $[HA]$  as a function of the solution's pH, one can calculate the  $pK_a$  of the acid and thus the equilibrium constant  $K_a$  for the dissociation reaction (Figure 2-26). Knowing the  $pK_a$  of a molecule not only provides an important description of its properties, but also allows us to exploit these properties to manipulate the acidity of an aqueous solution and to understand how biological systems control this critical characteristic of their aqueous fluids.

## Buffers Maintain the pH of Intracellular and Extracellular Fluids

A living, actively metabolizing cell must maintain a constant pH in the cytoplasm of about 7.2–7.4, and it must do so even as its metabolism is producing many acids. Cells have a reservoir of weak bases and weak acids, called **buffers**, which ensure that the cell's cytoplasmic pH remains relatively constant despite small fluctuations in the amounts of  $H^+$  or  $OH^-$  being generated by metabolism or by the uptake or secretion of molecules and ions by the cell. Buffers do this by “soaking up” excess  $H^+$  or  $OH^-$  when these ions are added to the cell or are produced by metabolism. As we shall see below, buffers are most effective at preventing changes in pH when the pH of the solution is similar to the  $pK_a$  of the buffer.

**FIGURE 2-27 The titration curve of the buffer acetic acid ( $\text{CH}_3\text{COOH}$ ).** The  $\text{pK}_a$  for the dissociation of acetic acid to hydrogen and acetate ions is 4.75. At this pH, half the acid molecules are dissociated. Because pH is measured on a logarithmic scale, the solution changes from 91 percent  $\text{CH}_3\text{COOH}$  at pH 3.75 to 9 percent  $\text{CH}_3\text{COOH}$  at pH 5.75. The acid has maximum buffering capacity in this pH range.

If additional acid (or base) is added to a buffered solution whose pH is equal to the  $\text{pK}_a$  of the buffer ( $[\text{HA}] = [\text{A}^-]$ ), the pH of the solution changes, but it changes less than it would if the buffer had not been present. This is because protons released by the added acid are taken up by the ionized form of the buffer ( $\text{A}^-$ ); likewise, hydroxyl ions generated by the addition of a base are neutralized by protons released by the undissociated buffer ( $\text{HA}$ ). The capacity of a buffer or any other substance to release hydrogen ions or take them up depends partly on the extent to which the substance has already taken up or released protons, which in turn depends on the pH of the solution relative to the  $\text{pK}_a$  of the substance. The ability of a buffer to minimize changes in pH, its *buffering capacity*, depends on the concentration of the buffer and the relationship between its  $\text{pK}_a$  value and the pH, which is expressed by the Henderson-Hasselbalch equation.

The titration curve for acetic acid shown in Figure 2-27 illustrates the effect of pH on the fraction of molecules in the un-ionized ( $\text{HA}$ ) and ionized forms ( $\text{A}^-$ ). When the pH is equal to the  $\text{pK}_a$ , half of the acetic acid is dissociated (dashed lines). At one pH unit below the  $\text{pK}_a$  of an acid, 91 percent of the molecules are in the  $\text{HA}$  form; at one pH unit above the  $\text{pK}_a$ , 91 percent are in the  $\text{A}^-$  form. At pH values more than one unit above or below the  $\text{pK}_a$  (unshaded regions in Figure 2-27), the buffering capacity of weak acids and bases declines rapidly. In other words, the addition of the same number of moles of base—for example, hydroxyl ions added as sodium hydroxide ( $\text{NaOH}$ )—to a solution containing a

mixture of  $\text{HA}$  and  $\text{A}^-$  that is at a pH near the  $\text{pK}_a$  will cause less of a pH change than it would if the  $\text{HA}$  and  $\text{A}^-$  were not present or if the pH were far from the  $\text{pK}_a$  value.

All biological systems contain one or more buffers. Phosphate ions, the ionized forms of phosphoric acid, are present in considerable quantities in cells and are important in maintaining, or buffering, the pH of the cytoplasm. Phosphoric acid ( $\text{H}_3\text{PO}_4$ ) has three protons that are capable of dissociating, but they do not dissociate simultaneously. Loss of each proton can be described by a discrete dissociation reaction and  $\text{pK}_a$ , as shown in Figure 2-28. When hydroxyl ions are added to a solution of phosphoric acid, the pH change is much less steep at pH values near the three  $\text{pK}_a$  values (shaded region) than when the pH of the solution is not similar to any of the  $\text{pK}_a$ s. The titration curve for phosphoric acid shows that the  $\text{pK}_a$  for the dissociation of the second proton is 7.2. Thus, at pH 7.2, about 50 percent of cellular phosphate is  $\text{H}_2\text{PO}_4^-$  and about 50 percent is  $\text{HPO}_4^{2-}$  according to the Henderson-Hasselbalch equation. For this reason, phosphate is an excellent buffer at pH values around 7.2, the approximate pH of the cytoplasm of cells, and at pH 7.4, the pH of human blood. The amino (lysine), guanidinium (arginine), and carboxylate (aspartate, glutamate) portions of amino acid side chains of proteins as well as the amino and carboxylate groups at the N- and C-termini of proteins can also bind and release protons. Thus proteins that are present in high concentrations inside of cells and in many extracellular fluids can themselves serve as buffers.

**FIGURE 2-28 The titration curve of phosphoric acid ( $\text{H}_3\text{PO}_4$ ), a common buffer in biological systems.** This biologically ubiquitous molecule has three hydrogen atoms that dissociate at different pH values; thus phosphoric acid has three  $\text{pK}_a$  values, as noted on the graph. The shaded areas denote the pH ranges—within one pH unit of the three  $\text{pK}_a$  values—where the buffering capacity of phosphoric acid is high. In these regions, the addition of an acid (or base) will cause relatively small changes in the pH.

## KEY CONCEPTS OF SECTION 2.3

### Chemical Reactions and Chemical Equilibrium

- A chemical reaction is at equilibrium when the rate of the forward reaction is equal to the rate of the reverse reaction, and thus there is no net change in the concentration of the reactants or products.
- The equilibrium constant  $K_{eq}$  of a reaction reflects the ratio of products to reactants at equilibrium and thus is a measure of the extent of the reaction and the relative stabilities of the reactants and products.
- The  $K_{eq}$  depends on the temperature, pressure, and chemical properties of the reactants and products but is independent of the reaction rate and of the initial concentrations of reactants and products.
- For any reaction, the equilibrium constant  $K_{eq}$  equals the ratio of the forward rate constant to the reverse rate constant ( $k_f/k_r$ ). The rates of conversion of reactants to products and vice versa depend on the rate constants and the concentrations of the reactants or products.
- Within cells, the linked reactions in metabolic pathways generally are not at equilibrium, but rather at steady state, at which the rate of formation of the intermediates equals their rate of consumption (see Figure 2-23) and thus the concentrations of the intermediates are not changing.
- The dissociation constant  $K_d$  for the noncovalent binding of two molecules is a measure of the stability of the complex formed between the molecules (e.g., ligand-receptor or protein-DNA complexes).  $K_d$  values of  $\sim 10^{-9}$  M (nanomolar) are considered to be tight,  $\sim 10^{-6}$  M (micromolar) modestly tight, and  $\sim 10^{-3}$  M (millimolar) relatively weak.
- The pH is the negative logarithm of the concentration of hydrogen ions ( $-\log [H^+]$ ). The pH of the cytoplasm is normally about 7.2–7.4, whereas the interior of lysosomes has a pH of about 4.5.
- Acids release protons ( $H^+$ ), and bases bind them.
- Buffers are mixtures of a weak acid (HA) and its corresponding base form ( $A^-$ ), which minimize the change in pH of a solution when an acid or base is added. Biological systems use various buffers to maintain their pH within a very narrow range.

## 2.4 Biochemical Energetics

The transformation of energy, its storage, and its use are central to the economy of the cell. Energy may be defined as the ability to do work, a concept that is as applicable to cells as to automobile engines and electric power plants. The energy stored within chemical bonds can be harnessed to support chemical work and the physical movements of cells.

In this section, we review how energy influences the extents of chemical reactions (chemical thermodynamics) and the rates of chemical reactions (chemical kinetics).

### Several Forms of Energy Are Important in Biological Systems

There are two principal forms of energy: kinetic and potential. **Kinetic energy** is the energy of movement—the motion of molecules, for example. **Potential energy** is stored energy—the energy stored in covalent bonds, for example. Potential energy plays a particularly important role in the energy economy of cells.

*Thermal energy*, or heat, is a form of kinetic energy—the energy of the motion of molecules. For heat to do work, it must flow from a region of higher temperature—where the average speed of molecular motion is greater—to one of lower temperature. Although differences in temperature can exist between the internal and external environments of cells, these thermal gradients do not usually serve as the source of energy for cellular activities. The thermal energy in warm-blooded animals, which have evolved a mechanism for thermoregulation, is used chiefly to maintain constant organismal temperatures. This is an important homeostatic function because the rates of many cellular activities are temperature dependent. For example, cooling mammalian cells from their normal body temperature of 37 °C to 4 °C can virtually “freeze” or stop many cellular processes (e.g., intracellular membrane movements).

*Radiant energy*, the kinetic energy of photons, or waves of light, is critical to biology. Radiant energy can be converted to thermal energy, for instance, when light is absorbed by molecules and the energy is converted to molecular motion. Radiant energy absorbed by molecules can also change the electronic structure of the molecules by moving electrons into higher-energy orbitals, whence it can later be recovered to perform work. For example, during photosynthesis, light energy absorbed by pigment molecules such as chlorophyll is subsequently converted into the energy of chemical bonds (see Chapter 12).

*Mechanical energy*, a major form of kinetic energy in biology, usually results from the conversion of stored chemical energy. For example, changes in the lengths of cytoskeletal filaments generate forces that push or pull on membranes and organelles (see Chapters 17 and 18).

*Electric energy*—the energy of moving electrons or other charged particles—is yet another major form of kinetic energy, one with particular importance to membrane function, as in electrically active neurons (see Chapter 22).

Several forms of potential energy are biologically significant. Central to biology is **chemical potential energy**, the energy stored in the bonds connecting atoms in molecules. Indeed, most of the biochemical reactions described in this book involve the making or breaking of at least one covalent chemical bond. In general, energy must be expended to make covalent bonds in typical biomolecules, and energy is released when those bonds are broken. For example, the

high potential energy in the covalent bonds of glucose can be released by controlled enzymatic combustion in cells (see Chapter 12). This energy is harnessed by the cell to do many kinds of work.

A second biologically important form of potential energy is the energy in a **concentration gradient**. When the concentration of a substance on one side of a barrier, such as a membrane, is different from that on the other side, a concentration gradient exists. All cells form concentration gradients between their interior and the external fluids by selectively exchanging nutrients, waste products, and ions with their surroundings. Furthermore, the fluids within organelles in cells (e.g., mitochondria, lysosomes) frequently contain different concentrations of ions and other molecules than the cytoplasm; the concentration of protons within a lysosome, as we saw in the last section, is about 500 times that in the cytoplasm. Concentration gradients of protons across membranes are an important driver of energy production in mitochondria.

A third form of potential energy in cells is an **electric potential**—the energy of charge separation. For instance, there is a gradient of electric charge of about 200,000 volts per centimeter across the plasma membranes of virtually all cells. We discuss how concentration gradients and electric potential gradients are generated and maintained in Chapter 11 and how they are converted to chemical potential energy in Chapter 12.

## Cells Can Transform One Type of Energy into Another

According to the first law of thermodynamics, energy is neither created nor destroyed, but can be converted from one form to another. (In nuclear reactions, mass is converted to energy, but this is irrelevant in biological systems.) Energy conversions are very important in biology. In photosynthesis, for example, the radiant energy of light is transformed into the chemical potential energy of the covalent bonds between the atoms in a sucrose or starch molecule. In muscles and nerves, chemical potential energy stored in covalent bonds is transformed, respectively, into the kinetic energy of muscle contraction and the electric energy of neural transmission. In all cells, potential energy—released by breaking certain chemical bonds—is used to generate potential energy in the form of concentration and electric potential gradients. Similarly, energy stored in chemical concentration gradients or electric potential gradients is used to synthesize chemical bonds or to transport molecules from one side of a membrane to another to generate a concentration gradient. The latter process occurs during the transport of nutrients such as glucose into certain cells and the transport of many waste products out of cells.

Because all forms of energy are interconvertible, they can be expressed in the same units of measurement. Although the standard unit of energy is the joule, biochemists have traditionally used an alternative unit, the *calorie* (1 joule = 0.239 calorie). A calorie is the amount of energy required

to raise the temperature of one gram of water by 1 °C. Throughout this book, we use the *kilocalorie* to measure energy changes (1 kcal = 1000 cal). When you read or hear about the “Calories” in food (note the capital C), the reference is almost always to kilocalories as defined here.

## The Change in Free Energy Determines If a Chemical Reaction Will Occur Spontaneously

Chemical reactions can be divided into two types, depending on whether energy is absorbed or released in the process. In an **exergonic** (“energy-releasing”) reaction, the products contain less energy than the reactants. Exergonic reactions take place spontaneously. The liberated energy is usually released as heat (the energy of molecular motion) and generally results in a rise in temperature, as in the oxidation (burning) of wood. In an **endergonic** (“energy-absorbing”) reaction, the products contain more energy than the reactants, and energy is absorbed during the reaction. If there is no external source of energy to drive an endergonic reaction, it cannot take place. Endergonic reactions are responsible for the ability of the instant cold packs often used to treat injuries to rapidly cool below room temperature. Crushing the pack mixes the reactants, initiating the reaction.

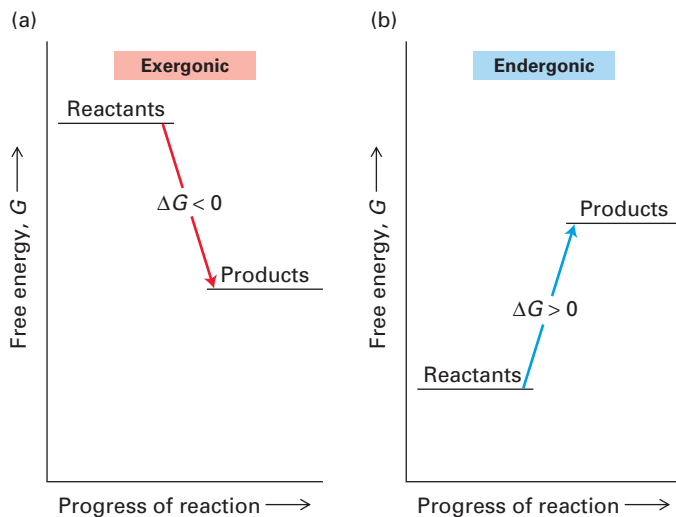

A fundamentally important concept in understanding if a reaction is exergonic or endergonic, and therefore if it occurs spontaneously or not, is **free energy** ( $G$ ), or *Gibbs free energy*, named after J. W. Gibbs. Gibbs, who received the first PhD in engineering in America in 1863, showed that “all systems change in such a way that free energy [ $G$ ] is minimized.” In other words, a chemical reaction occurs spontaneously when the free energy of the products is lower than the free energy of the reactants. In the case of a chemical reaction, reactants  $\rightleftharpoons$  products, the free-energy change,  $\Delta G$ , is given by

$$\Delta G = G_{\text{products}} - G_{\text{reactants}}$$

The relation of  $\Delta G$  to the direction of any chemical reaction can be summarized in three statements:

- If  $\Delta G$  is negative, the forward reaction will tend to occur spontaneously, and energy usually will be released as the reaction takes place (exergonic reaction) (Figure 2-29). A reaction with a negative  $\Delta G$  is referred to as thermodynamically favorable.
- If  $\Delta G$  is positive, the forward reaction will not occur spontaneously; energy will have to be added to the system in order to force the reactants to become products (endergonic reaction).
- If  $\Delta G$  is zero, both forward and reverse reactions will occur at equal rates, and there will be no spontaneous net conversion of reactants to products, or vice versa; the system is at equilibrium.

By convention, the *standard free-energy change* of a reaction ( $\Delta G^\circ$ ) is the value of the change in free energy at

**FIGURE 2-29** Changes in the free energy ( $\Delta G$ ) of exergonic and endergonic reactions. (a) In exergonic reactions, the free energy of the products is less than that of the reactants. Consequently, these reactions occur spontaneously, and energy is released as the reactions proceed. (b) In endergonic reactions, the free energy of the products is greater than that of the reactants, and these reactions do not occur spontaneously. An external source of energy must be supplied if the reactants are to be converted into products.

298 K (25 °C), 1 atm pressure, pH 7.0 (as in pure water), and initial concentrations of 1 M for all reactants and products except protons, which are kept at  $10^{-7}$  M (pH 7.0). Most biological reactions differ from these standard conditions, particularly in the concentrations of reactants, which are normally less than 1 M.

The free energy of a chemical system can be defined as  $G = H - TS$ , where  $H$  is the bond energy, or **enthalpy**, of the system;  $T$  is its temperature in degrees Kelvin (K); and  $S$  is the **entropy**, a measure of its randomness or disorder. According to the second law of thermodynamics, the natural tendency of any isolated system is to become more disordered—that is, for entropy to increase. A reaction can occur spontaneously only if the combined effects of changes in enthalpy and entropy lead to a lower  $\Delta G$ . That is, if temperature remains constant, a reaction proceeds spontaneously only if the free-energy change,  $\Delta G$ , in the following equation is negative:

$$\Delta G = \Delta H - T\Delta S \quad (2-6)$$

In an **exothermic** (“heat-releasing”) chemical reaction,  $\Delta H$  is negative. In an **endothermic** (“heat-absorbing”) reaction,  $\Delta H$  is positive. The combined effects of the changes in the enthalpy and entropy determine if the  $\Delta G$  for a reaction is positive or negative, and thus if the reaction occurs spontaneously. An exothermic reaction ( $\Delta H < 0$ ), in which entropy increases ( $\Delta S > 0$ ), occurs spontaneously ( $\Delta G < 0$ ). An endothermic reaction ( $\Delta H > 0$ ) will occur spontaneously

if  $\Delta S$  increases enough so that the  $T\Delta S$  term can overcome the positive  $\Delta H$ .

Many biological reactions lead to an increase in order and thus a decrease in entropy ( $\Delta S < 0$ ). An obvious example is the reaction that links amino acids to form a protein. A solution of protein molecules has a lower entropy than does a solution of the same amino acids unlinked because the free movement of any amino acid is more restricted (greater order) when it is bound into a long chain than when it is not. Thus, when cells synthesize polymers such as proteins from their constituent monomers, the polymerizing reaction will be spontaneous only if the cells can efficiently transfer energy to both generate the bonds that hold the monomers together and overcome the loss in entropy that accompanies polymerization. Often cells accomplish this feat by “coupling” such synthetic, entropy-lowering reactions with independent reactions that have a very highly negative  $\Delta G$ , such as the hydrolysis of nucleoside triphosphates (see below). In this way, cells can convert sources of energy in their environment into the highly organized structures and metabolic pathways that are essential for life.

The actual change in free energy during a reaction is influenced by temperature, pressure, and the initial concentrations of reactants and products, so it usually differs from the standard free-energy change  $\Delta G^\circ$ . Most biological reactions—like others that take place in aqueous solutions—are also affected by the pH of the solution. We can estimate free-energy changes for temperatures and initial concentrations that differ from the standard conditions by using the equation

$$\Delta G = \Delta G^\circ + RT \ln Q = \Delta G^\circ + RT \ln \frac{[\text{products}]}{[\text{reactants}]} \quad (2-7)$$

where  $R$  is the gas constant of 1.987 cal/(degree-mol),  $T$  is the temperature (in degrees Kelvin), and  $Q$  is the *initial* ratio of products to reactants. For a reaction  $A + B \rightleftharpoons C$ , in which two molecules combine to form a third,  $Q$  in Equation 2-7 equals  $[C]/[A][B]$ . In this case, an increase in the initial concentration of either  $[A]$  or  $[B]$  will result in a larger negative value for  $\Delta G$  and thus drive the reaction toward spontaneous formation of  $C$ .

Regardless of the  $\Delta G^\circ$  of a particular biochemical reaction, it will proceed spontaneously within cells only if  $\Delta G$  is negative given the intracellular concentrations of reactants and products. For example, the conversion of glyceraldehyde 3-phosphate (G3P) to dihydroxyacetone phosphate (DHAP), two intermediates in the breakdown of glucose,

has a  $\Delta G^\circ$  of  $-1840$  cal/mol. If the initial concentrations of G3P and DHAP are equal, then  $\Delta G = \Delta G^\circ$  because  $RT \ln = 0$ ; in this situation, the reversible reaction  $\text{G3P} \rightleftharpoons \text{DHAP}$  will proceed spontaneously in the direction of DHAP formation until equilibrium is reached. However, if the initial  $[\text{DHAP}]$  is 0.1 M and the initial  $[\text{G3P}]$  is 0.001 M, with

other conditions standard, then  $Q$  in Equation 2-7 equals  $0.1/0.001 = 100$ , giving a  $\Delta G$  of  $+887$  cal/mol. Under these conditions, the reaction will proceed in the direction of formation of G3P.

The  $\Delta G$  of a reaction is independent of the reaction rate. Indeed, under normal physiological conditions, few, if any, of the biochemical reactions needed to sustain life would occur without some mechanism for increasing reaction rates. As we describe below and in more detail in Chapter 3, the rates of reactions in biological systems are usually determined by the activity of **enzymes**, the protein catalysts that accelerate the formation of products from reactants without altering the value of  $\Delta G$ .

### The $\Delta G^\circ$ of a Reaction Can Be Calculated from Its $K_{eq}$

A chemical mixture at equilibrium is in a stable state of minimal free energy. For a system at equilibrium ( $\Delta G = 0$ ,  $Q = K_{eq}$ ) under standard conditions, we can write

$$\Delta G^\circ = -2.3RT \log K_{eq} = -1362 \log K_{eq} \quad (2-8)$$

(note the change to base 10 logarithms). Thus, if we determine the concentrations of reactants and products at equilibrium (i.e., the  $K_{eq}$ ), we can calculate the value of  $\Delta G^\circ$ . For example, the  $K_{eq}$  for the interconversion of glyceraldehyde 3-phosphate to dihydroxyacetone phosphate (G3P  $\rightleftharpoons$  DHAP) is 22.2 under standard conditions. Substituting this value into Equation 2-8, we can easily calculate the  $\Delta G^\circ$  for this reaction as  $-1840$  cal/mol.

By rearranging Equation 2-8 and taking the antilogarithm, we obtain

$$K_{eq} = 10^{-(\Delta G^\circ/2.3RT)} \quad (2-9)$$

From this expression, it is clear that if  $\Delta G^\circ$  is negative, the exponent will be positive, and hence  $K_{eq}$  will be greater than 1. Therefore, at equilibrium there will be more products than reactants; in other words, the formation of products from reactants is favored. Conversely, if  $\Delta G^\circ$  is positive, the exponent will be negative, and  $K_{eq}$  will be less than 1. The relationship between  $K_{eq}$  and  $\Delta G^\circ$  further emphasizes the influence of the relative free energies of reactants and products on the extent to which a reaction will occur spontaneously.

### The Rate of a Reaction Depends on the Activation Energy Necessary to Energize the Reactants into a Transition State

As a chemical reaction proceeds, reactants approach each other; some bonds begin to form while others begin to break. One way to think of the state of the molecules during this transition is that there are strains in the electronic configurations of the atoms and their bonds. The collection of atoms

moves from the relatively stable state of the reactants to this transient, intermediate, and higher-energy state during the course of the reaction (Figure 2-30). The state during a chemical reaction at which the system is at its highest energy level is called the **transition state**, and the collection of reactants in that state is called the **transition-state intermediate**. The energy needed to excite the reactants to this higher-energy state is called the **activation energy** of the reaction. The activation energy is usually represented by  $\Delta G^\ddagger$ , which is analogous to the representation of the change in Gibbs free energy ( $\Delta G$ ) already discussed. From the transition state, the collection of atoms can either release energy as the reaction products are formed or release energy as the atoms go “backward” and re-form the original reactants. The velocity ( $V$ ) at which products are generated from reactants during the reaction under a given set of conditions (temperature, pressure, reactant concentrations) will depend on the concentration of material in the transition state, which in turn will depend on the activation energy, and on the characteristic rate constant ( $\nu$ ) at which the material in the transition state is converted to products. The higher the activation energy, the lower the fraction of reactants that reach the transition state, and the slower the overall rate of the reaction. The relationship between the concentration of reactants,  $\nu$ , and  $V$  is

$$V = \nu [\text{reactants}] \times 10^{-(\Delta G^\ddagger/2.3RT)}$$

From this equation, we can see that lowering the activation energy—that is, decreasing the free energy of the transition

**FIGURE 2-30 Activation energy of uncatalyzed and catalyzed chemical reactions.** This hypothetical reaction pathway (blue) depicts the changes in free energy,  $G$ , as a reaction proceeds. A reaction will take place spontaneously if the free energy ( $G$ ) of the products is less than that of the reactants ( $\Delta G < 0$ ). However, all chemical reactions proceed through one (shown here) or more high-energy transition states, and the rate of a reaction is inversely proportional to the activation energy ( $\Delta G^\ddagger$ ), which is the difference in free energy between the reactants and the transition state. In a catalyzed reaction (red), the free energies of the reactants and products are unchanged, but the free energy of the transition state is lowered, thus increasing the velocity of the reaction.

state  $\Delta G^\ddagger$ —leads to an acceleration of the overall reaction rate  $V$ . A reduction in  $\Delta G^\ddagger$  of 1.36 kcal/mol leads to a ten-fold increase in the rate of the reaction, whereas a 2.72 kcal/mol reduction increases the rate a hundredfold. Thus relatively small changes in  $\Delta G^\ddagger$  can lead to large changes in the overall rate of the reaction.

Catalysts such as enzymes (discussed further in Chapter 3) accelerate reaction rates by lowering the relative energy of the transition state and thus the activation energy required to reach it (see Figure 2-30). The relative energies of reactants and products determine if a reaction is thermodynamically favorable (negative  $\Delta G$ ), whereas the activation energy determines how rapidly products form—that is, the reaction kinetics. Thermodynamically favorable reactions will not occur at appreciable rates if the activation energies are too high.

## Life Depends on the Coupling of Unfavorable Chemical Reactions with Energetically Favorable Ones

Many processes in cells are energetically unfavorable ( $\Delta G > 0$ ) and will not proceed spontaneously. Examples include the synthesis of DNA from nucleotides and the transport of a substance across the plasma membrane from a lower to a higher concentration. Cells can carry out an energy-requiring, or endergonic, reaction ( $\Delta G_1 > 0$ ) by coupling it to an energy-releasing, or exergonic, reaction ( $\Delta G_2 < 0$ ) if the sum of the two reactions has an overall net negative  $\Delta G$ .

Suppose, for example, that the reaction  $A \rightleftharpoons B + X$  has a  $\Delta G$  of +5 kcal/mol and that the reaction  $X \rightleftharpoons Y + Z$  has a  $\Delta G$  of −10 kcal/mol:

In the absence of the second reaction, there would be much more A than B at equilibrium. However, because the conversion of X to Y + Z is such a favorable reaction, it will pull the first process toward the formation of B and the consumption of A. Energetically unfavorable reactions in cells are often coupled to the energy-releasing hydrolysis of ATP.

## Hydrolysis of ATP Releases Substantial Free Energy and Drives Many Cellular Processes

In almost all organisms, the nucleoside triphosphate **adenosine triphosphate**, or **ATP** (Figure 2-31), is the most important molecule for capturing, transiently storing, and subsequently transferring energy to perform work (e.g., biosynthesis, mechanical motion). Commonly referred to as a cell's energy “currency,” ATP is a type of usable potential energy that cells can “spend” in order to power their activities. The storied history of ATP begins with its discovery in 1929, apparently simultaneously by Kurt Lohmann, who

**FIGURE 2-31 Hydrolysis of adenosine triphosphate (ATP).**

The two phosphoanhydride bonds (red) in ATP (*top*), which link the three phosphate groups, each have a  $\Delta G^\circ$  of about −7.3 kcal/mol for hydrolysis. Hydrolysis of the terminal phosphoanhydride bond by the addition of water results in the release of phosphate and generation of ADP. Hydrolysis of the phosphoanhydride bonds of ATP, especially the terminal one, is the source of energy that drives many energy-requiring reactions in biological systems.

was working with the great biochemist Otto Meyerhof in Germany and who published first, and by Cyrus Fiske and Yellapragada SubbaRow in the United States. Muscle contractions were shown to depend on ATP in the 1930s. The proposal that ATP is the main intermediary for the transfer of energy in cells is credited to Fritz Lipmann around 1941. Many Nobel Prizes have been awarded for the study of ATP and its role in cellular energy metabolism, and its importance in understanding molecular cell biology cannot be overstated.

The useful energy in an ATP molecule is contained in **phosphoanhydride bonds**, which are covalent bonds formed from the condensation of two molecules of phosphate by the loss of water:

As shown in Figure 2-31, an ATP molecule has two key phosphoanhydride (also called phosphodiester) bonds. Forming these bonds (represented here by the symbol  $\sim$ ) in ATP requires an input of energy. When these bonds are hydrolyzed, or broken by the addition of water, that energy is released. Hydrolysis of a phosphoanhydride bond in each of the following reactions has a highly negative  $\Delta G^{\circ'}$  of about  $-7.3$  kcal/mol:

$\text{P}_i$  stands for inorganic phosphate ( $\text{PO}_4^{3-}$ ) and  $\text{PP}_i$  for inorganic pyrophosphate, two phosphate groups linked by a phosphoanhydride bond. As the top two reactions show, the removal of a phosphate group from ATP leaves adenosine diphosphate (ADP), and the removal of a pyrophosphate group from ATP leaves adenosine monophosphate (AMP).

A phosphoanhydride bond or other “high-energy bond” (commonly denoted by  $\sim$ ) is not intrinsically different from other covalent bonds. High-energy bonds simply release substantial amounts of energy when hydrolyzed. For instance, the  $\Delta G^{\circ'}$  for hydrolysis of a phosphoanhydride bond in ATP ( $-7.3$  kcal/mol) is more than three times the  $\Delta G^{\circ'}$  for hydrolysis of the phosphoester bond (red) in glycerol 3-phosphate ( $-2.2$  kcal/mol):

A principal reason for this difference is that ATP and its hydrolysis products, ADP and  $\text{P}_i$ , are charged at neutral pH. During synthesis of ATP, a large amount of energy must be used to force the negative charges in ADP and  $\text{P}_i$  together. Conversely, this energy is released when ATP is hydrolyzed to ADP and  $\text{P}_i$ . In comparison, formation of the phosphoester bond between an uncharged hydroxyl in glycerol and  $\text{P}_i$  requires less energy, and less energy is released when this bond is hydrolyzed.

Cells have evolved protein-mediated mechanisms for transferring the free energy released by hydrolysis of phosphoanhydride bonds to other molecules, thereby driving reactions that would otherwise be energetically unfavorable. For example, if the  $\Delta G$  for the reaction  $\text{B} + \text{C} \rightarrow \text{D}$  is positive but less than the  $\Delta G$  for hydrolysis of ATP, the reaction can be driven to the right by coupling it to hydrolysis of the terminal phosphoanhydride bond in ATP. In one common mechanism of such *energy coupling*, some of the energy stored in this phosphoanhydride bond is transferred to one of the reactants (here, B) by the breaking of the bond

in ATP and the formation of a covalent bond between the released phosphate group and that reactant. The phosphorylated intermediate generated in this way can then react with reactant C to form product  $\text{D} + \text{P}_i$  in a reaction that has an overall negative  $\Delta G$ :

The overall reaction

is energetically favorable ( $\Delta G < 0$ ). Similarly, hydrolysis of GTP to GDP can provide energy to perform work, including the synthesis of ATP (see Chapter 12), but most often GTP hydrolysis is used to control cellular systems (e.g., protein synthesis, hormonal signaling) rather than as a source of energy.

An alternative mechanism of energy coupling is to use the energy released by ATP hydrolysis to change the conformation of a molecule to an “energy-rich” stressed state. In turn, the energy stored as conformational stress can be released as the molecule “relaxes” back into its unstressed conformation. If this relaxation process can be coupled to another reaction, the released energy can be harnessed to drive cellular processes.

As with many biosynthetic reactions, transport of molecules into or out of the cell often has a positive  $\Delta G$  and thus requires an input of energy to proceed. Such simple transport reactions do not *directly* involve the making or breaking of covalent bonds; thus their  $\Delta G^{\circ'}$  is 0. In the case of a substance moving into a cell, Equation 2-7 becomes

$$\Delta G = RT \ln \frac{[\text{C}_{\text{in}}]}{[\text{C}_{\text{out}}]} \quad (2-10)$$

where  $[\text{C}_{\text{in}}]$  is the initial concentration of the substance inside the cell and  $[\text{C}_{\text{out}}]$  is its concentration outside the cell. We can see from Equation 2-10 that  $\Delta G$  is positive for transport of a substance into a cell against its concentration gradient (when  $[\text{C}_{\text{in}}] > [\text{C}_{\text{out}}]$ ); the energy to drive such “uphill” transport is often supplied by the hydrolysis of ATP. Conversely, when a substance moves down its concentration gradient ( $[\text{C}_{\text{out}}] > [\text{C}_{\text{in}}]$ ),  $\Delta G$  is negative. Such “downhill” transport releases energy that can be coupled to an energy-requiring reaction, such as the movement of another substance uphill across a membrane or the synthesis of ATP itself (see Chapters 11 and 12).

## ATP Is Generated During Photosynthesis and Respiration

ATP is continuously being hydrolyzed to provide energy for many cellular activities. Some estimates suggest that humans daily hydrolyze a mass of ATP equal to their entire body weight. Clearly, to continue functioning, cells must

constantly replenish their ATP supply. Constantly replenishing ATP requires that cells obtain energy from their environment. For nearly all cells, the ultimate source of energy used to make ATP is sunlight. Some organisms can use sunlight directly. Through the process of **photosynthesis**, plants, algae, and certain photosynthetic bacteria trap the energy of sunlight and use it to synthesize ATP from ADP and  $P_i$ . Much of the ATP produced in photosynthesis is hydrolyzed to provide energy for the conversion of carbon dioxide to six-carbon sugars, a process called **carbon fixation**:

The sugars made during photosynthesis are a source of food, and thus energy, for the photosynthetic organisms making them and for the non-photosynthetic organisms, such as animals, that consume the plants either directly or indirectly by eating other animals that have eaten the plants. In this way, sunlight is the direct or indirect source of energy for most organisms (see Chapter 12).

In plants, animals, and nearly all other organisms, the free energy in sugars and other molecules derived from food is released in the processes of **glycolysis** and **cellular respiration**. During cellular respiration, energy-rich molecules in food (e.g., glucose) are oxidized to carbon dioxide and water. The complete oxidation of glucose,

has a  $\Delta G^\circ$  of  $-686$  kcal/mol and is the reverse of photosynthetic carbon fixation. Cells employ an elaborate set of protein-mediated reactions to couple the oxidation of 1 molecule of glucose to the synthesis of as many as 30 molecules of ATP from 30 molecules of ADP. This oxygen-dependent (**aerobic**) degradation (**catabolism**) of glucose is the major pathway for generating ATP in all animal cells, all non-photosynthetic plant cells, and many bacterial cells. Catabolism of fatty acids can also be an important source of ATP. We discuss the mechanisms of photosynthesis and cellular respiration in Chapter 12.

Although light energy captured in photosynthesis is the primary source of chemical energy for cells, it is not the only source. Certain microorganisms that live in or around deep-sea hydrothermal vents, where adequate sunlight is unavailable, derive the energy for converting ADP and  $P_i$  into ATP from the oxidation of reduced inorganic compounds. These reduced compounds originate deep in the earth and are released at the vents.

## NAD<sup>+</sup> and FAD Couple Many Biological Oxidation and Reduction Reactions

In many chemical reactions, electrons are transferred from one atom or molecule to another; this transfer may or may not accompany the formation of new chemical bonds or the release of energy that can be coupled to other reactions. The loss of electrons from an atom or a molecule is called

**oxidation**, and the gain of electrons by an atom or a molecule is called **reduction**. An example of oxidation is the removal of electrons from the sulfhydryl group-containing side chains of two cysteine amino acids to form a disulfide bond, described above in Section 2.2. Electrons are neither created nor destroyed in a chemical reaction, so if one atom or molecule is oxidized, another must be reduced. For example, oxygen draws electrons from  $\text{Fe}^{2+}$  (ferrous) ions to form  $\text{Fe}^{3+}$  (ferric) ions, a reaction that occurs as part of the process by which carbohydrates are degraded in mitochondria. Each oxygen atom receives two electrons, one from each of two  $\text{Fe}^{2+}$  ions:

Thus  $\text{Fe}^{2+}$  is oxidized and  $\text{O}_2$  is reduced. Such reactions in which one molecule is reduced and another is oxidized are often referred to as **redox reactions**. Oxygen is an electron acceptor in many redox reactions in cells under aerobic conditions.

Many biologically important oxidation and reduction reactions involve the removal or addition of hydrogen atoms (protons plus electrons) rather than the transfer of isolated electrons on their own. The oxidation of succinate to fumarate, which occurs in mitochondria, is an example (Figure 2-32). Protons are soluble in aqueous solutions (as  $\text{H}_3\text{O}^+$ ), but electrons are not, so they must be transferred directly from one atom or molecule to another without a water-dissolved intermediate. In this type of oxidation reaction, electrons are often transferred to small electron-carrying molecules, sometimes referred to as *coenzymes*. The most common of these electron carriers are **NAD<sup>+</sup>** (**nicotinamide adenine dinucleotide**), which is reduced to NADH, and **FAD** (**flavin adenine dinucleotide**), which is reduced to  $\text{FADH}_2$  (Figure 2-33). The reduced forms of these coenzymes can transfer protons and electrons to other molecules, thereby reducing them.

To describe redox reactions, such as the reaction of ferrous ion ( $\text{Fe}^{2+}$ ) and oxygen ( $\text{O}_2$ ), it is easiest to divide them into two half-reactions:

**FIGURE 2-32 Conversion of succinate to fumarate.** In this oxidation reaction, which occurs in mitochondria as part of the citric acid cycle, succinate loses two electrons and two protons. These protons and electrons are transferred to FAD, reducing it to  $\text{FADH}_2$ .

**FIGURE 2-33 The electron-carrying coenzymes NAD<sup>+</sup> and FAD.**

(a) NAD<sup>+</sup> (nicotinamide adenine dinucleotide) is reduced to NADH by the addition of two electrons and one proton simultaneously. In many biological redox reactions, a pair of hydrogen atoms (two protons and two electrons) is removed from a molecule. In some cases, one of the protons and both electrons are transferred to NAD<sup>+</sup>; the other

proton is released into solution. (b) FAD (flavin adenine dinucleotide) is reduced to FADH<sub>2</sub> by the addition of two electrons and two protons, as occurs when succinate is converted to fumarate (see Figure 2-32). In this two-step reaction, addition of one electron together with one proton first generates a short-lived semiquinone intermediate (not shown), which then accepts a second electron and proton.

In this case, the reduced oxygen (O<sup>2-</sup>) readily reacts with two protons to form one water molecule (H<sub>2</sub>O). The readiness with which an atom or a molecule *gains* an electron is its **reduction potential** (*E*). The tendency to *lose* electrons, the **oxidation potential**, has the same magnitude as the reduction potential for the reverse reaction, but has the opposite sign.

Reduction potentials are measured in volts (V) from an arbitrary zero point set at the reduction potential of the following half-reaction under standard conditions (25 °C, 1 atm, and reactants at 1 M):

The value of *E* for a molecule or an atom under standard conditions is its standard reduction potential, *E'*<sub>0</sub>. A molecule or an ion with a positive *E'*<sub>0</sub> has a higher affinity for electrons than the H<sup>+</sup> ion does under standard conditions. Conversely, a molecule or ion with a negative *E'*<sub>0</sub> has a lower affinity for electrons than the H<sup>+</sup> ion does under standard conditions. Like the values of Δ*G*<sup>o'</sup>, standard reduction potentials may differ somewhat from those found under the conditions in a cell because the concentrations of reactants in a cell are not 1 M.

In a redox reaction, electrons move spontaneously toward atoms or molecules having *more positive* reduction potentials. In other words, a molecule having a more negative reduction potential can transfer electrons spontaneously to, or reduce, a molecule with a more positive reduction potential. In this type of reaction, the change in electric potential Δ*E* is the sum of the reduction and oxidation potentials for the two half-reactions. The Δ*E* for a redox reaction is related to the change in free energy Δ*G* by the following expression:

$$\Delta G \text{ (cal/mol)} = -n (23,064) \Delta E \text{ (volts)} \quad (2-11)$$

where *n* is the number of electrons transferred. Note that a redox reaction with a positive Δ*E* value will have a negative Δ*G* and thus will tend to proceed spontaneously from left to right.

## KEY CONCEPTS OF SECTION 2.4

### Biochemical Energetics

- The change in free energy, Δ*G*, is the most useful measure for predicting the potential of chemical reactions to occur spontaneously in biological systems. Chemical reactions tend to proceed spontaneously in the direction for which Δ*G* is negative. The magnitude of Δ*G* is independent of the reaction rate. A reaction with a negative Δ*G* is referred to as thermodynamically favorable.
- The chemical free-energy change, Δ*G*<sup>o'</sup>, equals  $-2.3 RT \log K_{\text{eq}}$ . Thus the value of Δ*G*<sup>o'</sup> can be calculated from the experimentally determined concentrations of reactants and products at equilibrium.
- The rate of a reaction depends on the activation energy needed to energize reactants to a transition state. Catalysts such as enzymes speed up reactions by lowering the activation energy of the transition state.
- A chemical reaction having a positive Δ*G* can proceed if it is coupled with a reaction having a negative Δ*G* of larger magnitude.
- Many otherwise energetically unfavorable cellular processes are driven by the hydrolysis of phosphoanhydride bonds in ATP (see Figure 2-31).
- Directly or indirectly, light energy captured by photosynthesis in plants, algae, and photosynthetic bacteria is the

ultimate source of chemical energy for nearly all cells on Earth.

- An oxidation reaction (loss of electrons) is always coupled with a reduction reaction (gain of electrons).
- Biological oxidation and reduction reactions are often coupled by electron-carrying coenzymes such as  $\text{NAD}^+$  and FAD (see Figure 2-33).
- Oxidation-reduction reactions with a positive  $\Delta E$  have a negative  $\Delta G$  and thus tend to proceed spontaneously.

## Review the Concepts

1. The gecko is a reptile with an amazing ability to climb smooth surfaces, including glass. Geckos appear to stick to smooth surfaces via van der Waals interactions between septa on their feet and the smooth surface. How is this method of stickiness advantageous over covalent interactions? Given that van der Waals forces are among the weakest molecular interactions, how can the gecko's feet stick so effectively?
2. The  $\text{K}^+$  channel is an example of a transmembrane protein (a protein that spans the phospholipid bilayer of the plasma membrane). What types of amino acids are likely to be found (a) lining the channel through which  $\text{K}^+$  passes, (b) in contact with the hydrophobic core of the phospholipid bilayer containing fatty acyl groups, (c) in the cytosolic domain of the protein, and (d) in the extracellular domain of the protein?
3. V-M-Y-F-E-N: This is the single-letter amino acid abbreviation for a peptide. What is the net charge of this peptide at pH 7.0? An enzyme called a protein tyrosine kinase can attach phosphates to the hydroxyl groups of tyrosine (Y). What is the net charge of the peptide at pH 7.0 after it has been phosphorylated by a tyrosine kinase? What is the likely source of phosphate used by the kinase for this reaction?
4. Disulfide bonds help to stabilize the three-dimensional structure of proteins. What amino acids are involved in the formation of disulfide bonds? Does the formation of a disulfide bond increase or decrease entropy ( $\Delta S$ )?
5. In the 1960s, the drug thalidomide was prescribed to pregnant women to treat morning sickness. However, thalidomide caused severe limb defects in the children of some women who took the drug, and its use for morning sickness was discontinued. It is now known that thalidomide was administered as a mixture of two stereoisomeric compounds, one of which relieved morning sickness and the other of which was responsible for the birth defects. What are stereoisomers? Why might two such closely related compounds have such different physiological effects?
6. Name the compound shown below.

Is this nucleotide a component of DNA, RNA, or both? Name one other function of this compound.

7. The chemical basis of blood-group specificity resides in the carbohydrates displayed on the surfaces of red blood cells. Carbohydrates have the potential for great structural diversity. Indeed, the structural complexity of the oligosaccharides that can be formed from four sugars is greater than that of the oligopeptides that can be formed from four amino acids. What properties of carbohydrates make this great structural diversity possible?

8. Calculate the pH of 1 L of pure water at equilibrium. How will the pH change after 0.008 moles of the strong base sodium hydroxide (NaOH) are dissolved in the water? Now, calculate the pH of a 50 mM aqueous solution of the weak acid 3-(N-morpholino) propane-1-sulfonic acid (MOPS) in which 61 percent of the solute is in its weak acid form and 39 percent is in the form of MOPS's corresponding base (the  $pK_a$  for MOPS is 7.20). What is the final pH after 0.008 moles of NaOH are added to 1 L of this MOPS buffer?

9. Ammonia ( $NH_3$ ) is a weak base that under acidic conditions becomes protonated to the ammonium ion in the following reaction:

$NH_3$  freely permeates biological membranes, including those of lysosomes. The lysosome is a subcellular organelle with a pH of about 4.5–5.0; the pH of cytoplasm is about 7.0. What is the effect on the pH of the fluid content of lysosomes when cells are exposed to ammonia? *Note:* Ammonium ( $NH_4^+$ ) does not diffuse freely across membranes.

10. Consider the binding reaction  $L + R \rightarrow LR$ , where L is a ligand and R is its receptor. When  $1 \times 10^{-3}$  M of L is added to a solution containing  $5 \times 10^{-2}$  M of R, 90 percent of the L binds to form LR. What is the  $K_{eq}$  of this reaction? How will the  $K_{eq}$  be affected by the addition of a protein that facilitates (catalyzes) this binding reaction? What is the dissociation equilibrium constant  $K_d$ ?

11. What is the ionization state of phosphoric acid in the cytoplasm? Why is phosphoric acid such a physiologically important compound?

12. The  $\Delta G^\circ$  for the reaction  $X + Y \rightarrow XY$  is  $-1000$  cal/mol. What is the  $\Delta G$  at  $25^\circ C$  ( $298^\circ K$ ) starting with 0.01 M each of X, Y, and XY? Suggest two ways one could make this reaction energetically favorable.

13. According to health experts, saturated fatty acids, which come from animal fats, are a major factor contributing to coronary heart disease. What distinguishes a saturated fatty acid from an unsaturated fatty acid, and to what does the term *saturated* refer? Recently, trans unsaturated fatty acids,

or trans fats, which raise total cholesterol levels in the body, have also been implicated in heart disease. How does the cis stereoisomer differ from the trans configuration, and what effect does the cis configuration have on the structure of the fatty acid chain?

14. Chemical modifications of amino acids contribute to the diversity and function of proteins. For instance,  $\gamma$ -carboxylation of specific amino acids is required to make some proteins biologically active. What particular amino acid undergoes this modification, and what is its biological relevance? Warfarin, a derivative of coumarin, which is present in many plants, inhibits  $\gamma$ -carboxylation of this amino acid and was used in the past as a rat poison. At present, it is also used clinically in humans. What patients might be prescribed warfarin and why?

Molecular ribbon model of a protein “needle” used by pathogenic bacteria to inject proteins into human cells to initiate infection. Many disease-causing bacteria, including *Salmonella typhimurium* (food poisoning) and *Yersinia pestis* (bubonic plague), use a syringe-like protein complex called a type III secretion system to inject proteins into their mammalian target cells. The structure of the needle portion of the syringe used by *Salmonella typhimurium*, determined using a combination of nuclear magnetic resonance (NMR), electron microscopy, and computational methods, is a long tube with many  $\alpha$  helices (illustrated as coiled ribbons) forming the walls of the needle. [Data from A. Loquet et al., 2012, *Nature* **486**:276, PDB ID 2lpz.]

Proteins, which are polymers of amino acids, come in many sizes and shapes. Their three-dimensional diversity principally reflects variations in their lengths and amino acid sequences. In general, the linear, unbranched polymer of amino acids composing any protein will fold into only one or a few closely related three-dimensional shapes—called **conformations**. The conformation of a protein, together with the distinctive chemical properties of its amino acid side chains, determines its function. In some cases, the conformation, and thus the function, of a protein can change when that protein noncovalently or covalently associates with other molecules. Because of their many different shapes and chemical properties, proteins can perform a dazzling array of distinct functions inside and outside cells that either are essential for life or provide a

# Protein Structure and Function

selective evolutionary advantage to the cell or organism that contains them. It is, therefore, not surprising that characterizing the structures and activities of proteins is a fundamental prerequisite for understanding how cells work. Much of this textbook is devoted to examining how proteins act together to allow cells to live and function properly.

Although their structures are diverse, most proteins can be grouped into one of a few broad functional classes. *Structural proteins*, for example, determine the shapes of cells and their extracellular environments and serve as guide wires or rails to direct the intracellular movement of molecules and organelles. They are usually formed by the assembly of multiple protein subunits into very large, long structures. *Scaffold proteins* bring other proteins together into ordered

arrays to perform specific functions more efficiently than those proteins would if they were not assembled together. *Enzymes* are proteins that catalyze chemical reactions. *Membrane transport proteins* permit the flow of ions and molecules across cellular membranes. *Regulatory proteins* act as signals, sensors, and switches to control the activities of cells by altering the functions of other proteins and genes. Regulatory proteins include *signaling proteins*, such as the hormones and cell-surface receptors that transmit extracellular signals to the cell interior. *Motor proteins* are responsible for moving other proteins, organelles, cells—even whole organisms. Any one protein can be a member of more than one protein class, as is the case with some cell-surface signaling receptors that are both enzymes and regulator proteins because they transmit signals from outside to inside cells by catalyzing chemical reactions. To accomplish their diverse missions efficiently, some proteins assemble into large complexes, often called *molecular machines*.

How do proteins perform so many diverse functions? They do so by exploiting a few simple activities. Most fundamentally, proteins *bind*—to one another, to other macromolecules such as DNA, and to small molecules and ions. In many cases, such binding induces a conformational change (a change in the three-dimensional structure) in the protein and thus influences its activity. Binding is based on molecular complementarity between a protein and its binding partner, as described in Chapter 2. A second key activity is enzymatic *catalysis*. Appropriate folding of a protein will place some amino acid side chains and some carboxyl and amino groups of its backbone into positions that permit the catalysis of covalent bond rearrangements. A third activity is *folding into a channel or pore* within a membrane through which molecules and ions can flow. Although these are especially crucial protein activities, they are not the only ones. For example, fish that live in frigid waters—the Antarctic borchs and Arctic cods—have antifreeze proteins in their circulatory systems to prevent water crystallization.

A complete understanding of how proteins permit cells to live and thrive requires the identification and characterization of all the proteins used by a cell. In a sense, molecular cell biologists want to compile a complete protein “parts list” and construct a “user’s manual” that describes how these proteins work. Compiling a comprehensive inventory of proteins has become feasible in recent years with the sequencing of the entire genomes—complete sets of genes—of more and more organisms. From a computer analysis of a genome’s sequence, researchers can deduce the amino acid sequences and approximate number of the proteins it encodes (see Chapter 6). The term **proteome** was coined to refer to the entire protein complement of an organism. The human genome contains some 20,000–23,000 genes that encode proteins. However, variations in mRNA production, such as alternative splicing (see Chapter 10), and more than a hundred types of protein modifications may generate hundreds of thousands of distinct human proteins. By comparing the sequences and structures of proteins of unknown function with those of proteins of known function, scientists can often deduce much about what the unknown

proteins do. In the past, characterization of protein function by genetic, biochemical, or physiological methods often preceded the identification of particular proteins. In the modern genomic and proteomic era, a protein is usually identified before its function is determined.

In this chapter, we begin our study of how the structure of a protein gives rise to its function, a theme that recurs throughout this book (Figure 3-1). The first section examines how linear chains of amino acid building blocks are arranged in a three-dimensional structural hierarchy. The next section discusses how proteins fold into these structures. We then turn to protein function, focusing on enzymes, those proteins that catalyze chemical reactions. Various mechanisms that cells use to control the activities and life spans of proteins are covered next. The chapter concludes with a discussion

**FIGURE 3-1 Overview of protein structure and function.** (a) Proteins have a hierarchical structure. A polypeptide’s linear sequence of amino acids linked by peptide bonds (primary structure) folds into local helices or sheets (secondary structure) that pack into a complex three-dimensional shape (tertiary structure). Some individual polypeptides associate into multichain complexes (quaternary structure), which in some cases can be very large, consisting of tens to hundreds of subunits (supramolecular complexes). (b) Proteins perform numerous functions, including organizing the genome, organelles, cytoplasm, protein complexes, and membranes in three-dimensional space (structure); controlling protein activity (regulation); monitoring the environment and transmitting information (signaling); moving small molecules and ions across membranes (transport); catalyzing chemical reactions (via enzymes); and generating force for movement (via motor proteins). These functions and others arise from specific binding interactions and conformational changes in the structure of a properly folded protein.

of commonly used techniques for identifying, isolating, and characterizing proteins, and a discussion of the burgeoning field of proteomics.

### 3.1 Hierarchical Structure of Proteins

In many proteins, the polymer chain folds into a distinct three-dimensional shape that is stabilized primarily by noncovalent interactions between regions in the linear sequence of amino acids. A key concept in understanding how proteins work is that *function is often derived from three-dimensional structure, and three-dimensional structure is determined by both a protein's amino acid sequence and intramolecular noncovalent interactions*. The principles relating biological structure and function were initially formulated by the biologists Johann von Goethe (1749–1832), Ernst Haeckel (1834–1919), and D'Arcy Thompson (1860–1948), whose work has been widely influential in biology and beyond. Indeed, their ideas greatly influenced the school of “organic” architecture pioneered in the early twentieth century that is epitomized by the dicta “form follows function” (Louis Sullivan) and “form is function” (Frank Lloyd Wright). Here we consider the architecture of proteins at four levels of organization: primary, secondary, tertiary, and quaternary (Figure 3-2).

**FIGURE 3-2 Four levels of protein hierarchy.** (a) The linear sequence of amino acids linked together by peptide bonds is the primary structure. (b) Folding of the polypeptide chain into local α helices or β sheets represents secondary structure. (c) Secondary structural elements, together with various loops and turns in a single polypeptide chain, pack into a larger, independently stable tertiary structure, which may include distinct domains. (d) Some proteins consist of more than one polypeptide associated together in a quaternary structure.

### The Primary Structure of a Protein Is Its Linear Arrangement of Amino Acids

As discussed in Chapter 2, proteins are polymers constructed out of 20 different types of amino acids. Individual amino acids are linked together in linear, unbranched chains by covalent amide bonds, called **peptide bonds**. Peptide bond formation between the amino group of one amino acid and the carboxyl group of another results in the net release of a water molecule and thus is a form of dehydration reaction (Figure 3-3a). The repeated amide N, α carbon ( $C_\alpha$ ), carbonyl C, and oxygen atoms of each amino acid residue form the backbone of a protein molecule from which the various side-chain groups project (Figure 3-3b, c). As a consequence of

**FIGURE 3-3 Structure of a polypeptide.** (a) Individual amino acids are linked together by peptide bonds, which form via reactions that result in a loss of water (dehydration).  $R_1$ ,  $R_2$ , etc., represent the side chains (“R groups”) of amino acids. (b) Linear polymers of peptide-bond-linked amino acids are called *polypeptides*, which have a free amino end (N-terminus) and a free carboxyl end (C-terminus). (c) A ball-and-stick model shows peptide bonds (yellow) linking the amino nitrogen atom (blue) of one amino acid (aa) with the carbonyl carbon atom (gray) of an adjacent one in the chain. The R groups (green) extend from the α carbon atoms (black) of the amino acids. These side chains largely determine the distinct properties of individual proteins.

the peptide linkage, the backbone exhibits directionality, usually referred to as an N-to-C orientation, because all the amino groups are located on the same side of the  $C_\alpha$  atoms. Thus one end of a protein has a free (unlinked) amino group (the *N-terminus*), and the other end has a free carboxyl group (the *C-terminus*). The sequence of a protein chain is conventionally written with its N-terminal amino acid on the left and its C-terminal amino acid on the right, and the amino acids are numbered sequentially starting from the N-terminus.

The **primary structure** of a protein is simply the linear covalent arrangement, or sequence, of the amino acid residues that compose it. The first primary structure of a protein determined was that of insulin in the early 1950s. Today the number of known sequences exceeds 10 million and is growing daily. Many terms are used to denote the chains formed by the polymerization of amino acids. A short chain of amino acids linked by peptide bonds and having a defined sequence is called an **oligopeptide**, or simply a **peptide**; longer chains are referred to as **polypeptides**. Peptides generally contain fewer than 20–30 amino acid residues, whereas polypeptides are often 200–500 residues long. The longest protein described to date is the muscle protein titin, some forms of which can be more than 34,000 residues long. We generally reserve the term **protein** for a polypeptide (or complex of polypeptides) that has a well-defined three-dimensional structure.

The size of a protein or a polypeptide is expressed either as its mass in **daltons** (a dalton is 1 atomic mass unit) or as its molecular weight (MW), which is a dimensionless number equal to the mass in daltons. For example, a 10,000-MW protein has a mass of 10,000 daltons (Da), or 10 kilodaltons (kDa). Later in this chapter, we will consider different methods for measuring the sizes and other physical characteristics of proteins. The precise molecular weight of a protein that has not been covalently modified is readily determined by summing up the weights of all of its constituent amino acids as determined from its amino acid sequence. The proteins encoded by the yeast genome, for example, have an average molecular weight of 52,728 and contain, on average, 466 amino acid residues. The average molecular weight of amino acids in proteins is 113, taking into account their average relative abundances. This value can be used to estimate the number of residues in a protein of unknown sequence if you know its molecular weight or, conversely, to estimate from the number of residues in a protein its likely molecular weight. Covalent modification of one or more amino acids in a protein—for example, by phosphorylation or glycosylation (see Chapters 2 and 13)—alters the mass of those residues and thus the mass of the protein in which they reside.

How many proteins are there in a typical eukaryotic (nucleated) cell? Let's do a simple calculation for one such cell, a hepatocyte (a major type of cell in the mammalian liver). This type of cell, roughly a cube  $15\ \mu\text{m}$  ( $0.0015\ \text{cm}$ ) on a side, has a volume of  $3.4 \times 10^{-9}\ \text{cm}^3$  (or milliliters, ml). Assuming a cell density of  $1.03\ \text{g/ml}$ , the cell would weigh  $3.5 \times 10^{-9}\ \text{g}$ . Since protein accounts for approximately 20 percent

of a cell's weight, the total weight of cellular protein is  $7 \times 10^{-10}\ \text{g}$ . Assuming that an average protein has a molecular weight of 52,728 g/mol, we can calculate the total number of protein molecules per hepatocyte as about  $7.9 \times 10^9$  from the total protein weight and Avogadro's number, the number of molecules per mole of any chemical compound ( $6.02 \times 10^{23}$ ). To carry this calculation one step further, consider that a hepatocyte contains about 10,000 different proteins; thus each cell, on average, would contain close to a million molecules of each type of protein. In fact, the abundances of different proteins vary widely, from the quite rare insulin-binding receptor protein (20,000 molecules per cell) to the structural protein actin ( $5 \times 10^8$  molecules per cell). Every cell closely regulates the abundance of each protein such that each is present in the appropriate quantity for its cellular functions at any given time. We will learn more about the mechanisms used by cells to regulate protein levels later in this chapter and in Chapters 9 and 10.

## Secondary Structures Are the Core Elements of Protein Architecture

The second level in the hierarchy of protein structure is **secondary structure**. Secondary structures are stable spatial arrangements of segments of a polypeptide chain held together by hydrogen bonds between backbone amide and carbonyl groups and often involving repeating structural patterns. The propensity of a segment of a polypeptide chain to form any given secondary structure depends on its amino acid sequence (see Section 3.2 below). A single polypeptide may contain multiple types of secondary structure in various portions of the chain, depending on its sequence. The principal secondary structures are the **alpha ( $\alpha$ ) helix**, the **beta ( $\beta$ ) sheet**, and the short U-shaped **beta ( $\beta$ ) turn**. Parts of the polypeptide that don't form these structures but nevertheless have a well-defined, stable shape are said to have an *irregular* structure. The term *random coil* applies to highly flexible parts of a polypeptide chain that have no fixed three-dimensional structure. In an average protein, 60 percent of the polypeptide chain exists as  $\alpha$  helices and  $\beta$  sheets; the remainder of the molecule is in irregular structures, coils, and turns. Thus  $\alpha$  helices and  $\beta$  sheets are the major internal supportive elements in most proteins. Here we explore the shapes of secondary structures and the forces that favor their formation. In later sections, we examine how arrays of secondary structure fold together into larger, more complex arrangements called tertiary structure.

**The  $\alpha$  Helix** In a polypeptide segment folded into an  $\alpha$  helix, the backbone forms a spiral structure in which the carbonyl oxygen atom of each peptide bond is hydrogen-bonded to the amide hydrogen atom of the amino acid four residues farther along the chain in the direction of the C-terminus (Figure 3-4). Within an  $\alpha$  helix, all the backbone amino and carboxyl groups are hydrogen-bonded to one another except at the very beginning and end of the helix. This periodic arrangement of bonds confers an amino-to-carboxy-terminal

**FIGURE 3-4 The  $\alpha$  helix, a common secondary structure in proteins.** The polypeptide backbone (seen as a ribbon) is folded into a spiral that is held in place by hydrogen bonds between backbone oxygen and hydrogen atoms. Only hydrogens involved in bonding are shown. The outer surface of the helix is covered by the side-chain R groups (green).

directionality on the helix because all the hydrogen bond acceptors (i.e., the carbonyl groups) have the same orientation (pointing in the downward direction in Figure 3-4), resulting in a structure in which there is a complete turn of the spiral every 3.6 residues. An  $\alpha$  helix 36 amino acids long has 10 turns of the helix and is 5.4 nm long (0.54 nm per turn).

The stable arrangement of hydrogen-bonded amino acids in the  $\alpha$  helix holds the backbone in a straight, rodlike cylinder from which the side chains point outward. The relative hydrophobic or hydrophilic quality of a particular helix within a protein is determined entirely by the characteristics of the side chains. In water-soluble proteins, hydrophilic helices with polar side chains extending outward tend to be found on the outside surfaces, where they can interact with the aqueous environment, whereas hydrophobic helices with nonpolar, hydrophobic side chains tend to be buried within the core of the folded protein. Proteins embedded in the hydrophobic core of cellular membranes (see Chapter 7)

often use one or more hydrophobic helices that are 20–25 residues long to cross the membrane. The amino acid proline is usually not found in  $\alpha$  helices because the covalent bonding of its amino group with a carbon in the side chain prevents its participation in stabilizing the backbone through normal hydrogen bonding. While the classic  $\alpha$  helix is the most intrinsically stable and most common helical form in proteins, there are variations, such as more tightly or loosely twisted helices. For example, in a specialized helix called a coiled coil (described several sections farther on), the helix is more tightly wound (3.5 residues and 0.51 nm per turn).

**The  $\beta$  Sheet** Another type of secondary structure, the  $\beta$  sheet, consists of laterally packed  $\beta$  strands. Each  $\beta$  strand is a short (5–8-residue), nearly fully extended polypeptide segment. In contrast to the  $\alpha$  helix, in which hydrogen bonds occur between the backbone amino and carboxyl groups of nearly adjacent residues, hydrogen bonds in the  $\beta$  sheet occur between backbone atoms in separate, but adjacent,  $\beta$  strands and are oriented perpendicularly to the chains of backbone atoms (Figure 3-5a). These distinct  $\beta$  strands (indicated as green and blue arrows in the figure) may be either within a single polypeptide chain, with short or long loops between the  $\beta$  strand segments, or on different polypeptide chains in a protein composed of multiple polypeptides. Figure 3-5b shows how two or more  $\beta$  strands align into adjacent rows, forming a nearly two-dimensional  $\beta$  pleated sheet (or simply *pleated sheet*), in which hydrogen bonds within the plane of the sheet hold the  $\beta$  strands together as the side chains stick out above and below the plane. Like  $\alpha$  helices,  $\beta$  strands have a directionality defined by the orientation of the peptide bonds. Therefore, in a pleated sheet, adjacent  $\beta$  strands can be oriented in alternating opposite (antiparallel) directions (see Figure 3-5a) or in the same (parallel) direction (Figure 3-5c). In some proteins,  $\beta$  sheets form part of the hydrophobic core of the protein (described below) or the side of an open space that binds other molecules; in some proteins embedded in membranes, the  $\beta$  sheets curve around and form a hydrophilic central pore through which ions and small molecules may flow (see Chapter 7).

**The  $\beta$  Turn** Composed of four residues,  $\beta$  turns are located on the surface of a protein, forming sharp bends that reverse the direction of the polypeptide backbone, often toward the protein's interior. These short, U-shaped secondary structures are often stabilized by a hydrogen bond between their end residues (Figure 3-6). Glycine and proline are commonly found in  $\beta$  turns. The lack of a large side chain in glycine and the presence of a built-in bend in proline allow the polypeptide backbone to fold into a tight U shape.  $\beta$  Turns help long polypeptides fold into highly compact structures. A reversal in the direction of the polypeptide backbone may also be mediated by segments of the polypeptide that are longer than four residues and that form bends or loops. In contrast to tight  $\beta$  turns, which exhibit just a few well-defined conformations, longer loops can have many different conformations.

**FIGURE 3-5 The  $\beta$  sheet, another common secondary structure in proteins.** (a) Top view of a three-stranded  $\beta$  sheet. Each strand is highlighted by a ribbon-like arrow with alternating blue and green segments that is pointed with an N-to-C orientation, with the loops of connecting residues indicated by thick black lines. In this antiparallel  $\beta$  sheet, each strand (arrow) points in the direction opposite to that of the adjacent strand. The stabilizing hydrogen bonds between the  $\beta$  strands are indicated by green dashed lines. (b) Side view of an antiparallel  $\beta$  sheet. The projection of the R groups (green) above and below the plane of the sheet is obvious in this view. The fixed bond angles in the polypeptide backbone produce a pleated contour represented in panel (a) by the alternating colored segments. (c) Top view of two  $\beta$  sheets, whose individual strands (N-to-C orientations represented by arrows) are either antiparallel, in which the strands alternately point in opposite directions (left), or parallel, in which all strands point in the same direction (right).

## Tertiary Structure Is the Overall Folding of a Polypeptide Chain

**Tertiary structure** refers to the overall conformation of a polypeptide chain—that is, the three-dimensional arrangement of all its amino acid residues. In contrast to secondary structures, which are stabilized only by hydrogen bonds, tertiary structure is stabilized primarily by hydrophobic interactions between nonpolar side chains, together with hydrogen

**FIGURE 3-6 Structure of a  $\beta$  turn.** Composed of four residues,  $\beta$  turns reverse the direction of a polypeptide chain (resulting in a  $180^\circ$  U-turn). The  $C_\alpha$  carbons of the first and fourth residues are usually less than 0.7 nm apart, and those residues are often linked by a hydrogen bond.  $\beta$  turns facilitate the folding of long polypeptides into compact structures.

bonds involving polar side chains and backbone amino and carboxyl groups. These stabilizing forces hold together elements of secondary structure— $\alpha$  helices,  $\beta$  strands, turns, and coils. Because the stabilizing interactions are often weak, however, the tertiary structure of a protein is not rigidly fixed, but undergoes continual minute fluctuations, and some segments within the tertiary structure of a protein can be so mobile that they are considered to be disordered—that is, lacking well-defined, stable, three-dimensional structure. This variation in structure has important consequences for the function and regulation of proteins.

The chemical properties of amino acid side chains help define tertiary structure. In some proteins—for example, those that are secreted from cells or are cell-surface proteins that face the extracellular environment—*disulfide bonds* between the side chains of cysteine residues can covalently link regions of the proteins, thus restricting the proteins' flexibility and increasing the stability of their tertiary structures. Amino acids with charged hydrophilic polar side chains tend to be on the outer surfaces of proteins; by interacting with water, they help to make the proteins soluble in aqueous solutions and can form noncovalent interactions with other water-soluble molecules, including other proteins. In contrast, amino acids with hydrophobic nonpolar side chains are usually sequestered away from the water-facing surfaces of a protein, in many cases forming a water-insoluble central core. This observation led to what's known as the "oil drop model" of protein conformation because the core of a protein is relatively hydrophobic, or "oily" (Figure 3-7). Uncharged hydrophilic polar side chains are found both on the surface and in the inner core of proteins.

## There Are Four Broad Structural Categories of Proteins

Proteins usually fall into one of four broad structural categories based on their tertiary structure: *globular proteins*, *fibrous proteins*, *integral membrane proteins*, and *intrinsically disordered*

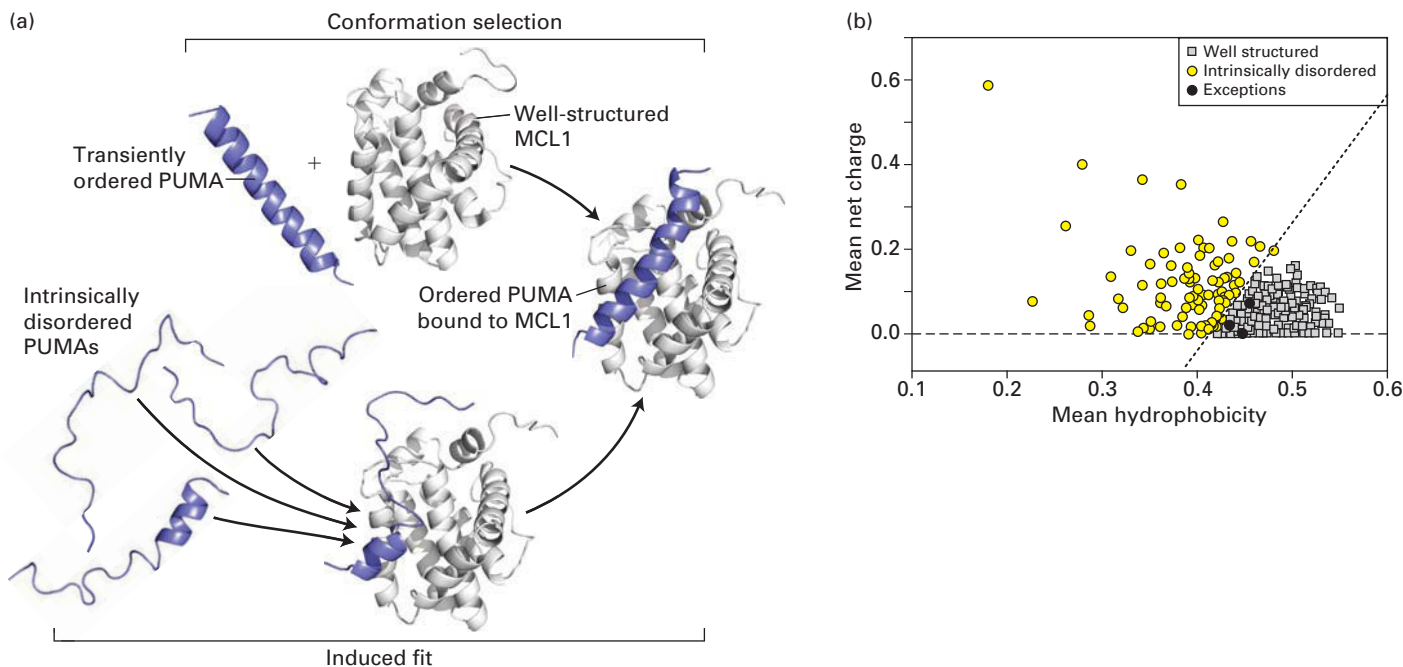

**FIGURE 3-7 The oil drop model of protein folding.** The hydrophobic and hydrophilic residues of a polypeptide chain can be distributed throughout its linear sequence as illustrated in the unfolded protein (top). The color scale denotes the most most hydrophilic residues (blue) to the most hydrophobic (yellow). When the protein folds (bottom left), hydrophilic (charged and uncharged polar) side chains will often be exposed on the protein's surface, where they can form stabilizing interactions with surrounding water and ions. In contrast, the hydrophobic residues tend to cluster together in the inner core, somewhat like drops of oil in an aqueous liquid, driven away from the aqueous surroundings by the hydrophobic effect (see Chapter 2). These core residues are more easily seen when several surface residues are removed (bottom right). [Data from M. C. Vaney et al., 1996, *Acta Crystallogr., Sect. D* **52**:505, PDB ID 193L]

*proteins*. These four broad categories of proteins are not mutually exclusive—some proteins are made up of combinations of segments that fall into two or more of these categories. *Globular proteins* are generally water-soluble, compactly folded structures, often but not exclusively spheroidal, that comprise a mixture of secondary structures [see the structures of ras (Figure 3-9 below) and myoglobin (Figure 3-14 below)]. *Fibrous proteins* are large, elongated, often stiff molecules. Some fibrous proteins are composed of a long polypeptide chain comprising many tandem copies of a short amino acid sequence that forms a single repeating secondary structure (see the structure of collagen, the most abundant protein in mammals, in Figure 20-25). Other fibrous proteins are composed of repeating globular protein subunits, such as the helical array of G-actin protein monomers that forms F-actin microfilaments (see Chapter 17). Fibrous proteins, which often aggregate into large multiprotein fibers that do not readily dissolve in water, usually play a structural role or participate in cellular movements. *Integral membrane proteins* are embedded within the phospholipid bilayer of the membranes that enclose cells and organelles and are discussed in detail in Chapter 7.

*Intrinsically disordered proteins* are fundamentally distinct from the well-ordered proteins in the other three categories. Many proteins we consider in this book adopt only one or a few very closely related conformations when they are in their normal functional state, called the *native state*. Intrinsically disordered proteins, however, do not have well-ordered structures in their native, functional states; instead, their polypeptide chains are very flexible—indeed, disordered—with no fixed conformation. Sometimes only a segment of a polypeptide chain, rather than the entire chain, will be intrinsically disordered. The exceptional conformational flexibilities of intrinsically disordered proteins or protein segments appear to be key to their functional activities, such as the ability to interact with multiple partner proteins or to fold into a well-defined conformation only after binding to such partners (Figure 3-8a).

Intrinsically disordered proteins typically, but not exclusively, serve as signaling molecules, regulators of the activities of other molecules, or as scaffolds for multiple proteins, small molecules, and ions (e.g., binding ions via multiple charged residues). Regions of intrinsic disorder can provide flexible links, or tethers, between well-ordered regions of a protein; serve as sites of some types of post-translational protein modification [e.g., covalent addition of phosphate groups (phosphorylation) or sugars (glycosylation)]; serve as targets of protease digestion that regulates protein activity; inhibit the activity of the protein in which they are embedded (autoinhibition sites); or serve as signals for intracellular sorting of proteins (see Chapter 13). The activities of many proteins containing intrinsically disordered segments are described in subsequent chapters. For example, phosphorylation of the disordered C-terminal domain (CTD) of RNA polymerase II (see Figure 8-12), which is composed of multiple repeats of a seven-amino-acid sequence containing proline, threonine, and serine, regulates key steps in the synthesis of mRNA (see Chapters 9 and 10). The N-termini of histone proteins that control DNA organization in chromatin (see Chapter 8) are sites of important post-translational modifications, and the disordered, proline-rich FH1 region in the protein formin controls the assembly of actin filaments (see Chapter 17).

Intrinsically disordered proteins can be identified experimentally using various biochemical techniques, such as tests of sensitivity to protease digestion (disordered regions usually exhibit greater protease sensitivity), and a wide variety of biophysical techniques, including spectroscopy. The intrinsic disorder of these proteins apparently arises as a consequence of their having a sequence that, relative to well-ordered proteins, is richer in polar amino acids, proline, and net charge, and poorer in hydrophobic residues (Figure 3-8b). Algorithms primarily based on calculations of amino acid composition—particularly net charge and hydrophobicity—are used to predict which proteins or segments of proteins are intrinsically disordered. By some estimates, about 30 percent or more of eukaryotic proteins are predicted to have at least one segment of 50 or more consecutive residues that is disordered.

**EXPERIMENTAL FIGURE 3-8 Intrinsically disordered proteins: mechanisms of binding to well-ordered proteins and identification based on hydrophobicity and net charge.** (a) The binding of an intrinsically disordered protein (PUMA, blue) to a well-ordered protein (MCL1, gray) results in the formation of a well-defined structure in the previously disordered protein. PUMA and MCL1 are intracellular proteins that can influence the regulated process of cell death called apoptosis (see Chapter 21). Two mechanisms have been proposed for generating a bound complex in which both proteins are structured: conformational selection (top pathway) and induced fit (bottom pathway). In conformational selection, the disordered protein (PUMA) occasionally and transiently adopts in solution the structure it would have in the bound state. The well-ordered binding partner (MCL1) can then bind to (select) PUMA in that transient, ordered conformation, forming a relatively stable bound complex. In induced fit, the disordered protein begins to bind to the well-ordered partner while still disordered and then, while bound, is induced to form the ordered conformation present in the relatively stable, heterodimeric complex. Recent experiments suggest

that the induced fit mechanism best describes the binding of PUMA and MCL1. (b) The sequences of 275 well-ordered, monomeric globular proteins (gray squares) and 91 intrinsically disordered proteins (black and yellow circles) were used to calculate the mean hydrophobicity per residue in each protein using a scale of 0 (least hydrophobic) to 1 (most hydrophobic, x axis), and the mean net charge per residue at pH 7.0 (y axis). With only three exceptions (black circles), the proteins define two distinct distributions: low hydrophobicity, high net charge (intrinsically disordered, yellow circles) and high hydrophobicity, low net charge (well-ordered, gray squares). The three disordered proteins (black circles) that overlap with the well-ordered population each contain substantial segments predicted to be disordered (low hydrophobicity, high net charge) that apparently overwhelm the rest of the proteins' sequences that might otherwise result in a well-ordered conformation.

Soc.*, 2013, 135 (4), pp1415-1422. <http://pubs.acs.org/doi/pdf/10.1021/ja309527h>. Part (b) data from V. N. Uversky, J. R. Gillespie, and A. L. Fink, 2000, *Proteins* **41**:415–427.]

## Different Ways of Depicting the Conformation of Proteins Convey Different Types of Information

The simplest way to represent three-dimensional protein structure is to trace the course of the backbone atoms, sometimes only the  $C_{\alpha}$  atoms, with a solid line (called a  $C_{\alpha}$  backbone trace, Figure 3-9a); the most complex representation, called a ball-and-stick model, shows every atom (Figure 3-9b). The  $C_{\alpha}$  backbone trace shows the overall folding of the polypeptide chain without consideration of the amino acid side chains; the ball-and-stick model (with balls representing atoms and sticks representing bonds) details the interactions between side-chain atoms, including those that stabilize the protein's conformation and interact with other molecules, as well as the atoms of the backbone. Even though both views are useful, the elements of secondary structure are not always easily discerned in them. Another type of representation, called a ribbon diagram, uses common shorthand symbols for depicting secondary structure—for example,

coiled ribbons or solid cylinders for  $\alpha$  helices, flat ribbons or arrows for  $\beta$  strands, and flexible thin strands for  $\beta$  turns, coils, and loops (Figure 3-9c). In a variation of the basic ribbon diagram, ball-and-stick or space-filling models of all or only a subset of side chains can be attached to the backbone ribbon. In this way, side chains that are of interest can be visualized in the context of the secondary structure that is especially clearly represented by the ribbons.

However, none of these three ways of representing protein structure conveys much information about the atoms that are on the protein's surface and in contact with the watery environment. The surface is of interest because it is where other molecules usually bind to a protein. Thus a useful alternative way to represent proteins is to show only the water-accessible surface and use colors to highlight regions having a common chemical character, such as hydrophobicity or hydrophilicity, and charge characteristics, such as positive (basic) or negative (acidic) side chains (Figure 3-9d). Such models reveal the topography of the protein surface

and the distribution of charge, both important features of binding sites, as well as clefts in the surface where other molecules may bind. This view represents a protein as it is “seen” by another molecule.

### Structural Motifs Are Regular Combinations of Secondary Structures

A particular combination of two or more secondary structures that form a distinct three-dimensional structure is called a **structural motif** when it appears in multiple proteins. A structural motif is often, but not always, associated with a specific function. Any particular structural motif will frequently perform a common function in different proteins, such as binding to a particular ion or small molecule—for example, calcium or ATP. Some structural motifs, when isolated from the rest of a protein, are stable, and are thus called *structural domains*, as we shall see shortly. However other structural motifs do not form thermodynamically stable structures in the absence of other portions of the protein and are thus not considered to be independent structural domains.

One common structural motif is the  $\alpha$  helix–based **coiled coil**, or heptad repeat. Many proteins, including fibrous proteins and DNA-regulating proteins called transcription factors (see Chapter 9), assemble into dimers or trimers by using a coiled-coil motif, in which  $\alpha$  helices from two, three, or even four separate polypeptide chains coil about one another—resulting in a coil of coils; hence the name (Figure 3-10a). The individual helices bind tightly to one

another because each helix has a strip of aliphatic (hydrophobic, but not aromatic) side chains (leucine, valine, etc.) running along one side of the helix that interacts with a similar strip in the adjacent helix, thus sequestering the hydrophobic groups away from water and stabilizing the assembly of multiple independent helices. These hydrophobic strips are generated along only one side of the helix because the primary structure of each helix is composed of repeating seven-amino-acid units, called **heptads**, in which the side chains of the first and fourth residues are aliphatic and the other side chains are often hydrophilic (see Figure 3-10a). Because hydrophilic side chains extend from one side of the helix and hydrophobic side chains extend from the opposite side, the overall helical structure is **amphipathic**. Because leucine frequently appears in the fourth positions and the hydrophobic side chains merge together like the teeth of a zipper, these structural motifs are also called **leucine zippers**.

Many other structural motifs contain  $\alpha$  helices. A common calcium-binding motif called the **EF hand** contains two short helices connected by a loop (Figure 3-10b). This structural motif, one of several **helix-turn-helix** and **helix-loop-helix** structural motifs, is found in more than a hundred proteins and is used for sensing calcium levels. The binding of a  $\text{Ca}^{2+}$  ion to oxygen atoms in conserved residues in the loop depends on the concentration of  $\text{Ca}^{2+}$  in the cell and sometimes induces a conformational change in the protein, altering its activity. Thus calcium concentrations can directly control proteins’ structures and functions. Somewhat different helix-turn-helix and **basic helix-loop-helix**

**FIGURE 3-10 Motifs of protein secondary structure.** (a) This parallel two-stranded coiled-coil motif (*left*) is characterized by two  $\alpha$  helices wound around each other. Helix packing is stabilized by interactions between hydrophobic side chains (red and blue) present at regular intervals along each strand and found along the seam of the intertwined helices. Each  $\alpha$  helix exhibits a characteristic heptad repeat sequence with a hydrophobic residue often, but not always, at positions 1 and 4, as indicated. The coiled-coil nature of this structural motif is more apparent in long coiled coils containing many such motifs (*right*). (b) An EF hand, a type of helix-loop-helix motif, consists of two helices connected by a short loop in a specific conformation. This structural motif is common to many proteins, including many calcium-binding and DNA-binding regulatory proteins.

(bHLH) structural motifs are used for protein binding to DNA and, consequently, for the regulation of gene activity (see Chapter 9). Yet another structural motif commonly found in proteins that bind RNA or DNA is the **zinc finger**, which contains three secondary structures—an  $\alpha$  helix and two  $\beta$  strands with an antiparallel orientation—that form a fingerlike bundle held together by a zinc ion (Figure 3-10c).

The relationship between the primary structure of a polypeptide chain and the structural motifs into which it folds is not always straightforward. The amino acid sequences responsible for any given structural motif in different proteins may be very similar to one another. In other words, a common *sequence motif* can result in a common structural motif. This is the case for the heptad repeats that form coiled coils. However, it is also possible for seemingly unrelated amino acid sequences to fold into a common structural motif, so it is not always possible to predict which amino acid sequences will fold into a given structural motif. Conversely, it is possible that a commonly occurring sequence motif will not fold into a well-defined structural motif. Sometimes short sequence motifs that have an unusual abundance of a particular amino acid, such as proline or aspartate or glutamate, are called “domains”; however, these

In calcium-binding proteins such as calmodulin, oxygen atoms from five residues in the acidic glutamate- and aspartate-rich loop and one water molecule form ionic bonds with a  $\text{Ca}^{2+}$  ion. (c) The zinc-finger motif is present in many DNA-binding proteins that help regulate transcription. A  $\text{Zn}^{2+}$  ion is held between a pair of  $\beta$  strands (blue) and a single  $\alpha$  helix (red) by a pair of cysteine residues and a pair of histidine residues. The two invariant cysteine residues are usually at positions 3 and 6, and the two invariant histidine residues are at positions 20 and 24 in this 25-residue motif. [Part (a) data from L. Gonzalez, Jr., D. N. Woolfson, and T. Alber, 1996, *Nat. Struct. Biol.* **3**:1011–1018, PDB IDs 1zik and 2tma. Part (b) data from R. Chattopadhyaya et al., 1992, *J. Mol. Biol.* **228**:1177–1192, PDB ID 1cll. Part (c) data from S. A. Wolfe, R. A. Grant, and C. O. Pabo, 2003, *Biochemistry* **42**:13401–13409, PDB ID 1llm.]

and other short contiguous segments are more appropriately called “sequence motifs” than “domains,” as the latter term has a distinct meaning that we will define shortly.

We will encounter numerous additional motifs in our discussions of proteins in this and other chapters. The presence of the same structural motif in different proteins with similar functions clearly indicates that these useful combinations of secondary structures have been conserved in evolution.

## Domains Are Modules of Tertiary Structure

Distinct regions of protein structure are often referred to as **domains**. There are three main classes of protein domains: functional, structural, and topological. A *functional domain* is a region of a protein that exhibits a particular activity characteristic of that protein, usually even when isolated from the rest of the protein. For instance, a particular region of a protein may be responsible for its catalytic activity (e.g., a kinase domain that covalently adds a phosphate group to another molecule) or its binding ability (e.g., a DNA-binding domain or a membrane-binding domain). Functional domains are often identified experimentally by whittling down a protein to its smallest active fragment with the aid of proteases,

**FIGURE 3-11 Tertiary and quaternary levels of structure.** The protein pictured here, hemagglutinin (HA), is found on the surface of the influenza virus. This long multimeric molecule has three identical subunits, each composed of two polypeptide chains, HA<sub>1</sub> and HA<sub>2</sub>. (a) The tertiary structure of each HA subunit comprises the folding of its helices and strands into a compact structure that is 13.5 nm long and divided into two domains. The membrane-distal domain (silver) is folded into a globular conformation. The membrane-proximal domain (gold) has a fibrous, stemlike conformation owing to the alignment of two long  $\alpha$  helices (cylinders) of HA<sub>2</sub> with  $\beta$  strands in HA<sub>1</sub>. Short turns and longer loops, many of them at the surface of the molecule, connect the helices and strands in each chain. (b) The quaternary structure of HA is stabilized by lateral interactions between the long helices (cylinders) in the fibrous domains of the three subunits (gold, blue, and green), forming a triple-stranded coiled-coil stalk. Each of the distal globular domains in HA binds sialic acid (red) on the surface of target cells. Like many membrane proteins, HA contains several covalently linked carbohydrate chains (not shown). [Data from S. J. Gamblin et al., 2004, *Science* **303**:1838–1842, PDB ID 1ruz.]

enzymes that cleave one or more peptide bonds in a target polypeptide. Alternatively, the DNA encoding a protein can be modified so that when the modified DNA is used to generate a protein, only a particular region, or domain, of the full-length protein is made. Thus it is possible to determine if specific parts of a protein are responsible for particular activities exhibited by the protein. Indeed, functional domains are often also associated with corresponding structural domains.

A *structural domain* is a region about 40 or more amino acids in length, arranged in a single, stable, and distinct structure often comprising one or more secondary structures. Many structural domains can fold into their characteristic structures independently of the rest of the protein in which they are embedded. As a consequence, distinct structural domains can be linked together—sometimes by short or long spacers—to form a large multidomain protein. Each of the polypeptide chains in the trimeric flu virus hemagglutinin, for example, contains a globular domain and a fibrous domain (Figure 3-11a). Structural domains can be incorporated as modules into different proteins. The modular approach to protein architecture is particularly easy to recognize in large proteins, which tend to be mosaics of different domains that confer distinct activities and thus can perform different functions simultaneously. As many as 75 percent of the proteins in eukaryotes have multiple structural domains. Structural domains frequently are also functional domains in that they can have an activity independent of the rest of the protein.

The epidermal growth factor (EGF) domain is a structural domain that is present in several proteins (Figure 3-12). EGF

is a small, soluble peptide hormone that binds to cells in the embryo and in skin and connective tissue in adults, causing them to divide. It is generated by proteolytic cleavage (breaking of a peptide bond) between repeated EGF domains in the EGF precursor protein, which is anchored in the plasma membrane by a membrane-spanning domain. EGF domains with sequences similar to, but not identical to, that of the EGF peptide hormone are present in other proteins and can be liberated by proteolysis. These proteins include tissue plasminogen activator (TPA), a protease that is used to dissolve blood

**FIGURE 3-12 Modular nature of protein domains.** Epidermal growth factor (EGF) is generated by proteolytic cleavage of a precursor protein containing multiple EGF domains (green) and a membrane-spanning domain (blue). An EGF domain is also present in the Neu protein and in tissue plasminogen activator (TPA). These proteins also contain other widely distributed domains, indicated by shape and color. See I. D. Campbell and P. Bork, 1993, *Curr. Opin. Struc. Biol.* **3**:385.

clots in heart attack victims; Neu protein, which takes part in embryonic differentiation; and Notch protein, a receptor protein in the plasma membrane that functions in developmentally important signaling (see Chapter 16). Besides the EGF domain, these proteins have other domains in common with other proteins. For example, TPA possesses a trypsin domain, a functional domain found in some proteases. It is estimated that there are about a thousand different types of structural domains in all proteins. Some of these are not very common, whereas others are found in many different proteins. Indeed, by some estimates, only nine major types of structural domains account for as much as a third of all the structural domains in all proteins. Structural domains can be recognized in proteins whose structures have been determined by x-ray crystallography or nuclear magnetic resonance (NMR) analysis or in images captured by electron microscopy.

Regions of proteins that are defined by their distinctive spatial relationships to the rest of the protein are *topological domains*. For example, some proteins associated with cell-surface membranes have a part extending inward into the cytoplasm (cytoplasmic domain), a part embedded within the phospholipid bilayer (membrane-spanning domain), and a part extending outward into the extracellular space (extracellular domain). Each of these parts can comprise one or more structural and functional domains.

In Chapter 8, we will consider the mechanism by which the gene segments that correspond to domains became shuffled in the course of evolution, resulting in their appearance in many proteins. Once a functional, structural, or topological domain has been identified and characterized in one protein, it is possible to use that information to search for similar domains in other proteins and to suggest potentially similar functions for those domains in those proteins.

## Multiple Polypeptides Assemble into Quaternary Structures and Supramolecular Complexes

**Multimeric** proteins consist of two or more polypeptide chains, which in this context are referred to as *subunits*. A fourth level of structural organization, **quaternary structure**, describes the number (stoichiometry) and relative positions of the subunits in multimeric proteins (Figure 3-2). Flu virus hemagglutinin, for example, is a trimer of three identical subunits (a homotrimer) held together by noncovalent bonds (Figure 3-11b). Other multimeric proteins are composed of various numbers of identical (homomeric) or different (heteromeric) subunits. Hemoglobin, the oxygen-carrying molecule in blood, is an example of a heteromeric multimeric protein, as it has two copies each of two different polypeptide chains (as discussed below). In many cases, the individual monomer subunits of a multimeric protein cannot function normally unless they are assembled into the multimeric protein. In other cases, assembly into a multimeric protein permits proteins that act sequentially in a pathway to increase their efficiency of operation owing to their juxtaposition in space, a phenomenon referred to as *metabolic coupling*. Classic examples of metabolic coupling are the fatty acid synthases, the enzymes in fungi that synthesize fatty acids, and the polyketide synthases,

the large multiprotein complexes in bacteria that synthesize a diverse set of pharmacologically relevant molecules called polyketides, including the antibiotic erythromycin.

The highest level in the hierarchy of protein structure is the association of proteins into supramolecular complexes. Typically, such structures are very large, in some cases exceeding 1 megadalton (MDa) in mass, approaching 30–300 nm in size, and containing tens to hundreds of polypeptide chains and sometimes other biopolymers such as nucleic acids. The capsid that encases the nucleic acids of the viral genome is an example of a supramolecular complex with a structural function. The bundles of cytoskeletal filaments that support and give shape to the plasma membrane are another example. Other supramolecular complexes act as molecular machines, carrying out the most complex cellular processes by integrating multiple proteins, each with distinct functions, into one large assembly. For example, a transcriptional machine is responsible for synthesizing messenger RNA (mRNA) using a DNA template. This transcriptional

**FIGURE 3-13 A molecular machine: the transcription initiation complex.** The core RNA polymerase, general transcription factors, a mediator complex containing about 20 subunits, and other protein complexes not depicted here assemble at a promoter in DNA. The polymerase carries out transcription of DNA; the associated proteins are required for initial binding of the polymerase to a specific promoter. The multiple components function together as a molecular machine.

machine, the operational details of which are discussed in Chapters 5 and 9, consists of RNA polymerase, itself a multimeric protein, and at least 50 additional components, including general transcription factors, promoter-binding proteins, helicase, and other protein complexes (Figure 3-13). Ribosomes, also discussed in Chapter 5, are complex multiprotein and multi-nucleic acid machines that synthesize proteins. One of the most complex multiprotein assemblies is the nuclear pore, a structure that allows communication and passage of macromolecules between the nucleus and the cytoplasm (see Chapter 14). It is composed of multiple copies of about 30 distinct proteins and forms an assembly with an estimated mass of 50 MDa. The fatty acid synthases and polyketide synthases referred to above are also molecular machines.

### Comparing Protein Sequences and Structures Provides Insight into Protein Function and Evolution

Analyses of many diverse proteins have conclusively established a relation between the amino acid sequence, three-dimensional structure, and function of proteins. One of the earliest examples involved a comparison of two oxygen-carrying proteins: myoglobin in muscle and hemoglobin in red blood cells. Myoglobin—a monomer (consisting of one polypeptide chain/protein molecule)—and hemoglobin—a

tetramer (consisting of two  $\alpha$  and two  $\beta$  polypeptides, or subunits, per protein)—both contain a heme group noncovalently attached to each polypeptide chain (Figure 3-14a). The heme group binds oxygen. A mutation in the gene encoding the  $\beta$  chain of hemoglobin that results in the substitution of a valine for a glutamic acid disturbs this protein's folding and function and causes sickle-cell disease (also called sickle-cell anemia). The properly aligned sequences of the 141-residue myoglobin and the 153-residue  $\beta$  subunit of hemoglobin have 40 residues in equivalent positions in the sequences that are identical and another 21 that have side chains that are chemically very similar. This high degree of identity and similarity (43 percent of the myoglobin residues) is consistent with their similar oxygen-binding functions. X-ray crystallographic analysis showed that the three-dimensional structures of myoglobin and of the  $\alpha$  and  $\beta$  subunits of hemoglobin, as well as that of the evolutionarily distant oxygen-carrying leghemoglobin from plants, are remarkably similar (see Figure 3-14a).

A good rule of thumb is that the greater the similarity of the sequences of two polypeptide chains, the more likely they are to have similar three-dimensional structures and similar functions. While this comparative approach is very powerful, caution must always be exercised when attributing to one protein, or a part of a protein, a function or structure similar to that of another protein based only on amino acid sequence

**FIGURE 3-14 Evolution of the globin protein family.**

(a) Hemoglobin is a tetramer of two  $\alpha$  and two  $\beta$  subunits. The structural similarity of these subunits to leghemoglobin and myoglobin, both of which are monomers, is evident. A heme molecule (red) noncovalently associated with each globin polypeptide is directly responsible for oxygen binding in these proteins. (b) A primitive monomeric oxygen-binding globin is thought to be the ancestor of modern-day blood hemoglobins, muscle myoglobins, and plant leghemoglobins. Sequence comparisons have revealed that the evolution of the globin

proteins parallels the evolution of animals and plants. Major changes occurred with the divergence of plant globins from animal globins and of myoglobin from hemoglobin. Later, gene duplication gave rise to the  $\alpha$  and  $\beta$  subunits of hemoglobin. See R. C. Hardison, 1996, *P. Natl. Acad. Sci. USA* **93**:5675. [Part (a) data from G. Fermi et al., 1984, *J. Mol. Biol.* **175**:159–174, PDB ID 2hbb (hemoglobin), H. C. Watson, 1969, *Prog. Stereochem.* **4**:299, PDB ID 1mbn (myoglobin), and M. S. Hargrove et al., 1997, *J. Mol. Biol.* **266**:1032–1042, PDB ID 1bin (leghemoglobin).]

similarities. There are examples in which proteins with similar overall structures display different functions, as well as cases in which functionally unrelated proteins with dissimilar amino acid sequences nevertheless have very similar folded tertiary structures, as will be explained below. Nevertheless, in many cases, such comparisons of sequences provide important insights into protein structure and function.

Use of sequence comparisons to deduce protein structure and function has expanded substantially in recent years as the genomes and messenger RNAs of more and more organisms have been sequenced, permitting a vast array of protein sequences to be deduced. Indeed, the molecular revolution in biology during the last decades of the twentieth century created a new scheme of biological classification based on similarities and differences in the amino acid sequences of proteins. Proteins that have a common ancestor are referred to as **homologs**. The main evidence for **homology** among proteins, and hence for their common ancestry, is similarity in their sequences, which is often reflected in similar structures. We can describe homologous proteins as belonging to a “family” and can trace their lineage—how closely or distantly they are related to one another in an evolutionary sense—from comparisons of their sequences. Generally, more closely related proteins exhibit greater sequence similarity than more distantly related proteins because, over evolutionary time, mutations accumulate in the genes encoding these proteins. The folded three-dimensional structures of homologous proteins may be similar even if some parts of their primary structure show little evidence of sequence homology. Initially, proteins with relatively high sequence similarities (>50 percent exact amino acid matches, or “identities”) and related functions or structures were defined as an evolutionarily related *family*, while a *superfamily* encompassed two or more families in which the interfamily sequences matched less well (~30–40 percent identities) than within one family. It is generally thought that proteins with about 30 percent sequence identity are likely to have similar three-dimensional structures; however, such high sequence identity is not required for proteins to share similar structures. Revised definitions of *family* and *superfamily* have been proposed, in which a family comprises proteins with a clear evolutionary relationship (>30 percent identity or additional structural and functional information showing common descent but <30 percent identity), while a superfamily comprises proteins with only a probable common evolutionary origin—for example, lower sequence identities but one or more common motifs or domains.

The kinship among homologous proteins is most easily visualized by a tree diagram based on sequence analyses. For example, the amino acid sequences of globins—the proteins hemoglobin and myoglobin and their relatives from bacteria, plants, and animals—suggest that they evolved from an ancestral monomeric oxygen-binding protein (Figure 3-14b). With the passage of time, the gene for this ancestral protein slowly changed, initially diverging into lineages leading to animal and plant globins. Subsequent changes gave rise to myoglobin and to the  $\alpha$  and  $\beta$  subunits of the tetrameric hemoglobin molecule ( $\alpha_2\beta_2$ ) of the vertebrate circulatory system.

## KEY CONCEPTS OF SECTION 3.1

### Hierarchical Structure of Proteins

- Proteins are linear polymers of amino acids linked together by peptide bonds. A protein can have a single polypeptide chain or multiple polypeptide chains. The primary structure of a polypeptide chain is the sequence of covalently linked amino acids that compose the chain. Various, mostly noncovalent interactions between amino acids in the linear sequence stabilize a protein's specific folded three-dimensional structure, or conformation.
- The  $\alpha$  helix,  $\beta$  strand and sheet, and  $\beta$  turn are the most prevalent elements of protein secondary structure. Secondary structures are stabilized by hydrogen bonds between atoms of the peptide backbone (see Figures 3-4–3-6).
- Protein tertiary structure results from hydrophobic interactions between nonpolar side groups and from hydrogen bonds and ionic interactions involving polar side groups and the polypeptide backbone. These interactions stabilize the folding of the protein, including its secondary structural elements, into an overall three-dimensional arrangement.
- Entire proteins or segments of proteins usually fall into one of four broad structural categories: globular proteins, fibrous proteins, integral membrane proteins, and intrinsically disordered proteins.
- The exceptional conformational flexibilities of intrinsically disordered proteins contribute to their functions as binding partners, signaling molecules, regulators of other molecules, scaffolds, flexible links between well-ordered regions of a protein, sites of post-translational protein modification, autoinhibitors, and signals for intracellular protein sorting.
- Certain combinations of secondary structures give rise to structural motifs, which are found in a variety of proteins and are often associated with specific functions (see Figure 3-10).
- Proteins often contain distinct domains, independently folded regions with characteristic structural, functional, and/or topological properties.
- The incorporation of domains as modules in different proteins in the course of evolution has generated diversity in protein structure and function.
- The number and organization of individual polypeptide subunits in multimeric proteins define their quaternary structure.
- Cells contain large supramolecular assemblies, sometimes called molecular machines, in which all the necessary participants in complex cellular processes (e.g., DNA, RNA, and protein synthesis; photosynthesis; signal transduction) are bound together.
- Proteins with similar amino acid sequences generally can be assumed to have similar three-dimensional structures and similar functions. There are also examples of polypeptide chains with dissimilar sequences folding into similar three-dimensional structures.

- Homologous proteins are proteins that evolved from a common ancestor and thus have similar sequences, structures, and functions. They can be classified into families and superfamilies.

## 3.2 Protein Folding

As noted above, when it comes to the architecture of proteins, “form follows function.” Thus it is essential that a polypeptide be synthesized with the proper amino acid sequence, and that it fold into the proper three-dimensional conformation, with the appropriate secondary, tertiary, and possibly quaternary structure, if it is to fulfill its biological role within or outside cells. How is a protein with a proper sequence generated? A polypeptide chain is synthesized by a complex process called **translation**, which occurs in the cytoplasm on a large protein–nucleic acid complex called a **ribosome**. During translation, a sequence of **messenger RNA (mRNA)** serves as a template for the assembly of a corresponding amino acid sequence. The mRNA is initially generated by a process called **transcription**, whereby a nucleotide sequence in DNA is converted, by transcriptional machinery in the nucleus, into a sequence of mRNA. The intricacies of transcription and translation are considered in Chapter 5. Here we describe the key determinants of the proper folding of a newly formed or forming (nascent) polypeptide chain as it emerges from the ribosome.

### Planar Peptide Bonds Limit the Shapes into Which Proteins Can Fold

A critical structural feature of polypeptides that limits how the chain can fold is the planar structure of the peptide bond. Figure 3-3 illustrates the amide group in peptide bonds in a polypeptide chain. Because the peptide bond itself behaves somewhat like a planar double bond (*center and right*),

the portions of the polypeptide chain on either side of the peptide bond ( $\text{P}_1$  and  $\text{P}_2$ ) can be oriented in either a *trans* (*center*) or *cis* (*right*) configuration relative to the peptide bond. We saw similar *cis* and *trans* isomers of carbon–carbon double bonds in unsaturated fatty acids in Chapter 2. Analysis of crystal structures indicates that in proteins, about 99.97 percent of the peptide bonds that have any residue other than proline at  $\text{P}_2$  are in the *trans* configuration. (We will consider those with proline at  $\text{P}_2$  shortly.) In a peptide bond, the carbonyl carbon and amide nitrogen and those atoms directly bonded to them must all lie in a fixed plane (Figure 3-15); little rotation about the peptide bond itself is possible. As a consequence, the only flexibility in a polypeptide chain, allowing it to twist and turn—and thus fold into different three-dimensional

**FIGURE 3-15 Rotation between planar peptide groups in proteins.** Rotation about the  $\text{C}_\alpha$ –amino nitrogen bond (the  $\Phi$  angle) and the  $\text{C}_\alpha$ –carbonyl carbon bond (the  $\Psi$  angle) permits polypeptide backbones, in principle, to adopt a very large number of potential conformations. However, steric restraints due to the structure of the polypeptide backbone and the properties of the amino acid side chains dramatically restrict the potential conformations that any given protein can assume.

shapes—is rotation of the fixed planes of adjacent peptide bonds with respect to one another about two bonds: the  $\text{C}_\alpha$ –amino nitrogen bond (rotational angle called  $\Phi$ ) and the  $\text{C}_\alpha$ –carbonyl carbon bond (rotational angle called  $\Psi$ ).

Yet a further constraint on the potential conformations that a polypeptide chain can adopt is the fact that only a limited number of  $\Phi$  and  $\Psi$  angles are possible because for most  $\Phi$  and  $\Psi$  angles, the backbone or side-chain atoms would come too close to one another, and thus the associated conformation would be highly unstable or even physiologically impossible to achieve.

### The Amino Acid Sequence of a Protein Determines How It Will Fold

While the constraints of backbone bond angles seem very restrictive, any polypeptide chain containing only a few residues could, in principle, still fold into many conformations. For example, if the  $\Phi$  and  $\Psi$  angles were limited to only eight combinations, an  $n$ -residue-long peptide would potentially have  $8^n$  conformations; for even a small polypeptide of only 10 residues, that’s about 8.6 million possible conformations! In general, however, the native state of any particular protein that is not intrinsically disordered adopts only one or a few very closely related conformations; for the vast majority of these proteins, the native state is a stably folded form of the molecule and the one that permits it to function normally. In thermodynamic terms, the native state is usually the conformation with the lowest free energy ( $G$ ) (see Chapter 2).

What features of natively well-ordered proteins limit their folding from so many potential conformations to just one or a few? The properties of the side chains (e.g., size, hydrophobicity, ability to form hydrogen and ionic bonds), together with their particular sequence along the polypeptide backbone, impose key restrictions. For example, a large side chain, such as that of tryptophan, might sterically block

one region of the chain from packing closely against another region, whereas a side chain with a positive charge, such as that of arginine, might attract a segment of the polypeptide that has a complementary negatively charged side chain (e.g., aspartic acid). Another example we have already discussed is the effect of the aliphatic side chains in heptad repeats in promoting the association of helices and the consequent formation of coiled coils. Thus a polypeptide's primary structure determines its secondary, tertiary, and quaternary structures.

The initial evidence that the information necessary for a protein to fold properly is encoded in its amino acid sequence came from *in vitro* studies (in test tubes) on the refolding of purified proteins, especially the Nobel Prize-winning studies in the 1960s by Christian Anfinsen of the refolding of ribonuclease A, an enzyme that cleaves RNA. Others had previously shown that various chemical and physical perturbations can disrupt the weak noncovalent interactions that stabilize the native conformation of a protein, leading to the loss of its normal tertiary structure. The disruption of a protein's structure (and this can include secondary as well as tertiary structure) is called **denaturation**. Denaturation can be induced by thermal energy from heat, extremes of pH that alter the charges on amino acid side chains, or exposure to *denaturants* such as urea or guanidine hydrochloride at concentrations of 6–8 M, all of which disrupt structure-stabilizing noncovalent interactions. Treatment with reducing agents, such as  $\beta$ -mercaptoethanol, that break disulfide bonds can further destabilize disulfide-containing proteins. Under denaturing conditions, a population of uniformly folded protein molecules is destabilized and converted into a collection of many unfolded, or denatured, molecules that have many different non-native and biologically inactive conformations. As we have seen, a large number of possible non-native conformations exist (e.g.,  $8^n - 1$ ). There are two broad classes of non-native conformations seen in proteins: (1) monomeric unfolded or denatured structures and (2) aggregates, which can either be amorphous or have a well-organized structure, as is the case for the disease-associated amyloid fibrils described later in this chapter. In principle, aggregates can comprise many copies of a single protein (homogeneous aggregates) or contain a mixture of distinct proteins (heterogeneous aggregates).

The spontaneous unfolding of proteins under denaturing conditions is not surprising, given the substantial increase in entropy that occurs because a denatured protein can adopt many non-native conformations (increased disorder). What is striking, however, is that when a pure sample of a single type of unfolded protein in a test tube is shifted back very carefully to normal conditions (body temperature, normal pH levels, reduction in the concentration of denaturants), some denatured polypeptides can spontaneously refold into their native, biologically active states, as in Anfinsen's experiments. This kind of refolding experiment, as well as studies showing that synthetic proteins made chemically can fold properly, established that the information contained in a protein's primary structure can be sufficient to direct correct refolding. Newly synthesized proteins appear to fold into their proper conformations just as denatured proteins

**FIGURE 3-16 Hypothetical protein-folding pathway.** Folding of a monomeric protein follows the structural hierarchy of primary (a) → secondary (b–d) → tertiary (e) structure. Formation of small structural motifs (c) appears to precede formation of domains (d) and the final tertiary structure (e).

do. The observed similarity in the folded, three-dimensional structures of proteins with similar amino acid sequences, noted in Section 3.1, provided additional evidence that the primary sequence also determines protein folding *in vivo* (in live organisms). It appears that formation of secondary structures and structural motifs occurs early in the folding process, followed by assembly of more complex structural domains, which then associate into more complex tertiary and quaternary structures (Figure 3-16).

### Folding of Proteins in Vivo Is Promoted by Chaperones

The conditions under which a purified, denatured protein refolds in a test tube differ markedly from the conditions

under which a newly synthesized polypeptide folds in a cell. The presence of other biomolecules, some of which are themselves nascent and in the process of folding, can potentially interfere with the autonomous, spontaneous folding of an otherwise natively well-ordered protein by forming aggregates. The cytosolic concentrations of some proteins are very high, and the total cytosolic protein concentration can be ~300 mg/ml in mammalian cells. These high protein concentrations favor aggregate formation by increasing the chances a nascent protein will encounter other proteins prior to completing its folding. Unfolded and partly folded proteins tend to aggregate into large, often water-insoluble masses, from which it is extremely difficult for a protein to dissociate and then fold into its proper conformation. In part, this aggregation is due to the exposure of hydrophobic side chains that have not yet had a chance to be buried in the inner core of the folded protein. Exposed hydrophobic side chains on different molecules will stick to one another, owing to the hydrophobic effect (see Chapter 2), and thus promote aggregation. The risk of such aggregation is especially high for newly synthesized proteins that have not yet completed their proper folding. Intrinsically disordered proteins are much less likely to form aggregates because, at least in some cases, they have relatively fewer hydrophobic side chains that can mediate such aggregation. Although protein folding into a well-ordered native state can occur *in vitro*, this does not happen for all unfolded molecules in a timely fashion because of the very large number of potentially incorrect, intermediate conformations into which the protein might fold.

Given such impediments, cells require faster, more efficient mechanisms for folding natively well-ordered proteins into their correct shapes than sequence alone provides. Without such help, cells might waste much energy in the synthesis of improperly folded, nonfunctional proteins, which would have to be destroyed to prevent their disrupting cell function. Cells clearly have such mechanisms, since more than 95 percent of the proteins present within cells have been shown to be in their native conformations. Proteins that do not or cannot fold properly—for example, those encoded by genes with mutations that alter the amino acid sequence—are often recognized as unfolded and rapidly degraded (hydrolyzed) by enzymes. The explanation for the cell's remarkable efficiency in promoting proper protein folding is that cells make a set of proteins, called **chaperones**, that facilitate proper folding of nascent proteins. One way chaperones facilitate proper folding is to prevent aggregation by binding to the target polypeptide or sequestering it from other partially or fully unfolded proteins, thus giving the nascent protein time to fold properly. The importance of chaperones is highlighted by the observation that many are evolutionarily conserved. Chaperones are found in all organisms from bacteria to humans, and some are homologs with high sequence similarity that use almost identical mechanisms to assist protein folding.

Chaperones can fold newly made proteins into functional conformations, refold misfolded or unfolded proteins into functional conformations, disassemble potentially toxic protein aggregates that form due to protein misfolding,

assemble and dismantle large multiprotein complexes, and mediate transformations between inactive and active forms of some proteins. Chaperones, which in eukaryotes are located in every cellular compartment and organelle, bind to the target proteins—also called substrates or client proteins—whose folding they will assist. Chaperones use a cycle of ATP binding, ATP hydrolysis to ADP, and exchange of a new ATP molecule for the ADP to induce a series of conformational changes that are essential for their function. There are several different classes of chaperones with distinct structures, all of which use ATP binding and hydrolysis in a variety of ways, which include (1) enhancing the binding of the target protein and (2) switching their own conformation. This ATP-dependent conformational switching is used (1) to optimize folding, (2) to return the chaperone to its initial state so that it is available to help fold another molecule, and (3) to set the time permitted for refolding, which can be determined by the rate of ATP hydrolysis.

Two general families of chaperones have been identified:

- **Molecular chaperones**, which bind to a short segment of a protein substrate and stabilize unfolded or partly folded proteins, thereby preventing these proteins from aggregating and being degraded.
- **Chaperonins**, which form folding chambers into which all or part of an unfolded protein can be sequestered, giving it time and an appropriate environment to fold properly.

**Molecular Chaperones** The heat-shock protein Hsp70 in the cytosol and its homologs (Hsp70 in the mitochondrial matrix, BiP in the endoplasmic reticulum, and DnaK in bacteria) are molecular chaperones. They were first identified by their rapid appearance after a cell had been stressed by heat shock (*Hsp* stands for “heat-shock protein”). Hsp70 and its homologs are the major chaperones in all organisms that use an ATP-dependent cycle to fold their substrates (Figure 3-17a). When bound to ATP, the monomeric Hsp70 protein assumes an open conformation, in which an exposed hydrophobic substrate-binding pocket transiently binds to exposed hydrophobic regions of an incompletely folded or partially denatured target protein, and then rapidly releases this substrate, as long as ATP is bound (step **1** in Figure 3-17a). Hydrolysis of the bound ATP causes the molecular chaperone to assume a closed form that binds its substrate protein much more tightly, and this tighter binding appears to facilitate the target protein's folding, in part by preventing it from aggregating with other unfolded proteins (step **2** in Figure 3-17a). Next the exchange of ATP for the chaperone-bound ADP (step **3**) causes a conformational change in the chaperone that releases the target protein and regenerates an “empty,” ATP-bound Hsp70 ready to help fold another protein (step **4**). If the target is now properly folded, it cannot rebind to an Hsp70. If it remains at least partially unfolded, it can bind again to give a chaperone another chance to help fold it properly. As we will see later in this chapter, a variety of proteins use a cycle of trinucleotide hydrolysis to a dinucleotide, followed by

**FIGURE 3-17 Molecular chaperone-mediated protein folding.**

(a) Hsp70. Many proteins fold into their proper three-dimensional structures with the assistance of Hsp70 or one of several Hsp70-like proteins. These molecular chaperones transiently bind to a nascent polypeptide as it emerges from a ribosome or to a protein that has otherwise unfolded. In the Hsp70 cycle, an unfolded substrate protein binds in rapid equilibrium (step **1**) to Hsp70's substrate-binding site (red) in the open conformation of its substrate-binding domain (light and dark orange) when an ATP (purple) is bound at Hsp70's nucleotide-binding domain (light blue). The substrate-binding domain comprises two subdomains (light and dark orange) that change relative positions and conformations during the cycle. Co-chaperone accessory proteins (DnaJ/Hsp40) stimulate the hydrolysis of ATP to ADP (yellow) that induces a large conformational change in the substrate-binding domain, resulting in the closed conformation, in which the substrate is locked into the substrate-binding domain; here proper folding is facilitated (steps **2** and **3**). Exchange of ATP for the bound ADP, stimulated by other accessory co-chaperone proteins (GrpE/BAG1), converts the Hsp70 back to the open conformation (step **4**), releasing the properly folded substrate (step **5**) and regenerating the open conformation, which can then interact with additional substrates. (b) Three conformational states of the dimeric Hsp90 molecular chaperone thought to be involved in substrate (also called client) remodeling. Client proteins bind at the substrate-binding

site (red surface) shared by the substrate-binding (orange) and C-terminal dimerization (white) domains and are thought to be remodeled in response to ATP binding and hydrolysis. The Hsp90 cycle begins when there is no nucleotide bound to the nucleotide-binding domains (light blue) and the dimer is in a very flexible, open configuration (step **1**) that can bind a client. Rapid ATP binding leads to a conformational change (step **2**) in which the nucleotide-binding domains and the substrate-binding domains move together (intermediate shown in step **3**) into a closed conformation in which the nucleotide-binding domains are dimerized (step **4**). The precise locations in Hsp90 at which clients bind apparently vary for different clients, but the binding surface, including the intersection of the substrate-binding domains and C-terminal dimerization domains (highlighted by red shading) binds a number of clients. ATP hydrolysis results in a conformational change in Hsp90 (step **5**) that may include a highly compact form, folding of the client, and client protein release. The ADP-bound form of Hsp90 can adopt several conformations, including a highly compact form. Release of ADP (step **6**) regenerates the initial flexible open state, which can then interact with additional clients. See E. D. Kirschke et al., 2014, *Cell* **157**:1685 and M. Taipale, D. F. Jarosz, and S. Lindquist, 2010, *Nat. Rev. Mol. Cell Biol.* **11**:515. [Solvent-accessible surface model of HSP90 courtesy of Elaine Kirschke and David A. Agard, UCSF. Open (ATP) PDB ID 2ior, closed (ATP) PDB ID 2cg9, closed (ADP) based on PDB ID 2cg9.]

dinucleotide/trinucleotide exchange, to control their activities. Later in this chapter, we will discuss a group of proteins called GTPases that depend on the exchange of GTP, rather than ATP, for bound GDP (instead of ADP) to induce conformational changes that dramatically influence the proteins' activities and the subsequent hydrolysis of the bound GTP to GDP.

Additional proteins, such as the co-chaperone Hsp40 in eukaryotes (DnaJ in bacteria), help increase the efficiency of the Hsp70-mediated folding of many proteins not only by stimulating the binding of substrate, but also by increasing the rate of hydrolysis of ATP by 100- to 1000-fold (see step **2** in Figure 3-17a). Members of four different families of nucleotide

exchange factors (e.g., GrpE in bacteria; BAG, HspBP, and Hsp110 in eukaryotes) also interact with Hsp70 (or DnaK), promoting the exchange of ATP for ADP (see step 3). Multiple molecular chaperones are thought to bind to all nascent polypeptide chains as they are being synthesized on ribosomes. In bacteria, 85 percent of the proteins are released from their chaperones and proceed to fold normally; an even higher percentage of proteins in eukaryotes follow this pathway.

The Hsp70 protein family is not the only class of molecular chaperones. Another distinct class of molecular chaperones is the Hsp90 family, whose members usually recognize partially folded substrate proteins. Evolutionarily related Hsp90 family members are present in all organisms except archaea. Their strong evolutionary conservation is seen in the high amino acid sequence similarity (55 percent) of the Hsp90 from the bacterium *E. coli* and human Hsp90. In most eukaryotes, there are four distinct Hsp90s, two of which are in the cytosol (at 1–2 percent of total protein, Hsp90 is one of the most abundant cytosolic proteins) and one each in the endoplasmic reticulum and the mitochondrion. Although the range of protein substrates for Hsp90 chaperones is not as broad as for some other chaperones (at least 10 percent of yeast proteins are thought to be Hsp90 substrates), the Hsp90s are essential in eukaryotes. The Hsp90s help cells cope with denatured proteins generated by stress (e.g., heat shock), and they ensure that some of their substrates, usually called “clients,” can be converted from an inactive to an active state or otherwise held in a functional conformation. In some cases, an Hsp90 forms a relatively stable complex with a client until an appropriate signal causes its dissociation from the client, freeing the client to perform some regulated function in the cell. Hsp90 clients include transcription factors such as the receptors for the steroid hormones estrogen and testosterone. These steroid receptors regulate sexual development and function by controlling the activities of many genes (see Chapter 9). Another type of Hsp90 client is the set of enzymes called kinases, which control the activities of many proteins by phosphorylation (see Chapters 15 and 16).

Unlike monomeric Hsp70, Hsp90 functions as a dimer in a cycle in which ATP binding, hydrolysis, and ADP release are coupled to major conformational changes and to binding, folding or activation, and release of clients (Figure 3-17b). Although much about the mechanism of Hsp90 remains to be learned, it is clear that clients bind to the substrate-binding domains when the chaperone is in the “open” conformation (step 1 in Figure 3-17b), that ATP binding leads to interaction of the ATP-binding domains and formation of a “closed” conformation (steps 1 and 2 in Figure 3-17b), and that hydrolysis of ATP plays an important role in activation of some client proteins and their subsequent release from the Hsp90 (step 3). We also know that there are at least 20 co-chaperones that can have profound effects on the activity of Hsp90, including modulating its ATPase activity and determining which proteins will be clients (client specificity). Co-chaperones can also help coordinate the activities of Hsp90 and Hsp70. For example, Hsp70 can help begin the folding of a client that is then handed off by a co-chaperone to Hsp90 for additional

processing. Hsp90 activity can also be influenced by its covalent modification by small molecules. Finally, Hsp90 can help cells recognize misfolded proteins that are unable to refold and facilitate their degradation by mechanisms discussed later in this chapter. Thus, as part of the quality-control system in cells, molecular chaperones can help properly fold proteins or facilitate the destruction of those that cannot fold properly.

**Chaperonins** The proper folding of a large variety of newly synthesized proteins also requires the assistance of another class of proteins, the chaperonins, also called Hsp60s. These huge cylindrical supramolecular assemblies are formed from two rings of oligomers. There are two distinct groups of chaperonins that differ somewhat in their structures, detailed molecular mechanisms, and locations. Group I chaperonins, found in prokaryotes, chloroplasts, and mitochondria, are composed of two rings, each having seven subunits that interact with a homoheptameric co-chaperone “lid.” The bacteria group I chaperonin, known as GroEL/GroES, is shown in Figure 3-18a. In the bacterium *E. coli*, GroEL is thought to participate in the folding of about 10 percent of all proteins. Group II chaperonins, which are found in the cytosol of eukaryotic cells (e.g., TriC in mammals) and in archaea, can have eight to nine either homomeric or heteromeric subunits in each ring, and the “lid” function is incorporated into those subunits themselves—no separate lid protein is needed. It appears that ATP hydrolysis triggers the closing of the lid of group II chaperonins.

Figure 3-18b illustrates the GroEL/GroES cycle of protein folding. A partially folded or misfolded polypeptide of less than 60 kDa in mass is captured by hydrophobic residues near the entrance of the GroEL chamber and enters one of the folding chambers (upper chamber in Figure 3-18b). The second chamber is blocked by a GroES lid. Each of the 14 subunits of GroEL can bind ATP, hydrolyze it, and subsequently release ADP. These reactions are concerted for each set of seven subunits in a single ring and lead to major conformational changes. These changes control both the binding of the GroES lid that seals the chamber and the environment of the chamber in which polypeptide folding takes place. The polypeptide remains encased in the chamber capped by the lid. There it can undergo folding until ATP hydrolysis in that chamber, which is the slowest, rate-limiting step in the cycle ( $t_{1/2} \sim 10$  s), induces binding of ATP and a different GroES to the other ring. This then causes the GroES lid and ADP bound to the peptide-containing ring to be released, opening the chamber and permitting the folded protein to diffuse out of the chamber. If the polypeptide is folded properly, it can proceed to function in the cell. If it remains partially folded or misfolded, it can rebind to an unoccupied GroEL and the cycle can be repeated. There is a reciprocal relationship between the two rings in one GroEL complex. The capping of one chamber by GroES to permit sequestered substrate folding in that chamber is accompanied by the release of substrate polypeptide from the chamber of the second ring (simultaneous binding, folding, and release from the second chamber is not illustrated in Figure 3-18b). There is a striking similarity between the capped-barrel design of GroEL/GroES, in which proteins are sequestered for

**FIGURE 3-18 Chaperonin-mediated protein folding.** Proper folding of some proteins depends on chaperonins such as the prokaryotic group I chaperonin GroEL. (a) GroEL is a barrel-shaped complex of fourteen identical ~60,000-MW subunits, arranged in two stacked rings (blue) of seven subunits each that form two distinct internal polypeptide folding chambers. Homoheptameric lids (10,000-MW subunits), GroES (red), can bind to either end of the barrel and seal the chamber on that side. (b) The GroEL-GroES folding cycle. A partly folded or misfolded polypeptide enters one of the folding chambers (step **1**). The second chamber is blocked by a GroES lid. Each ring of seven GroEL subunits binds seven ATPs, hydrolyzes them, and then releases the ADPs in a set order coordinated with GroES binding and release and polypeptide binding, folding, and release. The major conformational changes that take place in the GroEL

rings control the binding of the GroES lid that seals the chamber (step **2**). The polypeptide remains encased in the chamber capped by the lid, where it can undergo folding until ATP hydrolysis—the slowest, rate-limiting step in the cycle ( $t_{1/2} \sim 10$  s) (step **3**)—induces binding of ATP and a different GroES to the other ring (transient intermediate shown in brackets). This binding then causes the GroES lid and ADP bound to the peptide-containing ring to be released, opening the chamber and permitting the folded protein to diffuse out of the chamber (step **4**). If the polypeptide has folded properly, it can proceed to function in the cell. If it remains partially folded or misfolded, it can rebind to an unoccupied GroEL and the cycle can be repeated. See D. L. Nelson and M. M. Cox, 2013, *Lehninger Principles of Biochemistry*, 6th ed., Macmillan. [Part (a) data from Z. Xu, A. L. Horwich, and P. B. Sieglar, 1997, *Nature* **388**:741–750, PDB ID 1aon.]

folding, and the structure of the 26S proteasome that participates in protein degradation (discussed in Section 3.4). In addition, a group of proteins that are part of the AAA<sup>+</sup> family of ATPases are composed of hexameric rings with a central pore into which substrates can enter for folding or unfolding or in some cases proteolysis; examples of these will be discussed in Section 3.4 and in Chapter 13.

### Protein Folding Is Promoted by Proline Isomerases

As we learned earlier, the portions of the polypeptide chain on either side of a peptide bond ( $P_1$  and  $P_2$ ) are almost always oriented in a trans configuration (Figure 3-19a).

However, the trans configuration is not dramatically more energetically favorable than a cis configuration when there is a proline at  $P_2$  (Figure 3-19b). Among those folded proteins whose structures have been determined, about 5 percent of peptide bonds with proline at  $P_2$  exhibit the cis configuration, as compared with 0.03 percent of all other peptide bonds without proline at  $P_2$ . As the rate of isomerization between the cis and trans configurations is relatively slow, cells use proline isomerase proteins to catalyze these cis/trans isomerizations to facilitate the folding with the proper isomer. Prolyl isomerizations have been proposed to act as switches to alter the conformation, and thus the activity, of already stably folded proteins. Indeed, such isomerizations can substantially alter the structure of some proteins (Figure 3-19c).

**FIGURE 3-19 Proline cis/trans isomerizations influence protein folding and structure.** (a) The planar, double bond-like character of peptide bonds leads to the potential of the portions of the polypeptide chain on either side (P<sub>1</sub> and P<sub>2</sub>) having cis or trans configurations. The trans configuration is present in about 99.97 percent of all peptide bonds in well-ordered proteins when P<sub>2</sub> is a residue other than proline. (b) When P<sub>2</sub> is proline, about 5 percent of peptide bonds are in the cis configuration. Proline isomerases catalyze the cis/trans isomerization to facilitate protein folding. (c) The structure of a portion of a protein, here an SH2 protein domain (see Chapter 16), can be dramatically altered by the cis/trans isomerization of a single proline, and this structural change can influence the protein's activity. [Part (c) trans data from E. V. Pletneva et al., 2006, *J. Mol. Biol.* **357**:550–561, PDB ID 2etz. Part (c) cis data from R. J. Mallis et al., 2002, *Nat. Struct. Biol.* **9**:900–905. ### Abnormally Folded Proteins Can Form Amyloids That Are Implicated in Diseases

After it is synthesized, a protein may fold into an alternative, abnormal three-dimensional structure as the result of mutations, inappropriate covalent modifications, or chemical (e.g., pH) or physical (e.g., heat)

alterations in its environment. Misfolding or denaturation can lead to a loss of the normal function of the protein and can result in the protein being marked for destruction (proteolytic degradation), as described later in this chapter. However, when degradation is incomplete or fails to keep pace with the production of misfolded protein, the misfolded protein or its proteolytic fragments can accumulate either inside or outside of cells in aggregates, or *plaques*, in various organs, including joints between bones, the liver, and the brain. Even those proteins or protein fragments that are normally highly resistant to aggregation, as is the case for intrinsically disordered proteins or protein fragments, will form aggregates if their concentrations are sufficiently elevated or when there are changes in environmental conditions. As noted above, such aggregates can either be amorphous or have a well-organized structure, which most commonly is the *amyloid state*. Strikingly, many diverse proteins can each aggregate into amyloid fibrils that have a common structure, called a cross- $\beta$  sheet (Figure 3-20a). Short segments, generally 6–12 residues long, in the unfolded or misfolded proteins hydrogen-bond to each other, forming a long array, or filament, of  $\beta$  sheets. In these arrays, each  $\beta$  strand is nearly perpendicular to the long axis of the filament, and two long, nearly flat  $\beta$  sheets pack closely together and twist around each other to form protofilaments, which then assemble together into thicker filaments, called *amyloid fibrils*. Within each protofilament the  $\beta$  strands can be either parallel or antiparallel (see Figure 3-5). Although some proteins form amyloid fibrils in their native, functional states, most amyloids are considered to be consequences of protein misfolding.

Amyloids were first recognized in protein aggregates that are deposited in tissues, are resistant to enzymatic degradation, and are associated with dozens of diseases, called amyloidoses. These diseases include neurodegenerative diseases such as Alzheimer's disease and Parkinson's disease in humans and transmissible spongiform encephalopathy ("mad cow" disease) in cows and sheep. Each of these diseases is characterized by the presence of filamentous plaques in a deteriorating brain (Figure 3-20b). Amyloidoses most commonly occur with aging; however, mutations in the genes encoding the aggregating protein can result in early amyloid formation and disease onset. The amyloid fibrils composing the plaques derive from abundant natural proteins. For example, fragments of the amyloid precursor protein, which is embedded in the plasma membrane, form the plaque found in the brains of patients with Alzheimer's disease; and prion protein, an "infectious" protein, forms fibrils in prion diseases. In Alzheimer's disease, a hyperphosphorylated form of the protein tau, normally a microtubule-binding protein (see Chapter 18), forms twisted fibers called "tangles." These amyloids, either as relatively short, water-soluble protofilaments or as long, insoluble fibrils, are thought to be toxic and to contribute directly to the pathology of amyloidoses. ■

**FIGURE 3-20 Misfolded proteins can form ordered amyloid aggregates based on a cross- $\beta$  sheet structure.** (a) In unfolded segments of proteins and polypeptides, exposed segments 6–12 residues long (short flat arrows) can assemble into  $\beta$  sheets (see also Figure 3-5) in which each  $\beta$  strand is oriented nearly perpendicularly to the long axis (vertical in this figure) of the resultant amyloid protofilament and hydrogen-bonded (light shading) to the strands above and below. Two long, nearly flat sheets pack closely together and twist around each other to form amyloid protofilaments, which then assemble together into thicker filaments called amyloid fibrils (b). Amyloid fibrils can be composed of varying numbers of protofilaments. A model of a four-protofilament-containing fibril fit into the electron density of acid-denatured insulin fibrils (left) and a cryoelectron microscopic image of two-protofilament-containing fibrils of fragments of transthyretin with an NMR-based model (yellow). Fibrils can aggregate into macroscopic plaques and tangles that are deposited in tissues and, when stained, are large enough to be visible using light microscopy. (c) Microscopic view of a section of human brain tissue from a patient with Alzheimer's disease with multiple amyloid plaques and fibrillary tangles. ## KEY CONCEPTS OF SECTION 3.2

### Protein Folding

- The primary structure (amino acid sequence) of a protein determines its three-dimensional structure, which determines its function. In short, function derives from structure; structure derives from sequence.
- Because protein function derives from protein structure, newly synthesized proteins must fold into the correct shape to function properly.
- The planar structure of the peptide bond limits the number of conformations a polypeptide can have (see Figure 3-15).

- The amino acid sequence of a protein dictates its folding into a specific three-dimensional conformation, the native state. Proteins will unfold, or denature, if treated under conditions that disrupt the noncovalent interactions stabilizing their three-dimensional structures.
- There are two broad classes of non-native conformations seen in misfolded or denatured proteins: (1) monomeric unfolded or denatured structures and (2) aggregates, which can either be amorphous or have a well-organized structure.
- Protein folding *in vivo* occurs with assistance from ATP-dependent chaperones. Chaperones can influence proteins in several ways, including preventing misfolding and

aggregation, facilitating proper folding, and maintaining an appropriate, stable structure required for subsequent protein activity (see Figure 3-17).

- There are two broad classes of chaperones: (1) molecular chaperones, which bind to a short segment of a substrate protein, and (2) chaperonins, which form folding chambers in which all or part of an unfolded protein can be sequestered, giving it time and an appropriate environment to fold properly. Cycles of ATP binding and hydrolysis, followed by exchange of the ADP produced with a new ATP molecule, play key roles in the mechanisms of protein folding by chaperones.
- Many misfolded or denatured proteins can form well-organized aggregates, called amyloid fibrils, made by short stretches of polypeptide that form a long array of  $\beta$  sheets nearly perpendicular to the fibril axis, called a cross- $\beta$  structure. Formation of amyloid fibrils that are resistant to degradation by diverse enzymes is associated with dozens of diseases called amyloidoses. Examples include the neurodegenerative diseases Alzheimer's disease and Parkinson's disease.

### 3.3 Protein Binding and Enzyme Catalysis

Proteins perform an extraordinarily diverse array of activities both inside and outside cells, yet most of these diverse functions are based on the ability of proteins to engage in a common activity: binding. Proteins bind to one another, to other macromolecules, to small molecules, and to ions. In this section, we describe some key features of protein binding and then turn to look at one group of proteins, enzymes, in greater detail. The activities of the other functional classes of proteins (structural, scaffold, transport, regulatory, motor) will be described in later chapters.

#### Specific Binding of Ligands Underlies the Functions of Most Proteins

The molecule to which a protein binds is called its **ligand**. In some cases, ligand binding causes a change in the shape of a protein. Such conformational changes are integral to the mechanism of action of many proteins and are important in regulating protein activity.

Two properties of a protein characterize how it binds ligands. *Specificity* refers to the ability of a protein to bind one molecule or a very small group of molecules in preference to all other molecules. *Affinity* refers to the tightness or strength of binding, usually expressed as the dissociation constant ( $K_d$ ). The  $K_d$  for a protein-ligand complex, which is the inverse of the equilibrium constant  $K_{eq}$  for the binding reaction, is the most common quantitative measure of affinity (see Chapter 2). The stronger the interaction between a protein and ligand, the lower the value of  $K_d$ . Both the specificity and the affinity of a protein for a ligand depend on the structure of the *ligand-binding site*. For high-affinity and highly specific interactions to take place, the shape and

chemical properties of the binding site must be complementary to those of the ligand molecule, a property termed **molecular complementarity**. As we saw in Chapter 2, molecular complementarity allows molecules to form multiple noncovalent interactions at close range and thus stick together.

One of the best-studied examples of protein-ligand binding, involving high affinity and exquisite specificity, is the binding of antibodies to antigens. **Antibodies** are proteins that circulate in the blood and are made by the immune system in response to **antigens**, which are usually macromolecules present in infectious agents (e.g., a bacterium or a virus) or other foreign substances (e.g., proteins or polysaccharides in pollens). Different antibodies are generated in response to different antigens, and these antibodies have the remarkable characteristic of binding specifically to ("recognizing") the part of the antigen, called an **epitope**, that initially induced the production of the antibody, and not to other molecules. Antibodies act as specific sensors for antigens, forming antibody-antigen complexes that initiate a cascade of protective reactions in cells of the immune system. Chapter 23 discusses antibodies and their roles in the immune system, and later in this chapter we will discuss techniques for studying proteins that exploit antibodies. Here we briefly introduce the structure of antibodies and their binding to epitopes.

Antibodies are Y-shaped molecules, often formed from two identical longer, or *heavy*, chains and two identical shorter, or *light*, chains. In IgG antibodies (also called immunoglobulins, shown in Figure 3-21a), there are four globular domains in each heavy chain and two in each light chain, all of which are called immunoglobulin (Ig) domains. Each of the two branching arms of an IgG antibody contains a single light chain linked to a heavy chain by a disulfide bond, and two disulfide bonds covalently link the two heavy chains together. Near the end of each arm are six highly variable loops, called *complementarity-determining regions* (CDRs), which form the antigen-binding sites. The sequences of the six loops are highly variable among antibodies, generating unique complementary ligand-binding sites that make them specific for different epitopes (Figure 3-21b). The intimate contact between antibody and epitope surfaces, stabilized by numerous noncovalent interactions, is responsible for the extremely precise binding specificity exhibited by an antibody.

The specificity of antibodies is so precise that they can distinguish between the cells of individual members of a species and in some cases between proteins that differ by only a single amino acid, or even between proteins with identical sequences that differ only in their post-translational modifications. Because of their specificity and the ease with which they can be produced (see Chapter 23), antibodies are highly useful reagents used in many of the experiments discussed in subsequent chapters.

We will see many examples of protein-ligand binding throughout this book, including binding of hormones to receptors (see Chapter 15), binding of regulatory molecules to DNA (see Chapter 9), and binding of cell-adhesion molecules to extracellular matrices (see Chapter 20), to name just a few. Here we focus on how the binding of one class of proteins, enzymes, to their ligands results in the catalysis of the chemical reactions essential for the survival and function of cells.

**FIGURE 3-21 Protein-ligand binding of antibodies.** (a) Hybrid (surface and ribbon) model of an antibody. Every antibody molecule of the immunoglobulin G (IgG) class consists of two identical heavy chains (medium and dark blue) and two identical light chains (light blue) covalently linked by disulfide bonds (yellow). The complementarity-determining regions (CDRs) that define the antigen-binding sites are represented by red shading. (b) The cartoon shows the overall structure

containing the two heavy (longer) and two light (shorter) chains, with yellow bars representing disulfide bonds. (c) The hand-in-glove fit between an antibody and the site to which it binds (epitope) on its target antigen—in this case, chicken egg-white lysozyme. The antibody contacts the antigen with residues from its CDRs. [Part (a) data from L. J. Harris, et al., 1997, *Biochemistry* **36**:1581-1597, PDB ID 1igt. Part (b) data from E. A. Padlan et al., 1989, *P. Natl. Acad. Sci. USA* **86**:5938-5942, PDB ID 3hfm.]

## Enzymes Are Highly Efficient and Specific Catalysts

Proteins that catalyze chemical reactions—the making and breaking of covalent bonds—are called **enzymes**, and the ligands of enzymes are called **substrates**. Enzymes make up a large and very important functional class of proteins—indeed, almost every chemical reaction in the cell is catalyzed by a specific catalyst, usually an enzyme. Another form of catalytic macromolecule in cells is made from RNA. These RNAs are called **ribozymes** (see Chapter 5).

Thousands of different types of enzymes, each of which catalyzes a single chemical reaction or a set of closely related reactions, have been identified. Certain enzymes are found in the majority of cells because they catalyze the synthesis of common cellular products (e.g., proteins, nucleic acids, and phospholipids) or take part in harvesting energy from nutrients (e.g., by the conversion of glucose and oxygen into carbon dioxide and water during cellular respiration). Other enzymes are present only in a particular type of cell because they catalyze chemical reactions unique to that cell type (e.g., the enzymes in neurons that convert tyrosine into dopamine, a neurotransmitter). Although most enzymes are located within cells, some are secreted and function at extracellular sites, such as the blood, the digestive tract, or even outside the organism (e.g., toxic enzymes in the venom of poisonous snakes).

Like all **catalysts** (see Chapter 2), enzymes increase the rate of a reaction, but they do not affect the extent of a reaction, which is determined by the change in free energy ( $\Delta G$ ) between reactants and products, and they are not themselves permanently changed as a consequence of the reaction they catalyze. Enzymes increase the reaction rate by lowering the energy of the *transition state*, and therefore the *activation energy*

required to reach it (Figure 3-22). In the test tube, catalysts such as charcoal and platinum facilitate reactions, but usually only at high temperatures or pressures, at extremes of high or low pH, or in organic solvents. Within cells, however, enzymes must function effectively in an aqueous environment at 37 °C

**FIGURE 3-22 Effect of an enzyme on the activation energy of a chemical reaction.** This hypothetical reaction pathway depicts the changes in free energy,  $G$ , as a reaction proceeds. A reaction will take place spontaneously only if the total  $G$  of the products is less than that of the reactants (negative  $\Delta G$ ). However, all chemical reactions proceed through one or more high-energy transition states, and the rate of a reaction is inversely proportional to the activation energy ( $\Delta G^{\ddagger}$ ), which is the difference in free energy between the reactants and the transition state (highest point along the pathway). Enzymes and other catalysts accelerate the rate of a reaction by reducing the free energy of the transition state and thus  $\Delta G^{\ddagger}$ .

and 1 atmosphere of pressure and at physiological pH values, usually 6.5–7.5 but sometimes lower. Remarkably, enzymes exhibit immense catalytic power, in some cases accelerating the rates of reactions to  $10^6$ – $10^{12}$  times those of the corresponding uncatalyzed reactions under otherwise similar conditions.

## An Enzyme's Active Site Binds Substrates and Carries Out Catalysis

Certain amino acids of an enzyme are particularly important in determining its specificity and catalytic power. In the native conformation of an enzyme, critically important amino acids (which usually come from different parts of the linear sequence of the polypeptide) are brought into proximity, forming a cleft in the enzyme surface called the **active site** (Figure 3-23). An active site usually makes up only a small part of the total protein; the remaining part is involved in the folding of the polypeptide, regulation of the active site, and interactions with other molecules.

An active site consists of two functionally important regions: the *substrate-binding site*, which recognizes and binds the substrate or substrates, and the *catalytic site*, which carries out the chemical reaction once the substrate has bound. The catalytic groups in the catalytic site are amino acid side chains and backbone carboxyl and amino groups. In some enzymes, the catalytic and substrate-binding sites overlap; in others, the two regions are structurally distinct.

The substrate-binding site is responsible for the remarkable specificity of enzymes. Alteration of the structure of an enzyme's substrate by only one or a few atoms, or a subtle change in the geometry (e.g., stereochemistry) of the substrate, can result in a variant molecule that is no longer a substrate of the enzyme. As with the specificity of antibodies for antigens described above, the specificity of enzymes for substrates is a

**FIGURE 3-23 Active site of the enzyme trypsin.** (a) An enzyme's active site (outlined by dashed line) is composed of a substrate-binding site (blue), which binds specifically to a substrate, and a catalytic site (purple), which carries out catalysis. (b) A hybrid surface/ribbon representation of a portion of the serine protease trypsin. Clearly visible are the active-site cleft containing the catalytic site (purple, includes the key catalytic triad of Ser-195, Asp-102, and His-57, see also Figure 3-27) and a portion of the substrate-binding site called the side-chain-specificity binding pocket (blue). [Data from B. Sandler, M. Murakami, and J. Clardy, 1998, *J. Am. Chem. Soc.* **120**:595-596, PDB ID 1aq7.]

consequence of the precise molecular complementarity between an enzyme's substrate-binding site and the substrate. Usually only one or a few substrates can fit precisely into a binding site.

The idea that substrates might bind to enzymes in the manner of a key fitting into a lock was first suggested by Emil Fischer in 1894. A variation of this proposal by Daniel Koshland in 1958, called *induced fit*, posited that the substrate-binding site is not rigid, as a lock is, but flexible, and is induced to change shape for more optimal catalysis when the substrate binds. In 1913, Leonor Michaelis and Maud Leonora Menten provided crucial evidence supporting the enzyme-substrate binding hypothesis. They showed that the rate of an enzymatic reaction was proportional to the substrate concentration at low substrate concentrations, but that as substrate concentrations increased, the rate reached a plateau, or **maximal velocity**,  $V_{\max}$ , and became substrate concentration independent, with a value of  $V_{\max}$  directly proportional to the amount of enzyme present in the reaction mixture (Figure 3-24).

**FIGURE 3-24  $K_m$  and  $V_{\max}$  for an enzyme-catalyzed reaction.**  $K_m$  and  $V_{\max}$  are determined from analysis of the dependence of the initial reaction rate on substrate concentration. The shape of these hypothetical kinetic curves is characteristic of a simple enzyme-catalyzed reaction in which one substrate (S) is converted into product (P). The initial reaction velocity is measured immediately after addition of enzyme to substrate, before the substrate concentration changes appreciably. (a) Plots of initial reaction velocity at two different concentrations of enzyme [E] as a function of substrate concentration [S]. The [S] that yields a half-maximal reaction rate is the Michaelis constant  $K_m$ , a measure of the affinity of E for turning S into P. Quadrupling the enzyme concentration causes a proportional increase in the reaction rate, so the maximal velocity  $V_{\max}$  is quadrupled;  $K_m$ , however, is unaltered. (b) Plots of initial reaction velocity versus substrate concentration with a substrate S for which the enzyme has a high affinity and with a substrate S' for which the enzyme has a lower affinity. Note that  $V_{\max}$  is the same with both substrates because [E] is the same, but that  $K_m$  is higher for S', the low-affinity substrate.

Michaelis and Menten deduced that these characteristics were due to the binding of substrate molecules (S) to a fixed and limited number of sites on the enzymes (E), and they called the bound species the enzyme-substrate (ES) complex. At high concentrations of substrate, all the binding sites on the enzymes have substrate bound, and the substrate-binding sites are said to be *saturated* with substrate—no additional binding to active sites is possible, and the maximal velocity of the reaction is achieved. Michaelis and Menten proposed that the ES complex is in equilibrium with the unbound enzyme and substrate and is an intermediate step in the ultimately irreversible conversion of substrate to product (P) (Figure 3-25):

and that the rate  $V_0$  of formation of product at a particular substrate concentration  $[S]$  is given by what is now called the *Michaelis-Menten equation*:

$$V_0 = V_{max} \frac{[S]}{[S] + K_m} \quad (3-1)$$

**FIGURE 3-25 Schematic model of an enzyme's reaction mechanism.** Enzyme kinetics suggest that enzymes (E) bind substrate molecules (S) at a fixed and limited number of sites—the enzymes' active sites. The bound species is known as an enzyme-substrate (ES) complex. The ES complex is in equilibrium with the unbound enzyme and substrate (double arrows) and is an intermediate step in the conversion of substrate to products (P).

where the **Michaelis constant**,  $K_m$ , a measure of the affinity of an enzyme for its substrate, is the substrate concentration that yields a half-maximal reaction rate (i.e.,  $\frac{1}{2} V_{max}$  in Figure 3-24). The  $K_m$  is somewhat similar in nature, but not identical, to the dissociation constant,  $K_d$  (see Chapter 2). The smaller the value of  $K_m$ , the more effective the enzyme is at making product from dilute solutions of substrate, and the lower the substrate concentration needed to reach half-maximal velocity. The smaller the  $K_d$ , the lower the ligand concentration needed to reach 50 percent of binding. The concentrations of the various small molecules in a cell vary widely, as do the  $K_m$  values for the different enzymes that act on them. A good rule of thumb is that the intracellular concentration of a substrate is often approximately the same as, or somewhat greater than, the  $K_m$  value of the enzyme to which it binds.

The rates of reaction at substrate saturation vary enormously among enzymes. The maximum number of substrate molecules converted to product at a single enzyme active site per second, called the *turnover number*, can be less than 1 for very slow enzymes. The turnover number for carbonic anhydrase, one of the fastest enzymes, is  $6 \times 10^5$  molecules per second.

Many enzymes catalyze the conversion of substrates to products by dividing the process into multiple, discrete chemical reactions, in which the product of one reaction is the substrate for the subsequent reaction. These sequential reactions generate multiple, distinct enzyme-substrate complexes (ES, ES', ES'', etc.) prior to the final release of the products:

The energy profiles for such multistep reactions involve multiple hills and valleys (Figure 3-26). Methods have been developed to trap the intermediates in such reactions to learn more about the details of how enzymes catalyze reactions.

## Serine Proteases Demonstrate How an Enzyme's Active Site Works

Serine proteases, a large family of protein-cleaving, or proteolytic, enzymes, are used throughout the biological world—to digest meals (the pancreatic enzymes trypsin, chymotrypsin, and elastase), to control blood clotting (the enzyme thrombin), even to help silk moths chew their way out of their cocoons (cocoanase). This class of enzymes usefully illustrates how an enzyme's substrate-binding site and catalytic site cooperate in multistep reactions to convert substrate to product. Here we consider how trypsin and its two evolutionarily closely related pancreatic proteases, chymotrypsin and elastase, catalyze cleavage of a peptide bond in a polypeptide substrate:

**FIGURE 3-26 Free-energy reaction profiles of uncatalyzed and multistep enzyme-catalyzed reactions.** (a) The free-energy reaction profile of a hypothetical simple uncatalyzed reaction converting substrate (S) to product (P) via a single high-energy transition state. (b) Many enzymes catalyze such reactions by dividing the process

into multiple discrete steps, in this case, the initial formation of an ES complex followed by conversion via a single transition state ( $EX^\ddagger$ ) to the free enzyme (E) and P. The activation energy for each of these steps is significantly less than the activation energy for the uncatalyzed reaction; thus the enzyme dramatically enhances the reaction rate.

where  $P_1$  is the part of the protein on the N-terminal side of the peptide bond to be cleaved and  $P_2$  is the portion on the C-terminal side. We first consider how serine proteases bind specifically to their substrates and then show in detail how catalysis takes place.

Figure 3-27a shows how a substrate polypeptide binds to the substrate-binding site in the active site of trypsin. There are two key binding interactions. First, the substrate (black polypeptide backbone) and enzyme (blue polypeptide backbone) form hydrogen bonds that resemble those of a  $\beta$  sheet. Second, a key side chain of the substrate that determines which peptide in the substrate is to be cleaved extends into the enzyme's *side-chain-specificity binding pocket*, at the bottom of which resides the negatively charged side chain of trypsin's Asp-189. Trypsin has a marked preference for hydrolyzing substrates at the carboxyl ( $C=O$ ) side of an amino acid with a long, positively charged side chain (arginine or lysine) because the side chain is stabilized in the enzyme's side-chain-specificity binding pocket by the negative Asp-189.

**FIGURE 3-27 Substrate binding in the active site of trypsin-like serine proteases.** (a) The active site of trypsin (purple and blue molecule) with a bound substrate (black molecule). The substrate forms a two-stranded  $\beta$  sheet with trypsin's substrate-binding site, and the side chain of an arginine ( $R_3$ ) in the substrate is bound in the side-chain-specificity binding pocket of the binding site. Its positively charged guanidinium group is stabilized by the negative charge on the side chain of the enzyme's Asp-189. This binding aligns the peptide bond of the arginine appropriately for hydrolysis catalyzed by the enzyme's active-site catalytic triad (side chains of Ser-195, His-57, and Asp-102). (b) The amino acids lining the side-chain-specificity binding pocket determine its shape and charge and thus its binding properties. Trypsin accommodates the positively charged side chains of arginine and lysine; chymotrypsin, large, hydrophobic side chains such as phenylalanine; and elastase, small side chains such as glycine and alanine. See J. J. Perona and C. S. Craik, 1997, *J. Biol. Chem.* **272**:29987–29990.

Slight differences in the structures of otherwise similar binding pockets help explain the differing substrate specificities of two serine proteases related to trypsin: chymotrypsin prefers large aromatic groups (as in Phe, Tyr, Trp), and elastase prefers the small side chains of Gly and Ala (Figure 3-27b). The uncharged Ser-189 in chymotrypsin

allows large, uncharged, hydrophobic side chains to bind stably in the binding pocket. The specificity of elastase is influenced by the replacement of glycines in the sides of the binding pocket in trypsin with the branched aliphatic side chains of valines (Val-216 and Val-190), which obstruct the binding pocket (see Figure 3-27b). As a consequence, large side chains in substrates are prevented from fitting into the binding pocket of elastase, whereas substrates with the short alanine or glycine side chains at this position can bind well and be subject to subsequent cleavage.

In the catalytic site, all three enzymes use the hydroxyl group on the side chain of a serine at position 195 to catalyze the hydrolysis of peptide bonds in substrate proteins. A catalytic triad formed by the three side chains of Ser-195, His-57, and Asp-102 participates in what is essentially a two-step hydrolysis reaction. Figure 3-28 shows how the

catalytic triad cooperates in breaking the peptide bond, with Asp-102 and His-57 supporting the attack of the hydroxyl oxygen of Ser-195 on the carbonyl carbon in the substrate. This attack initially forms an unstable transition state with four groups attached to the carbon (tetrahedral intermediate). Breaking of the C—N peptide bond then releases one part of the substrate protein ( $\text{NH}_3 - \text{P}_2$ ), while the other part remains covalently attached to the enzyme via an ester bond to the serine's oxygen, forming a relatively stable acyl enzyme intermediate. The subsequent replacement of this oxygen with one from water, in a reaction involving another unstable tetrahedral intermediate, leads to release of the final product ( $\text{P}_1 - \text{COOH}$ ). The tetrahedral intermediate transition states are partially stabilized by hydrogen bonding with the enzyme's backbone amino groups in what is called the *oxyanion hole*. The large family of serine proteases and

**FIGURE 3-28 Mechanism of serine protease-mediated hydrolysis of peptide bonds.** The catalytic triad of Ser-195, His-57, and Asp-102 in the active sites of serine proteases employs a multistep mechanism to hydrolyze peptide bonds in target proteins. (a) After a polypeptide substrate binds to the active site (see Figure 3-27), forming an ES complex, the hydroxyl oxygen of Ser-195 attacks the carbonyl carbon of the substrate's targeted peptide bond (yellow). Movements of electrons are indicated by arrows. (b) This attack results in the formation of a transition state called the *tetrahedral intermediate*, in which the negative charge on the substrate's oxygen is stabilized by hydrogen bonds formed with the enzyme's *oxyanion hole*. (c) Additional electron movements result in the breaking of the

peptide bond, release of one of the reaction products ( $\text{NH}_2 - \text{P}_2$ ), and formation of the acyl enzyme (ES' complex). (d) An oxygen from a solvent water molecule then attacks the carbonyl carbon of the acyl enzyme. (e) This attack results in the formation of a second tetrahedral intermediate. (f) Additional electron movements result in the breaking of the Ser-195—substrate bond (formation of the EP complex) and release of the final reaction product ( $\text{P}_1 - \text{COOH}$ ). The side chain of His-57, which is held in the proper orientation by hydrogen bonding to the side chain of Asp-102, facilitates catalysis by withdrawing and donating protons throughout the reaction (*inset*). If the pH is too low and the side chain of His-57 is protonated, it cannot participate in catalysis and the enzyme is inactive.

related enzymes, all of which have an active-site serine, illustrates how an efficient reaction mechanism is used over and over by distinct enzymes to catalyze similar reactions.

The serine protease mechanism points out several key features of enzymatic catalysis. First, enzyme catalytic sites have evolved to stabilize the binding of a transition state, thus lowering the activation energy and accelerating the overall reaction. Second, multiple side chains, together with the polypeptide backbone, carefully organized in three dimensions, work together to chemically transform substrate into product, often by multistep reactions.

Third, acid-base catalysis mediated by one or more amino acid side chains is often used by enzymes, as when the imidazole group of His-57 in serine proteases acts as a base to remove the hydrogen from Ser-195's hydroxyl group. As a consequence, only a particular ionization state (protonated or nonprotonated) of one or more amino acid side chains in the catalytic site may be compatible with catalysis, and thus the enzyme's activity may be pH dependent. For example, the imidazole of His-57 in serine proteases, whose  $pK_a$  is  $\sim 6.8$ , can help the Ser-195 hydroxyl attack the substrate only if it is not protonated. Thus the activity of the protease is low at  $pH < 6.8$ , at which the imidazole is protonated, and the shape of the pH activity profile in the pH range 4–8 matches the titration of the His-57 side chain, which is governed by the Henderson-Hasselbalch equation, with an inflection near pH 6.8 (see chymotrypsin data in Figure 3-29 and see Chapter 2). The activity drops at higher pH values, generating a bell-shaped activity curve, because the proper folding of the protein is disrupted when the amino group at

the protein's amino terminus ( $pK_a \sim 9$ ) is deprotonated; the conformation near the active site changes as a consequence.

The pH sensitivity of an enzyme's activity can be due to changes in the ionization of catalytic groups, groups that participate directly in substrate binding, or groups that influence the conformation of the protein. Pancreatic serine proteases evolved to function in the neutral or slightly basic conditions in the intestines; hence their pH optima are  $\sim 8$ . Proteases and other hydrolytic enzymes that function in acidic conditions must employ a different catalytic mechanism. This is the case for enzymes within the stomach (pH  $\sim 1$ ), such as the protease pepsin, and for those within lysosomes (pH  $\sim 4.5$ ), which play a key role in degrading macromolecules within cells (see the lysosomal hydrolase data in Figure 3-29). Indeed, lysosomal hydrolases, which degrade a wide variety of biomolecules (proteins, lipids, etc.), are relatively inactive at the pH in the cytosol ( $\sim 7$ ), which helps to protect a cell from self-digestion if these enzymes escape the confines of the membrane-bounded lysosome.

One key feature of enzymatic catalysis not seen in serine proteases but found in many other enzymes is a *cofactor* or *prosthetic group*. This “helper” group is a nonpolypeptide small molecule or ion (e.g., iron, zinc, copper, manganese) that is bound in the active site and plays an essential role in the reaction mechanism. Small organic prosthetic groups in enzymes are also called *coenzymes*. Some of these groups are chemically modified during the reaction and thus need to be replaced or regenerated after each reaction; others are not. Examples include  $NAD^+$  (nicotinamide adenine dinucleotide), FAD (flavin adenine dinucleotide) (see Figure 2-33), and the heme groups that bind oxygen in hemoglobin or transfer electrons in some cytochromes (see Figure 12-20). Thus the chemical reactions catalyzed by enzymes are not restricted by the limited number of types of amino acids in polypeptide chains. Many of the vitamins [for example, the B vitamins thiamine ( $B_1$ ), riboflavin ( $B_2$ ), niacin ( $B_3$ ), and pyridoxine ( $B_6$ ), as well as vitamin C], which cannot be synthesized in mammalian cells, function as, or are used to generate, coenzymes. That is why supplements of vitamins must be added to the liquid medium in which mammalian cells are grown in the laboratory (see Chapter 4).

Small molecules that can bind to active sites and disrupt catalytic reactions are called *enzyme inhibitors*. Such inhibitors are useful tools for studying the roles of enzymes in cells and organisms. Inhibitors that bind directly to an enzyme's binding site and thus compete directly with the normal substrate are called competitive inhibitors. Noncompetitive inhibitors are those that interfere with enzyme activity in other ways—for example, by binding to some other site on the enzyme and changing its conformation. Enzyme inhibitors complement the use of genetic mutations and a technique called RNA interference (RNAi) for probing an enzyme's function in cells (see Chapter 6). In all three approaches, the cellular consequences of disrupting an enzyme's activity can be used to deduce the normal function of the enzyme. The same approaches can be used to study the functions of nonenzymatic macromolecules. Interpreting the results of inhibitor studies

**FIGURE 3-29 The pH dependence of enzyme activity.** In some cases, ionizable (pH-titratable) groups in enzyme active sites or elsewhere in enzymes must be either protonated or deprotonated to permit proper substrate binding or catalysis, or to permit the enzyme to adopt the correct conformation. Measurement of enzyme activity as a function of pH can be used to identify the  $pK_a$ 's of these groups. The pancreatic serine proteases, such as chymotrypsin, exhibit maximum activity at around pH 8 because of titration of the active-site His-57 (required for catalysis,  $pK_a \sim 6.8$ ) and of the amino terminus of the protein (required for proper conformation,  $pK_a \sim 9$ ). Many lysosomal hydrolases have evolved to exhibit a lower pH optimum ( $\sim 4.5$ ) to match the low internal pH in the lysosomes in which they function.

[Data from P. Lozano, T. De Diego, and J. L. Iborra, 1997, *Eur. J. Biochem.*

**248**:80–85, and W. A. Judice et al., 2004, *Eur. J. Biochem.* **271**:1046–1053.]

can be complicated, however, if, as is often the case, the inhibitors block the activity of more than one protein.

 Small-molecule inhibition of protein activity is the basis for many drugs as well as for chemical warfare agents. Aspirin inhibits enzymes called cyclooxygenases, whose products can cause pain. Sarin and other nerve gases react with the active serine hydroxyl groups of both serine proteases and a related enzyme, acetylcholine esterase, which is a key enzyme in regulating nerve conduction (see Chapter 22). ■

### Enzymes in a Common Pathway Are Often Physically Associated with One Another

Enzymes taking part in a common metabolic process (e.g., the degradation of glucose to pyruvate during glycolysis; see Chapter 12) are generally located in the same cellular compartment, be it in the cytosol, at a membrane, or within a particular organelle. Within this compartment, products from one reaction can move by diffusion to the next enzyme in the metabolic pathway. Diffusion, however, entails random movement and can be a slow, relatively inefficient process for moving molecules between enzymes (Figure 3-30a).

**FIGURE 3-30 Assembly of enzymes into efficient multienzyme complexes.** In the hypothetical reaction pathways illustrated here, the initial reactants are converted into final products by the sequential action of three enzymes: A, B, and C. (a) When the enzymes are free in solution, or even constrained within the same cellular compartment, the intermediates in the reaction sequence must diffuse from one enzyme to the next, an inherently slow process. (b) Diffusion is greatly reduced or eliminated when the individual enzymes associate into multisubunit complexes, either by themselves or with the aid of a scaffold protein. (c) The closest integration of different catalytic activities occurs when the enzymes are fused at the genetic level, becoming domains in a single polypeptide chain.

To overcome this impediment, cells have evolved mechanisms for bringing enzymes in a common pathway into close proximity, a process called metabolic coupling.

In the simplest such mechanism, polypeptides with different catalytic activities cluster closely together as subunits of a multimeric enzyme or assemble on a common “scaffold” that holds them together (Figure 3-30b). This arrangement allows the product of one reaction to be channeled directly to the next enzyme in the pathway. In some cases, independent proteins have been fused together at the genetic level to create a single multidomain, multifunctional enzyme (Figure 3-30c). Metabolic coupling usually involves large multiprotein complexes, as described earlier in this chapter.

### KEY CONCEPTS OF SECTION 3.3

#### Protein Binding and Enzyme Catalysis

- A protein’s function depends on its ability to bind other molecules, known as ligands. For example, antibodies bind to a group of ligands known as antigens, and enzymes bind to reactants called substrates that will be converted by chemical reactions into products.
- The specificity of a protein for a particular ligand refers to the preferential binding of one or a few closely related ligands. The affinity of a protein for a particular ligand refers to the strength of binding, usually expressed as the dissociation constant  $K_d$ .
- Proteins are able to bind to ligands because of molecular complementarity between the ligand-binding sites and the corresponding ligands.
- Enzymes are catalytic proteins that accelerate the rates of cellular reactions by lowering the activation energy and stabilizing transition-state intermediates (see Figure 3-22).
- An enzyme’s active site, which is usually only a small part of the protein, comprises two functional parts: a substrate-binding site and a catalytic site. The substrate-binding site is responsible for the exquisite specificity of enzymes owing to its molecular complementarity with the substrate.
- The initial binding of a substrate (S) to an enzyme (E) results in the formation of an enzyme-substrate complex (ES), which then undergoes one or more reactions catalyzed by the catalytic groups in the catalytic site until the final product (P) is formed.
- From plots of reaction rate versus substrate concentration, two characteristic parameters of an enzyme can be determined: the Michaelis constant,  $K_m$ , a rough measure of the enzyme’s affinity for converting substrate into product, and the maximal velocity,  $V_{max}$ , a measure of its catalytic power (see Figure 3-24).
- The rates of enzyme-catalyzed reactions vary enormously, with turnover numbers (numbers of substrate molecules converted to product at a single active site at substrate saturation) ranging from fewer than 1 to  $6 \times 10^5$  molecules per second.

- Many enzymes catalyze the conversion of substrates to products by dividing the process into multiple discrete chemical reactions that involve multiple distinct enzyme-substrate complexes (ES', ES'' etc.).
- Serine proteases hydrolyze peptide bonds in substrate proteins using as catalytic groups the side chains of Ser-195, His-57, and Asp-102. Amino acids lining the side-chain-specificity binding pocket in the binding site of serine proteases determine the residue in a substrate protein whose peptide bond will be hydrolyzed and account for differences in protease specificity (for example, trypsin vs. chymotrypsin and elastase).
- Enzymes often use acid-base catalysis mediated by one or more amino acid side chains, such as the imidazole group of His-57 in serine proteases, to catalyze reactions. The pH dependence of protonation of catalytic groups ( $pK_a$ ) is often reflected in the pH-rate profile of the enzyme's activity.
- Nonpolypeptide small molecules or ions, called cofactors or prosthetic groups, bind to the active sites of some enzymes and play an essential role in enzymatic catalysis. Small organic prosthetic groups in enzymes are also called coenzymes; many vitamins, which cannot be synthesized in higher animal cells, function as or are used to generate coenzymes.
- Enzymes in a common metabolic pathway are often located within the same cellular compartments and may be further associated as domains of a monomeric protein, subunits of a multimeric protein, or components of a protein complex assembled on a common scaffold (see Figure 3-30).

### 3.4 Regulating Protein Function

Most processes in cells do not take place independently of one another or at a constant rate. The activities of all proteins and other biomolecules are regulated to integrate their functions for optimal performance for survival. For example, the catalytic activity of enzymes is regulated so that the amount of reaction product is just sufficient to meet the needs of the cell. As a result, the steady-state concentrations of substrates and products may vary depending on cellular conditions. Regulation of nonenzymatic proteins—the opening or closing of membrane channels or the assembly of a macromolecular complex, for example—is also essential.

In general, there are three ways to regulate protein activity. First, cells can increase or decrease the steady-state level of the protein by altering its rate of synthesis, its rate of degradation, or both. Second, cells can change the intrinsic activity, as distinct from the amount, of the protein. For example, through noncovalent and covalent interactions, cells can change the affinity of substrate binding, or the fraction of time the protein is in an active versus an inactive conformation. Third, there can be a change in the location or the concentration within the cell of the protein itself, of the target of the protein's activity (e.g., an enzyme's substrate), or of some other molecule required for the protein's

activity (e.g., an enzyme's cofactor). All three types of regulation play essential roles in the lives and functions of cells. In this section, we first discuss mechanisms for regulating the amount of a protein, then turn to noncovalent and covalent interactions that regulate protein activity.

### Regulated Synthesis and Degradation of Proteins Is a Fundamental Property of Cells

The rate of synthesis of a protein is determined by the rate at which the DNA encoding the protein is converted to mRNA (transcription), the steady-state amount of the active mRNA in the cell, and the rate at which the mRNA is converted into newly synthesized protein (translation). These important processes are described in detail in Chapter 5.

The life spans of intracellular proteins vary from as short as a few minutes for mitotic cyclins, which help regulate passage through the mitotic stage of cell division (see Chapter 19), to as long as the age of an organism for proteins in the lens of the eye. Protein life span is controlled primarily by regulated protein degradation.

Protein degradation plays two especially important roles in the cell. First, it removes proteins that are potentially toxic, improperly folded or assembled, or damaged—including the products of mutated genes and proteins damaged by chemically active cell metabolites or stress (e.g., heat shock). Despite the existence of chaperone-mediated protein folding, some newly made proteins are rapidly degraded because they are misfolded. This degradation might be necessary due to failure of timely engagement of the necessary chaperones to guide the folding of the proteins or due to their defective assembly into complexes. Most other proteins are degraded more slowly, undergoing about 1–2 percent degradation per hour in mammalian cells. Second, the controlled destruction of otherwise normal proteins, along with controlled rates of synthesis, provides a powerful mechanism for maintaining the appropriate levels of the proteins and their activities and for permitting rapid changes in these levels to help the cells respond to changing conditions.

Eukaryotic cells have several pathways for degrading proteins. One major pathway is degradation by enzymes within lysosomes, membrane-limited organelles whose acidic interior (pH ~4.5) is filled with a host of hydrolytic enzymes. Lysosomal degradation is directed primarily toward aged or defective organelles of the cell—a process called autophagy (see Chapter 14)—and toward extracellular proteins taken up by the cell. Lysosomes will be discussed at length in later chapters. Here we focus on another important degradation pathway: cytoplasmic protein degradation by proteasomes, which can account for up to 90 percent of the protein degradation in mammalian cells.

### The Proteasome Is a Molecular Machine Used to Degrade Proteins

**Proteasomes** are very large protein-degrading molecular machines that influence many different cellular functions,

including the cell cycle (see Chapter 19), transcription, DNA repair (see Chapter 5), programmed cell death, or **apoptosis** (see Chapter 21), recognition of and response to infection by foreign organisms (see Chapter 23), and removal of misfolded proteins. There are approximately 30,000 proteasomes in a typical mammalian cell.

Proteasomes consist of roughly 60 protein subunits and have a mass of about  $2.4 \times 10^6$  Da. Proteasomes have a

cylindrical, barrel-like catalytic core (Figure 3-31a), called the *20S proteasome* (where *S* is a Svedberg unit based on the sedimentation properties of the particle and is proportional to its size), which is approximately 14.8 nm tall and 11.3 nm in diameter. Bound to the ends of this core are either one or two 19S cap complexes that regulate the activity of the 20S catalytic core. When the core and one or two caps are combined, they are referred to collectively as the *26S complex*,

**FIGURE 3-31 Ubiquitin- and proteasome-mediated proteolysis.**

(a) *Right*: The 26S proteasome has a cylindrical structure with a 19S cap at one or both ends of the 20S core particle. The nineteen different subunits of the 19S cap (shown in multiple colors) include six AAA-ATPase subunits (Rpt1–6, red), which assemble into a heterohexameric ring; two ubiquitin (Ub) receptors (Rpn10 and Rpn13, yellow); and a deubiquitinase enzyme (DUB, Rpn11, green), which forms a heterodimer with its evolutionarily related counterpart Rpn8. Moreover, the 19S cap contains scaffolding and other proteins (tan). The two 19S caps shown are facing in opposite directions relative to the plane of the page. The 20S core consists of four stacked heptameric rings ( $\sim 110$  Å diameter  $\times$  160 Å long), each containing either  $\alpha$  (outer rings) or  $\beta$  (inner rings) subunits (blue). *Left*: Cutaway view of the 20S core, showing the inner chambers. Proteolysis occurs within the central inner chamber of the core formed by the  $\beta$  rings. (b) Proteins are targeted for proteasomal degradation by polyubiquitylation. Enzyme E1 is activated by the ATP-dependent attachment of a ubiquitin (Ub) molecule

(step 1) and then transfers this Ub molecule to a cysteine residue in E2 (step 2). Ubiquitin ligase (E3) transfers the bound Ub molecule on E2 to the side-chain –NH<sub>2</sub> of a lysine residue in a target protein, forming an isopeptide bond (step 3). Additional Ub molecules are added to the Ub-modified target protein via isopeptide bonds to the previously added Ub by repeating steps 1–3, forming a polyubiquitin chain (step 4). The polyubiquitinated target is recognized by Ub receptors in the proteasome's 19S cap (step 5), and the Ub groups are removed by the deubiquitinase enzyme (step 6). In step 7a ATP hydrolysis enables the six protein (hexameric) ATPase subunits (red) to unfold the substrate and transfer the unfolded protein via a pore in the hexamer into the proteolysis chamber in the 20S core (step 7a), in some cases coordinately with step 6, and the protein is cleaved into short peptide digestion fragments (step 7b) that are then released (step 7c). [Part (a) courtesy of Antje Aufderheide and Friedrich Foerster, data from P. Unverdorben et al., 2014, *P. Natl. Acad. Sci. USA* 111(15):5544–5549, PDB ID 4cr2.]

even though the two-cap-containing complex is larger (30S). A 19S cap has 19 protein subunits, six of which can hydrolyze ATP (i.e., they are AAA-type ATPases) to provide the energy needed to unfold protein substrates and selectively transfer them into the inner chamber of the proteasome's catalytic core. Genetic studies in yeast have shown that cells cannot survive without functional proteasomes, thus demonstrating their importance. Furthermore, proper proteasomal activity is so important that cells will expend as much as 30 percent of the energy needed to synthesize a protein to degrade it in a proteasome.

The 20S proteasomal catalytic core comprises two inner rings of seven  $\beta$  subunits each, with three proteolytic active sites per ring facing toward the  $\sim 1.7$ -nm-diameter inner chamber formed by those rings, and two outer rings of seven  $\alpha$  subunits each, which limit substrate access (see Figure 3-31a) via an entry channel that can be opened by the 19S cap. Proteasomes can degrade most proteins thoroughly because the three active sites in each  $\beta$  subunit ring can cleave peptide bonds at hydrophobic residues, acidic residues, or basic residues. Polypeptide substrates must enter the chamber via a regulated  $\sim 1.3$ -nm-diameter aperture at the center of the outer  $\alpha$  subunit rings. In the 26S proteasome, the opening of the aperture, which is narrow and often allows the entry of only unfolded proteins, is controlled by ATPases in the 19S cap. These ATPases are responsible for unfolding protein substrates and translocating those unfolded polypeptides into the inner chamber of the catalytic core (Figure 3-31b, *bottom right*). The short peptide products of proteasomal digestion (2–24 residues long) exit the chamber and are further degraded rapidly by cytosolic peptidases, eventually being converted to individual (“free”) amino acids. One researcher has quipped that a proteasome is a “cellular chamber of doom” in which proteins suffer a “death by a thousand cuts.”

Inhibitors of proteasome function have proved to be exceptionally useful in the laboratory and the clinic. Small-molecule proteasome inhibitors, such as MG132, are used to block proteasomal degradation in the lab and to help evaluate the role of the proteasome and, as we shall see below, polyubiquitinylation in a wide variety of processes. Other small-molecule proteasome inhibitors have been used therapeutically. Because of the global importance of proteasome-mediated protein breakdown in cells, continuous, complete inhibition of proteasomes kills cells. However, partial proteasome inhibition for short intervals is widely used as an approach to cancer chemotherapy, especially to treat multiple myeloma, a cancer involving the abnormal proliferation of antibody (immunoglobulin)-producing cells. The myeloma cells produce abnormally high levels of potentially toxic, aberrant immunoglobulin polypeptide chains, which are degraded by proteasomes. Proteasome inhibition in these cancer cells leads to the buildup of toxic, misfolded immunoglobulin polypeptides within the cells, and thus to cell death. In addition, to survive and grow, myeloma cells require the robust activity of a regulatory protein called *NF- $\kappa$ B* (see Chapter 16) as well as other “pro-survival” and

“pro-proliferation” proteins. In turn, *NF- $\kappa$ B* can function fully and promote survival and proliferation only when its inhibitor, *I- $\kappa$ B*, is disengaged and degraded by proteasomes (see Chapter 16). Partial inhibition of proteasomal activity by a small-molecule inhibitor drug results in increased levels of *I- $\kappa$ B* and, consequently, reduced *NF- $\kappa$ B* activity (that is, loss of its protective activity). The cancer cells subsequently undergo less proliferation and die by apoptosis. Thus, multiple myeloma cells are more sensitive to proteasome inhibitors than normal cells. Consequently, *controlled* administration of proteasome inhibitors, at levels that kill the cancer cells but not normal cells, has proved to be an effective therapy for multiple myeloma. ■

## Ubiquitin Marks Cytosolic Proteins for Degradation in Proteasomes

If proteasomes are to rapidly degrade only those proteins that are either defective or scheduled to be removed, they must be able to distinguish between those proteins that need to be degraded and those that don't. Cells mark proteins that should be degraded by covalently attaching to them a linear chain of multiple copies of a 76-residue polypeptide called *ubiquitin* (Ub) that is highly conserved from yeast to humans. This “polyubiquitin tail” serves as a cellular “kiss of death,” marking the protein for destruction in the proteasome. The ubiquitinylation process (Figure 3-31b, steps **1–3**) involves three distinct steps:

1. Activation of *ubiquitin-activating enzyme* (E1) by the addition of a ubiquitin molecule, a reaction that requires ATP.
2. Transfer of this ubiquitin molecule to a cysteine residue in a *ubiquitin-conjugating enzyme* (E2).
3. Formation of a covalent bond between the carboxyl group of the C-terminal glycine 76 of the ubiquitin bound to E2 and the amino group of the side chain of a lysine residue in the target protein, a reaction catalyzed by a *ubiquitin-protein ligase* (E3). This type of bond is called an *isopeptide bond* because it covalently links a side-chain amino group, rather than the  $\alpha$  amino group, to the carboxyl group. Subsequent ligase reactions covalently attach the C-terminal glycine of an additional ubiquitin molecule via an isopeptide bond to the side chain of lysine 48 of the previously added ubiquitin to generate a polyubiquitin chain covalently attached to the target protein. (We will discuss ubiquitin linkages via other lysine side chains shortly.)

Generally, following attachment of four or more ubiquitins in a polyubiquitin chain, the 19S regulatory cap of the 26S proteasome (sometimes with the help of accessory proteins) recognizes the polyubiquitin-labeled protein using its Ub receptors (see Figure 3-31a), uses ATPases to unfold it, and transports it into the proteasome core for degradation. As a polyubiquitinated substrate is unfolded and passed into the core of the proteasome, enzymes called deubiquitinases (Dubs) hydrolyze the bonds between the individual ubiquitins and between the targeted protein and ubiquitin,

recycling the ubiquitins for additional rounds of protein modification (see Figure 3-31b). Analysis of the human genome sequence indicates the presence of about 90 distinct Dubs, about 80 percent of which use cysteine in a catalytic triad similar to that in the serine proteases described earlier (the sulfhydryl in the cysteine side chain is used in place of the hydroxyl in the side chain of the serine). In some Dubs, zinc is a key participant in the catalytic reactions.

**Specificity of Degradation** Targeting of specific proteins for proteasomal degradation is primarily achieved through the substrate specificity of E3 ligases (see Figure 3-31b, step 3). As a testament to their importance, there are an estimated 600 or more ubiquitin ligase genes in the human genome. The many E3 ligases in mammalian cells ensure that the wide variety of proteins to be polyubiquitinated can be modified when necessary. Some E3 ligases are associated with chaperones that recognize unfolded or misfolded proteins; for example, the E3 ligase CHIP is a co-chaperone for Hsp70. These and other proteins (co-chaperones, escort factors, adapters) can mediate E3 ligase-catalyzed polyubiquitination of dysfunctional proteins that cannot be readily refolded properly and, consequently, mediate their delivery to proteasomes for degradation. In such cases, the chaperone-ubiquitination-proteasome system works in concert for protein quality control.

In addition to quality control, the ubiquitin-proteasome system can be used to regulate the activity of important cellular proteins. An example is the regulated degradation of proteins called *cyclins*, which control the cell cycle (see Chapter 19). Cyclins contain the internal sequence Arg-X-X-Leu-Gly-X-Ile-Gly-Asp/Asn (where X can be any amino acid), which is recognized by specific ubiquitinating enzyme complexes. At a specific time in the cell cycle, each cyclin is phosphorylated by a cyclin kinase. This phosphorylation is thought to cause a conformational change that exposes the recognition sequence to the ubiquitinating enzymes, leading to polyubiquitination and proteasomal degradation.

**Other Functions of Ubiquitin and Ubiquitin-Related Molecules** There are several close relatives of ubiquitin that employ similar E1-, E2-, and E3-dependent mechanisms of activation and transfer to acceptor substrates. These ubiquitin-like modifiers control processes as diverse as nuclear import, regulated by the ubiquitin-like modifier Sumo, and autophagy, regulated by the ubiquitin-like modifier Atg8/LC3 (see Chapter 14). Furthermore, the attachment of ubiquitin to a target protein can be used for purposes other than to mark the protein for degradation, as we will see later in this section, and some of these functions involve polyubiquitin linkages other than those via Lys-48.

Like ubiquitination, deubiquitination is involved in processes other than proteasome-mediated protein degradation. Large-scale, mass-spectrometry-based “proteomic” methods described later in this chapter, together with sophisticated computational approaches, have suggested that Dubs, which are often bound in multiprotein complexes, are involved in an extraordinarily wide range of cell processes.

These processes vary from cell division and cell cycle control (see Chapter 19) to membrane trafficking (see Chapter 14) to cell signaling pathways (see Chapters 15 and 16).

## Noncovalent Binding Permits Allosteric, or Cooperative, Regulation of Proteins

In addition to regulating the amount of a protein, cells can also regulate the intrinsic activity of a protein. One of the most important mechanisms for regulating protein function is through allosteric interactions. Broadly speaking, **allostery** (from the Greek, “other shape”) refers to any change in a protein’s tertiary or quaternary structure, or in both, induced by the noncovalent binding of a ligand. When a ligand binds to one site (A) in a protein and induces a conformational change that alters the activity of a different site (B), the ligand is called an *allosteric effector* of the protein, while site A is called an *allosteric binding site*, and the protein is called an *allosteric protein*. By definition, allosteric proteins have multiple binding sites, at least one for the allosteric effector and at least one for other molecules with which the protein interacts. The allosteric change in activity can be positive or negative; that is, it can be an increase or a decrease in protein activity. Negative allostery often involves the end product of a multi-step biochemical pathway binding to, and reducing the activity of, an enzyme that catalyzes an early, rate-controlling step in that pathway. In this way, excessive buildup of the product is prevented. This kind of regulation of a metabolic pathway is also called *end-product inhibition* or *feedback inhibition*. Allosteric regulation is particularly prevalent in multimeric enzymes and other proteins in which conformational changes in one subunit are transmitted to an adjacent subunit.

*Cooperativity*, a term that is often used synonymously with *allostery*, usually refers to the influence (positive or negative) that the binding of a ligand at one site has on the binding of another molecule of the *same* type of ligand at a different site. Hemoglobin presents a classic example of positive cooperative binding in that the binding of a single ligand, molecular oxygen ( $O_2$ ), increases the affinity of hemoglobin for the next oxygen molecule. Each of the four subunits in hemoglobin contains one heme molecule. The heme groups are the oxygen-binding components of hemoglobin (see Figure 3-14a). The binding of oxygen to the heme molecule in one of the four hemoglobin subunits induces a local conformational change whose effect spreads to the other subunits, lowering the  $K_d$  (increasing the affinity) for the binding of additional oxygen molecules to the remaining hemes and yielding a sigmoidal oxygen-binding curve (Figure 3-32). Because of the sigmoidal shape of the oxygen-saturation curve, it takes only a fourfold increase in oxygen concentration for the saturation of the oxygen-binding sites in hemoglobin to go from 10 to 90 percent. Conversely, if there were no cooperativity and the shape of the curve was typical of that for Michaelis-Menten (see Figure 3-24), or noncooperative, binding, it would take an eighty-one-fold increase in oxygen concentration to accomplish the same increase in loading of its binding sites in hemoglobin. This cooperativity permits hemoglobin to take up oxygen very efficiently in the lungs, where the oxygen

### EXPERIMENTAL FIGURE 3-32 Hemoglobin binds oxygen

**cooperatively.** Each tetrameric hemoglobin molecule has four oxygen-binding sites; at saturation, all the sites are loaded with oxygen. The oxygen concentration in tissues is commonly measured as the partial pressure of oxygen ( $pO_2$ ) in torr units (a standard measure of pressure equivalent to 1 mm of mercury under standard conditions).  $P_{50}$  is the  $pO_2$  at which half the oxygen-binding sites are occupied; it is somewhat analogous to the  $K_m$  for an enzymatic reaction. The large change in the amount of oxygen bound over a small range of  $pO_2$  values permits efficient unloading of oxygen in peripheral tissues such as muscle. The sigmoidal shape of a plot of saturation versus ligand concentration is indicative of cooperative binding, in which the binding of one oxygen molecule allosterically influences the binding of subsequent oxygens. In the absence of cooperative binding, a binding curve is a hyperbola, similar to the curves in Figure 3-24. See J. M. Berg et al., 2015, *Biochemistry*, 8th ed., Macmillan.

concentration is high, and unload it in tissues, where the concentration is low. Thus cooperativity amplifies the sensitivity of a system to changes in the concentration of its ligands, providing in many cases a selective evolutionary advantage.

## Noncovalent Binding of Calcium and GTP Are Widely Used as Allosteric Switches to Control Protein Activity

Unlike oxygen, which causes graded allosteric changes in the activity of hemoglobin, some other allosteric effectors act as switches, turning the activity of many different proteins on or off by binding to them noncovalently. Two important allosteric switches that we will encounter many times throughout this book, especially in the context of cell signaling pathways (see Chapters 15 and 16), are  $Ca^{2+}$  and GTP.

**$Ca^{2+}$ /Calmodulin-Mediated Switching** The concentration of  $Ca^{2+}$  that is free in the cytosol (not bound to molecules other than water) is kept very low ( $\sim 10^{-7}$  M) by specialized membrane transport proteins that continually pump excess  $Ca^{2+}$  out of the cytosol (see Chapters 11 and 15). However, as we will learn in Chapters 11 and 15, the cytosolic  $Ca^{2+}$  concentration can increase tenfold to a hundredfold when  $Ca^{2+}$ -permeable channels in the cell-surface membranes open

and allow extracellular  $Ca^{2+}$  to flow into the cell. This rise in cytosolic  $Ca^{2+}$  is sensed by specialized  $Ca^{2+}$ -binding proteins, which alter cellular behavior by turning the activities of other proteins on or off. The importance of extracellular  $Ca^{2+}$  for cell activity was first documented by S. Ringer in 1883, when he discovered that isolated rat hearts suspended in an NaCl solution made with “hard” ( $Ca^{2+}$ -rich) London tap water contracted beautifully, whereas they beat poorly and stopped quickly if distilled,  $Ca^{2+}$ -depleted, water was used.

Many  $Ca^{2+}$ -binding proteins bind  $Ca^{2+}$  using the EF hand/helix-loop-helix structural motif discussed earlier (see Figure 3-10b). A well-studied EF hand protein, **calmodulin**, is found in all eukaryotic cells, where it may exist as an individual monomeric protein or as a subunit of a multimeric protein. This dumbbell-shaped molecule contains four  $Ca^{2+}$ -binding EF hands with  $K_d$ s of about  $10^{-6}$  M. The binding of  $Ca^{2+}$  to calmodulin causes a conformational change that permits  $Ca^{2+}$ /calmodulin to bind to conserved sequences in various target proteins (Figure 3-33), thereby switching their activities on or off. Calmodulin and similar EF hand proteins thus function as *switch proteins*, acting in concert with changes in  $Ca^{2+}$  levels to modulate the activity of other proteins.

(a) Calmodulin without calcium

(b)  $Ca^{2+}$ /calmodulin bound to target peptide

**FIGURE 3-33 Conformational changes induced by  $Ca^{2+}$  binding to calmodulin.** Calmodulin is a widely distributed cytosolic protein that contains four  $Ca^{2+}$ -binding sites, one in each of its EF hand (helix-loop-helix) motifs (EF1-ER4, see also Figure 3-10). At cytosolic  $Ca^{2+}$  concentrations above about  $5 \times 10^{-7}$  M, binding of  $Ca^{2+}$  to calmodulin changes the protein's conformation from the dumbbell-shaped,  $Ca^{2+}$ -free form (a) to one in which hydrophobic side chains become more exposed to solvent. The resulting  $Ca^{2+}$ /calmodulin complex can wrap around exposed helices (target peptides) with specialized sequences in various target proteins (b), thereby altering their activities. [Part (a) data from H. Kuboniwa et al., 1995, *Nat. Struct. Biol.* **2**:768–776, PDB ID 1cfd. Part (b) data from W. E. Meador, A. R. Means, and F. A. Quiocho, 1992, *Science* **257**:1251–1255, PDB ID 1cdli.]

**Switching Mediated by Guanine Nucleotide–Binding Proteins** Another group of intracellular switch proteins constitutes the **GTPase superfamily**. As the name suggests, these proteins are enzymes—GTPases—that can hydrolyze GTP (guanosine triphosphate) to GDP (guanosine diphosphate). They include the monomeric Ras protein (whose structure is shown in Figure 3-9, with bound GDP shown in blue) and the  $G_\alpha$  subunit of the trimeric G proteins, both discussed at length in Chapters 15 and 16. Both Ras and  $G_\alpha$  can bind to the plasma membrane, function in cell signaling, and play key roles in cell proliferation and differentiation. Other members of the GTPase superfamily function in protein synthesis, the transport of proteins between the nucleus and the cytoplasm, the formation of coated vesicles and their fusion with target membranes, and rearrangements of the actin cytoskeleton. Some GTPase proteins have a covalently attached lipid chain (see Figure 7-19) that mediates their binding to membranes. We examine the roles of various GTPase switch proteins in regulating intracellular signaling and other processes in several later chapters.

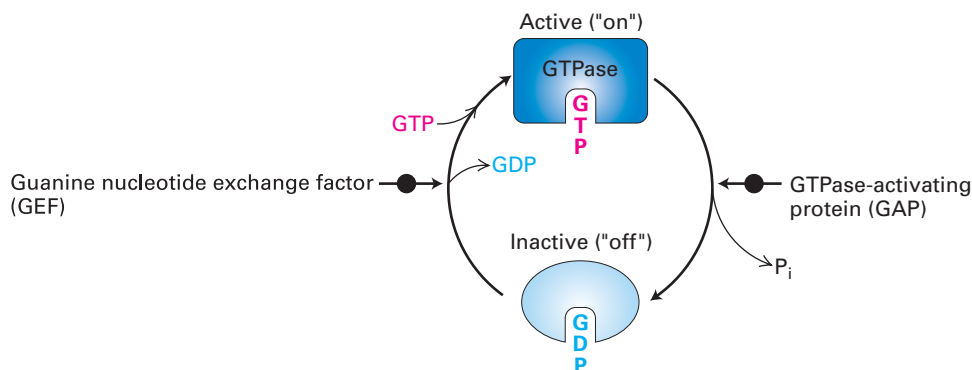

All the GTPase switch proteins exist in two forms, or conformations (Figure 3-34): (1) an active (“on”) form with bound GTP, which can influence the activity of specific target proteins to which they bind, and (2) an inactive (“off”) form with bound GDP. The switch is turned on—that is, the conformation of the protein changes from inactive to active—when a GTP molecule replaces a bound GDP in the inactive conformation. The switch is turned off when the relatively slow GTPase activity of the protein hydrolyzes bound GTP, converting it to GDP and leading the conformation to change to the inactive form. The amount of time any given GTPase switch remains in the active, GTP-bound form depends on the rate of its GTPase activity. Thus the GTPase activity acts as a timer to control this switch. Cells contain a variety of proteins that can modulate the baseline (or intrinsic) rate of GTPase activity for any given GTPase switch and so can control how long the switch remains on.

For example, GTPase-activating proteins, or GAPs, increase the rate of GTPase activity, thus reducing the time the GTPase is in the active form. Cells also have specific proteins whose function is to regulate the conversion of inactive GTPases to active ones—that is, to turn the switch on—by mediating the replacement of bound GDP with GTP (*GDP/GTP exchange*). These proteins are called guanine nucleotide exchange factors, or GEFs. GTPases with lipid anchors are also regulated by proteins called guanine nucleotide dissociation inhibitors (GDIs) that bind to the lipid chain and thus influence interactions with cellular membranes.

 The GAPs, GEFs, and GDIs are themselves subject to regulation and, together with their GTPases, participate in complex regulatory networks that control a vast array of cellular activities. It is, therefore, not surprising that disruptions of these finely tuned regulatory networks by mutations or pathogens are associated with a wide variety of diseases. Examples of genetic diseases affecting these networks include Noonan syndrome (a developmental disorder), retinitis pigmentosa (a degenerative eye disease), and X-linked mental retardation. Examples of disruptions of these networks by pathogens include bacterially induced food poisoning, dysenteries (inflammation of the intestines with diarrhea), Legionnaires’ disease (a severe type of pneumonia that involves lung inflammation), and even the plague [also called the Black Death, which between 1347 and 1351 decimated the populations of China (~50 percent death rate) and Europe (~33 percent death rate)]. ■

## Phosphorylation and Dephosphorylation Covalently Regulate Protein Activity

In addition to exploiting the noncovalent regulators described above, cells can use covalent modifications to regulate the intrinsic activity of a protein. One of the most common covalent mechanisms for regulating protein activity

**FIGURE 3-34 The GTPase switch.** GTPases are enzymes that bind to GTP and hydrolyze it to GDP. When bound to GTP, the GTPase protein adopts its active, or “on,” conformation and can interact with target proteins to regulate their activities. When the bound GTP is hydrolyzed to GDP by the intrinsic GTPase activity of the protein, the GTPase with GDP bound assumes an inactive, or “off,” conformation.

The GTPase switch can be turned back on when another protein, called a GEF (guanine nucleotide exchange factor), mediates the replacement (exchange) of the bound GDP with a GTP molecule from the surrounding fluid. GTPase-activating proteins, or GAPs, can influence the rates of GTP hydrolysis. The binding of the active form of the GTPase to its targets is a form of noncovalent regulation.

is **phosphorylation**, the reversible addition of phosphate groups to hydroxyl groups on the side chains of serine, threonine, or tyrosine residues. Phosphorylated proteins are called *phosphoproteins*. Phosphorylation is catalyzed by enzymes called protein **kinases**, while the removal of phosphates, known as *dephosphorylation*, is catalyzed by **phosphatases**. The counteracting activities of kinases and phosphatases provide cells with a “switch” that can turn on or turn off the function of various proteins that are the substrates (or targets) of these enzymes (Figure 3-35). Sometimes phosphorylation sites are masked transiently by reversible covalent modification with the sugar N-acetylglucosamine (called O-GlcNAcylation), which is an additional means of covalent regulation. Phosphorylation changes a protein’s charge and to some extent its surface shape; it can also result in conformational changes. As a consequence, phosphorylation (or dephosphorylation) can influence the location of a protein within cells (e.g., its attachment to the inner surface of the plasma membrane), its intrinsic (e.g., enzymatic) activity, its ability to bind to other molecules, including metabolites, DNA, or other proteins, its ability to undergo further covalent modification, or its stability (rate of degradation). In addition, several conserved protein domains, such as the SH2 domain (see Figure 16-11), bind specifically to phosphorylated peptides. Thus phosphorylation can mediate the formation of protein complexes that can generate or extinguish a wide variety of cellular activities, discussed in many subsequent chapters.

Nearly 3 percent of all yeast proteins are protein kinases or phosphatases, indicating the importance of phosphorylation and dephosphorylation reactions even in these simple cells. Analysis of the human genome indicates there are approximately 500 human protein kinases (the human “kinome”). All classes of proteins—including structural proteins, scaffolds, enzymes, membrane channels, and signaling molecules—have members regulated by kinase/phosphatase modifications. Different protein kinases and phosphatases

**FIGURE 3-35 Regulation of protein activity by phosphorylation and dephosphorylation.** The cyclic phosphorylation and dephosphorylation of a protein is a common cellular mechanism for regulating protein activity. In this example, the target protein is active (*top*) when phosphorylated and inactive (*bottom*) when dephosphorylated; some proteins have the opposite response to phosphorylation.

are specific for different target proteins, often recognizing different linear sequences in which the residue to be phosphorylated is embedded, and so can regulate distinct cellular pathways, as discussed in later chapters. Some kinases have many targets, so that a single kinase can serve to integrate the activities of many targets simultaneously. Frequently, the target of a kinase or phosphatase is yet another kinase or phosphatase, creating a cascade effect. There are many examples of such kinase cascades, which permit amplification of a signal and many levels of fine-tuning (see Chapters 15 and 16).

## Ubiquitylation and Deubiquitylation Covalently Regulate Protein Activity

Both ubiquitin and ubiquitin-like proteins (of which there are more than a dozen in humans) can be covalently linked to a target protein in a regulated fashion, in a manner analogous to phosphorylation. Deubiquitinases can reverse ubiquitylation in a manner analogous to the action of phosphatases. These ubiquitin modifications are structurally far more complex than phosphorylation, however, and so can mediate many distinct interactions between the ubiquitylated protein and other cellular proteins. Ubiquitylation can involve attachment of a single ubiquitin to a protein (**monoubiquitylation**), addition of multiple, single ubiquitin molecules to different sites on one target protein (**multiubiquitylation**), or addition of a polymeric chain of ubiquitins to a protein (**polyubiquitylation**). An additional source of variation is that different amino groups in the ubiquitin molecule can be used to form an isopeptide bond with the C-terminal Gly-76 in another ubiquitin to form a polyubiquitin chain. All seven lysine residues in ubiquitin (Lys-6, Lys-11, Lys-27, Lys-29, Lys-33, Lys-48, and Lys-63) and its N-terminal amino group can participate in inter-ubiquitin linkages. Different ubiquitin ligases are specific both for targets (substrates) to be ubiquitylated and for the lysine side chains on the ubiquitins that participate in the inter-ubiquitin isopeptide linkages (Lys-63 or Lys-48, etc.) (Figure 3-36). These multiple forms of ubiquitylation result in the generation of a wide variety of recognition surfaces that can participate in many protein-protein interactions with the hundreds of proteins (>200 in humans) that contain more than a dozen distinct ubiquitin-binding domains (UBD). In addition, any given polyubiquitin chain has the potential to bind simultaneously to more than one UBD-containing protein, leading to the formation of ubiquitylation-dependent multiprotein complexes. Some deubiquitinases can remove an intact polyubiquitin chain from a modified protein (“anchored” chain) and thus generate a polyubiquitin chain not covalently linked to another protein (“unanchored” chain). Even these unanchored chains may serve a regulatory role. With this great structural diversity, it is not surprising that cells use ubiquitylation and deubiquitylation to control many different cellular functions.

We have already seen how polyubiquitylation via Lys-48 residues is used to tag proteins for proteasomal degradation.

**FIGURE 3-36 Determination of polyubiquitin function by the lysine used for inter-ubiquitin isopeptide bonds.** Different ubiquitin ligases catalyze polyubiquitinylation of distinct target (substrate) proteins (colored ovals) using distinct lysine side chains of ubiquitin molecules (purple) to generate the inter-ubiquitin isopeptide linkages (blue) with Gly-76 of the adjacent ubiquitin. Dotted blue arrows represent additional ubiquitins in the chain that are not shown. The lysine used

for the isopeptide bonds determines the function of the polyubiquitinylation. For example, polyubiquitins with Lys-48:Gly-76 isopeptide bonds direct the target to proteasomes for degradation. Those that use Lys-63, Lys-33, and Lys-11 influence signaling, T-lymphocyte control, and cell division, respectively. Isopeptide bonds involving ubiquitin's Lys-6, Lys-27, and Lys-29 and bonds using its N-terminal amino group (not shown) can also be used to generate polyubiquitin chains.

There is evidence that polyubiquitinylation via other Lys residues (for example, Lys-11 and Lys-33, but not Lys-63) can also target proteins for proteasomal degradation. Strikingly, ubiquitinylation unrelated to protein degradation can also control diverse cell functions, including cellular internalization of molecules via endocytosis (see Chapter 14), repair of damaged DNA, metabolism, messenger RNA synthesis (transcription), defense against pathogens, cell division/cell cycle progression, cell signaling pathways, trafficking of proteins within a cell, and apoptosis. The lysine used to form the inter-ubiquitin isopeptide bonds can vary depending on the cellular system that is regulated (see Figure 3-36). For example, polyubiquitinylation with Lys-63 linkages is used in many cellular identification and signaling systems, such as recognition of the presence of intracellular viruses and bacteria and the consequent induction of a protective immune response, as well as direction of these pathogens to lysosomes for degradation. Lys-11-linked polyubiquitin chains regulate cell division. Lys-33-linked chains help suppress the activity of receptors on specialized white blood cells, called T lymphocytes (see Chapter 23), and so control the activity and function of those lymphocytes.

## Proteolytic Cleavage Irreversibly Activates or Inactivates Some Proteins

Unlike phosphorylation and ubiquitinylation, which are reversible, the activation or inactivation of protein function by proteolytic cleavage is an irreversible mechanism for regulating protein activity. For example, many polypeptide hormones, such as insulin, are synthesized as longer precursors, and prior to secretion from cells some of their peptide bonds must be hydrolyzed for them to fold properly. In some cases, a single long precursor *prohormone* polypeptide is cleaved into several distinct active hormones. To prevent the pancreatic serine proteases from inappropriately digesting proteins before they reach the small intestine, they are synthesized as *zymogens*, inactive precursor enzymes. Cleavage of a peptide bond near the N-terminus of trypsinogen (the zymogen of trypsin) by a highly specific protease in the small intestine generates a new N-terminal residue (Ile-16), whose amino group can form an ionic bond with the carboxylic acid side chain of an internal aspartic acid. This binding causes a conformational change that opens the substrate-binding site, activating the enzyme. The active trypsin can then activate

trypsinogen, chymotrypsinogen, and other zymogens. Similar but more elaborate protease cascades (with one protease activating inactive precursors of others) that can amplify an initial signal play important roles in several systems, such as the blood-clotting cascade and the complement system (see Chapter 23). The importance of carefully regulating such systems is clear—inappropriate clotting, for example, could fatally clog the circulatory system, while insufficient clotting could lead to uncontrolled bleeding.

An unusual and rare type of proteolytic processing, termed *protein self-splicing*, takes place in bacteria and some eukaryotes. This process is analogous to editing film: an internal segment of a polypeptide is removed and the ends of the polypeptide are rejoined (ligated). Unlike other forms of proteolytic processing, protein self-splicing is an autocatalytic process, which proceeds by itself without the participation of other enzymes. The excised peptide appears to eliminate itself from the protein by a mechanism similar to that used in the processing of some RNA molecules (see Chapter 10). In vertebrate cells, the processing of some proteins includes self-cleavage, but the subsequent ligation step is absent. One such protein is Hedgehog, a membrane-bound signaling molecule that is critical to a number of developmental processes (see Chapter 16).

### Higher-Order Regulation Includes Control of Protein Location

All the regulatory mechanisms heretofore described affect a protein locally at its site of action, altering the protein's concentration or turning its activity on or off. Normal functioning of a cell, however, also requires the segregation of proteins to particular compartments, such as the mitochondria, nucleus, or lysosomes. In regard to enzymes, compartmentation not only provides an opportunity for controlling the delivery of substrate or the exit of product, but also permits competing reactions to take place simultaneously in different parts of a cell. We describe the mechanisms that cells use to direct various proteins to different compartments in Chapters 13 and 14.

## KEY CONCEPTS OF SECTION 3.4

### Regulating Protein Function

- Proteins may be regulated at the level of protein synthesis, protein degradation, or the intrinsic activity of proteins through noncovalent or covalent interactions.
- The life span of intracellular proteins is largely determined by their susceptibility to proteolytic degradation.
- Many proteins are marked for destruction with a polyubiquitin tag by ubiquitin ligases and then degraded within proteasomes, large cylindrical complexes with multiple protease active sites in their interior chambers (see Figure 3-31).

- Ubiquitinylation of proteins is reversible due to the activity of deubiquitinating enzymes.
- In allostery, the noncovalent binding of one ligand molecule, the allosteric effector, induces a conformational change that alters a protein's activity or affinity for other ligands. The allosteric effector can be identical in structure to or different from the other ligands, whose binding it affects. The allosteric effector can be an activator or an inhibitor.
- In multimeric proteins, such as hemoglobin, that bind multiple identical ligand molecules (e.g., oxygen), the binding of one ligand molecule may increase or decrease the protein's affinity for subsequent ligand molecules. This type of allostery is known as cooperativity (see Figure 3-32).
- Several allosteric mechanisms act as switches, turning protein activity on and off in a reversible fashion.
- Two classes of intracellular switch proteins regulate a wide variety of cellular processes: (1)  $\text{Ca}^{2+}$ -binding proteins (e.g., calmodulin) and (2) members of the GTPase superfamily (e.g., Ras), which cycle between active GTP-bound and inactive GDP-bound forms (see Figure 3-34). GTPases participate in complex regulatory networks that include proteins (GAP, GEF, GDI) that regulate the cycling of the GTPase between its active and inactive forms.
- The phosphorylation and dephosphorylation of hydroxyl groups on serine, threonine, or tyrosine side chains by protein kinases and phosphatases provide reversible on/off regulation of numerous proteins (see Figure 3-35).
- Variations in the nature of the covalent attachment of ubiquitin to proteins (mono-, multi-, and polyubiquitinylation involving a variety of linkages between the ubiquitin monomers) are involved in a wide variety of cellular functions other than proteasome-mediated degradation, such as changes in the location or activity of proteins (see Figure 3-36).
- Many types of covalent and noncovalent regulation are reversible, but some forms of regulation, such as proteolytic cleavage, are irreversible.
- Higher-order regulation includes the intracellular location, or compartmentation, of proteins.

## 3.5 Purifying, Detecting, and Characterizing Proteins

A protein often must be purified before its structure and the mechanism of its action can be studied in detail. However, because proteins vary in size, shape, oligomerization state, charge, and water solubility, no single method can be used to isolate all proteins. To isolate one particular protein from the estimated 10,000 different proteins in a particular type of cell is a daunting task that requires methods both for separating proteins and for detecting the presence of specific proteins.

Any molecule, whether protein, carbohydrate, or nucleic acid, can be separated, or *resolved*, from other molecules on the basis of their differences in one or more physical or chemical characteristics. The larger and more numerous the differences between two proteins, the easier and more efficient their separation. As a practical matter, the more abundant a particular protein is in a biological sample, the easier it is to separate it from the other molecules in the sample. The three most widely used characteristics for separating proteins are *size*, defined as either length or mass; net electrical charge; and *affinity* for specific ligands. In this section, we briefly outline several important techniques for separating proteins; these separation techniques are also useful for the separation of nucleic acids and other biomolecules. (Specialized methods for removing membrane proteins from membranes are described in Chapter 7 after the unique properties of these proteins are discussed.) We then consider the use of radioactive compounds for tracking biological activity. Finally, we consider several techniques for characterizing a protein's mass, sequence, and three-dimensional structure.

## Centrifugation Can Separate Particles and Molecules That Differ in Mass or Density

The first step in a typical protein purification scheme is centrifugation. The principle behind centrifugation is that two types of particles in suspension (cells, cell fragments, organelles, or molecules) with different masses or densities will settle to the bottom of a test tube at different rates. Remember, mass is the weight of a sample (measured in daltons or molecular weight units), whereas density is the ratio of its mass to volume (often expressed as grams per liter because of the methods used to measure density). Proteins vary greatly in mass, but not in density. Unless a protein has an attached lipid or carbohydrate, its density will not vary by more than 15 percent from  $1.37 \text{ g/cm}^3$ , the average protein density. Heavier or denser molecules settle, or *sediment*, more quickly than lighter or less dense molecules.

A centrifuge speeds sedimentation by subjecting particles in suspension to centrifugal forces as great as 1 million times the force of gravity,  $g$ , which can sediment particles as small as 10 kDa. Modern ultracentrifuges achieve these forces by reaching speeds of 150,000 revolutions per minute (rpm) or greater. However, small particles with masses of 5 kDa or less will not sediment uniformly even at such remarkably high rotation rates. The extraordinary technical achievements of modern ultracentrifuges can be appreciated by considering that they can rotate a several-pound rotor (about the size of an American football) that holds the samples in tubes at rates as high as 2500 revolutions per second!

Centrifugation is used for two basic purposes: (1) as a preparative technique to separate one type of material from others with the goal of obtaining enough of the material to perform subsequent experiments and (2) as an analytical technique to measure physical properties (e.g., molecular

weight, density, shape, and equilibrium binding constants) of macromolecules. The sedimentation constant,  $s$ , of a protein is a measure of its sedimentation rate. The sedimentation constant is commonly expressed in Svedberg units (S), where a typical large protein complex is about 3–5S, a proteasome is 26S, and a eukaryotic ribosome is 80S.

**Differential Centrifugation** The most common initial step in protein purification from cells or tissues is the separation of water-soluble proteins from insoluble cellular material by *differential centrifugation*. A starting mixture, commonly a cell homogenate (mechanically broken cells), is poured into a tube and spun at a rotor speed, and for a period of time, that forces cell organelles such as nuclei as well as large unbroken cells or large cell fragments to collect as a pellet at the bottom; the soluble proteins remain in the supernatant (Figure 3-37a). The supernatant fraction then is poured off, and either it or the pellet can be subjected to other purification methods to separate the many different proteins that they contain.

**Rate-Zonal Centrifugation** On the basis of differences in their masses, water-soluble proteins can be separated by centrifugation through a solution of increasing density, called a *density gradient*. A concentrated sucrose solution is commonly used to form a density gradient in a centrifuge tube (with higher concentrations of sucrose, and thus a higher solution density, toward the bottom of the tube, Figure 3-37b). When a protein mixture is placed on top of a sucrose density gradient in a tube and subjected to centrifugation, each protein in the mixture migrates down the tube at a rate controlled by the protein's physical properties. All the proteins start from the thin layer of the sample that was placed at the top of the tube and separate into bands (actually, disks) of proteins of different masses as they travel at different rates through the gradient. In this separation technique, called *rate-zonal centrifugation*, samples are centrifuged just long enough to separate the molecules of interest into discrete bands, also called zones (see Figure 3-37b). If a sample is centrifuged for too short a time, the different protein molecules will not separate sufficiently. If a sample is centrifuged much longer than necessary, all the proteins will end up mixed together at the bottom of the tube.

Although the sedimentation rate is strongly influenced by particle mass, rate-zonal centrifugation is seldom effective in determining precise molecular weights because variations in shape also affect the sedimentation rate. The exact effects of shape are hard to assess, especially for proteins or other molecules, such as single-stranded nucleic acid molecules, that can assume many complex shapes. Nevertheless, rate-zonal centrifugation has proved to be a practical method for separating many different types of polymers and particles. A second density-gradient technique, called *equilibrium density-gradient centrifugation*, is used mainly to separate DNA, lipoproteins that carry lipids through the circulatory system, or organelles (see Figure 4-37).

Centrifugation techniques separate

particles that differ in mass or density. (a) In differential centrifugation, a cell homogenate or other mixture is spun long enough to sediment the larger particles (e.g., cell organelles, cells), which collect as a pellet at the bottom of the tube (step **2**). The smaller particles (e.g., soluble proteins, nucleic acids) remain in the liquid supernatant, which can be transferred to another tube (step **3**). (b) In rate-zonal centrifugation, a mixture is spun (step **1**) just long enough to separate molecules that differ in mass but may be similar in shape and density (e.g., globular proteins, RNA molecules) into discrete zones within a density gradient commonly formed by a concentrated sucrose solution. Fractions are removed from the bottom of the tube and subjected to testing (assayed).

## Electrophoresis Separates Molecules on the Basis of Their Charge-to-Mass Ratio

**Electrophoresis**, a technique for separating molecules in a mixture under the influence of an applied electric field, is one of the most frequently used techniques to study proteins and nucleic acids. Dissolved molecules in an electric field move, or migrate, at a speed determined by their charge-to-mass (charge:mass) ratio and the physical properties of the medium through which they migrate. For example, if two molecules have the same mass and shape, the one with the greater net charge will move faster toward an electrode of the opposite polarity.

**SDS-Polyacrylamide Gel Electrophoresis** Because many proteins or nucleic acids that differ in size and shape have nearly identical charge:mass ratios, electrophoresis of these macromolecules in a liquid solution results in little or no separation of molecules of different lengths. However, successful separation of proteins and nucleic acids can be

accomplished by electrophoresis in various gels (semisolid suspensions in water similar to the congealed gelatin found in desserts). These gels are commonly cast into flat, relatively thin slabs between a pair of glass plates. When a mixture of proteins is placed in a gel and an electric current is applied, the gel acts as a sieve, allowing smaller species to maneuver more rapidly through its pores than larger species do. The shape of a molecule can also influence its rate of migration (long asymmetric molecules migrate more slowly than spherical ones of the same mass).

Electrophoretic separation of proteins is most commonly performed in polyacrylamide gels. These gels are made by polymerizing a solution of acrylamide monomers into polyacrylamide chains and simultaneously cross-linking the chains into a semisolid matrix. The pore size of a gel can be varied by adjusting the concentrations of polyacrylamide and the cross-linking reagent. The rate at which a protein moves through a gel is influenced by the gel's pore size and the strength of the electric field. By suitable adjustment of

these parameters, proteins of widely varying sizes can be resolved (separated from one another) by this technique, known as *polyacrylamide gel electrophoresis* (PAGE).

In the most powerful technique for resolving protein mixtures, proteins are exposed to the ionic detergent SDS (sodium dodecylsulfate) before and during gel electrophoresis (Figure 3-38). SDS denatures proteins, in part because

**EXPERIMENTAL FIGURE 3-38 SDS-polyacrylamide gel electrophoresis (SDS-PAGE) separates proteins primarily on the basis of their masses.** (a) Initial treatment with SDS, a negatively charged detergent, dissociates multimeric proteins and denatures all the polypeptide chains (step 1). During electrophoresis, the SDS-protein complexes migrate through the polyacrylamide gel (step 2). Small complexes are able to move through the pores faster than larger ones. Thus the proteins separate into bands according to their sizes as they migrate. The separated protein bands are visualized by staining with a dye (step 3). (b) Example of SDS-PAGE separation of all the proteins in a whole-cell lysate (detergent-solubilized cells). (Left) The many separate stained proteins appear almost as a continuum. (Right) A single protein purified from the lysate by a single step of antibody-affinity chromatography. The proteins were visualized by staining with a silver-based dye. [Part (b) data from B. Liu and M. Krieger, 2002, *J. Biol. Chem.* **277**:34125–34135.]

it binds to hydrophobic side chains, destabilizing the hydrophobic interactions in the core of a protein that contribute to its stable conformation. SDS treatment is usually combined with heating, often in the presence of reducing agents that break disulfide bonds. Under these conditions, most multimeric proteins dissociate into their subunits. Typically, the amount of SDS that binds to the protein is proportional to the length of the polypeptide chain and relatively independent of the sequence. Two proteins of similar size will bind the same absolute quantity of SDS, whereas a protein twice that size will bind twice the amount of SDS. Denaturation of a complex protein mixture with SDS in combination with heat usually forces each polypeptide chain into an extended conformation and imparts on each of the proteins in the mixture a constant charge:mass ratio because the dodecylsulfate, which is negatively charged, is the major contributor of charge. As the SDS-bound proteins move through the polyacrylamide gel, they are separated according to size by the sieving action of the gel. SDS treatment thus eliminates the effect of differences in native conformation; therefore, chain length, which is proportional to mass, is the principal determinant of the migration rate of proteins in *SDS-polyacrylamide electrophoresis* (SDS-PAGE). Even chains that differ in molecular weight by less than 10 percent can be resolved by this technique. Moreover, the molecular weight of a protein can be estimated by comparing the distance that it migrates through a gel with the distances that proteins of known molecular weight (called molecular weight “standards”) migrate in the same gel (there is a roughly linear relationship between migration distance and the log of the molecular weight). Proteins within the gels can be extracted for further analysis (e.g., identification by the methods described below).

If two or more polypeptides are cross-linked by disulfide bonds, the protein’s migration rate in SDS-PAGE will depend on whether or not the protein has been reduced to break those bonds prior to electrophoresis. The cross-linked proteins will appear larger than the individual, reduced subunits. By examining samples with and without reduction, one can identify such proteins and their component polypeptides.

**Two-Dimensional Gel Electrophoresis** Electrophoresis of a mixture containing all cellular proteins by SDS-PAGE can separate proteins having relatively large differences in mass, but cannot readily resolve proteins having similar masses (e.g., a 41-kDa protein versus a 42-kDa protein). To separate proteins of similar masses, another physical characteristic must be exploited. Most commonly, this characteristic is electric charge, which is determined by the pH of the sample and by the relative number of the protein’s positively and negatively charged groups, which is in turn dependent on the  $pK_a$ ’s of the ionizable groups (see Chapter 2) on the proteins (usually the amino and carboxyl termini and side chains such as those in lysine and aspartic acid). Two unrelated proteins having similar masses are unlikely to have identical net charges because their sequences, and thus the number of acidic and basic residues, are different.

**EXPERIMENTAL FIGURE 3-39 Two-dimensional gel electrophoresis separates proteins on the basis of charge and mass.** (a) In this technique, proteins are first separated into bands on the basis of their charges by isoelectric focusing (step 1). The resulting gel strip is applied to an SDS-polyacrylamide gel (step 2), and the proteins are separated into spots by mass (step 3). (b) In this two-dimensional

electrophoresis gel of a protein extract from cultured cells, each spot represents a single polypeptide. Polypeptides can be detected by dyes, as here, or by other techniques, such as autoradiography. Each polypeptide is characterized by its isoelectric point (pI) and molecular weight. [Part (b) Michael J. Dunn.]

In *two-dimensional gel electrophoresis*, proteins are separated sequentially, first by their charges and then by their masses (Figure 3-39a). In the first step, a cell or tissue extract is fully denatured by high concentrations (8 M) of urea (and sometimes SDS) and then layered on a strip of gel that contains urea, which removes any bound SDS, and a continuous pH gradient. The pH gradient is formed by ampholytes, polyanionic and polycationic small molecules that are cast into the gel. When an electric field is applied to the gel, the ampholytes will migrate. Ampholytes with an excess of negative charges will migrate toward the anode, where they establish an acidic pH (many protons), while ampholytes with an excess of positive charges will migrate toward the cathode, where they establish an alkaline pH. The careful choice of the mixture of ampholytes and careful preparation of the gel allows the construction of stable pH gradients ranging from pH 3 to pH 10. A charged protein placed at one end of such a gel will migrate through the gradient under the influence of the electric field until it reaches its **isoelectric point (pI)**, the pH at which the net charge of the protein is zero. With no net charge, the protein will migrate no further. This technique, called *isoelectric focusing (IEF)*, can resolve proteins that differ by only one charge unit. This method is sensitive enough to separate phosphorylated and nonphosphorylated versions of the same protein.

Proteins that have been separated on an IEF gel can then be separated in a second dimension on the basis of

their molecular weights. To accomplish this separation, the IEF gel strip is placed lengthwise on one outside edge of a square or rectangular slab of polyacrylamide gel, this time saturated with SDS to confer on each separated protein a more or less constant charge:mass ratio. When an electric field is imposed, the proteins will migrate from the IEF gel into the SDS gel and then separate according to their masses. The sequential resolution of proteins by charge and mass can achieve excellent separation of cellular proteins and provides a powerful visual representation of the complexity of proteins in cells (Figure 3-39b). Today sophisticated mass spectrometry methods, described below, are often used in place of two-dimensional gel electrophoresis, both to separate and to identify the protein components of a complex sample as well as to compare changes in the amounts of those components in different biological specimens.

### Liquid Chromatography Resolves Proteins by Mass, Charge, or Affinity

A third common technique for separating mixtures of proteins or fragments of proteins, as well as other molecules, is based on the principle that molecules in solution can differentially interact with (bind to and dissociate from) a particular solid surface, depending on the physical and chemical properties of the molecule and the surface. If the solution is allowed to flow across the surface, then molecules that

(a) Gel filtration chromatography

(b) Ion-exchange chromatography

**EXPERIMENTAL FIGURE 3-40 Three commonly used liquid chromatographic techniques separate proteins on the basis of mass, charge, or affinity for a specific binding partner.** (a) Gel filtration chromatography separates proteins that differ in size. A mixture of proteins is carefully placed, or loaded, on the top of a cylinder packed with porous beads. Smaller proteins travel through the column more slowly than larger proteins. Thus the different proteins emerging in the eluate flowing out of the bottom of the column at different times (different elution volumes) can be collected in separate tubes, called fractions. (b) Ion-exchange chromatography separates proteins that differ in net charge in columns packed with beads that carry either a positive charge (shown here) or a negative charge. Proteins having the same net charge as the beads are repelled and flow through the column,

interact frequently with the surface will spend more time bound to the surface, and thus flow past the surface more slowly, than molecules that interact infrequently with it. In this technique, called *liquid chromatography (LC)*, the sample is placed on top of a tightly packed column of spherical beads held within a glass, metal, or plastic cylinder

(c) Antibody-affinity chromatography

whereas proteins having the opposite charge bind to the beads more or less tightly, depending on their structures. Bound proteins—in this case, negatively charged proteins—are subsequently eluted by passing a salt gradient (usually of NaCl or KCl) through the column. As the ions bind to the beads, they displace the proteins; more tightly bound proteins require higher salt concentrations in order to be released. (c) In antibody-affinity chromatography, a mixture of proteins is passed through a column packed with beads to which a specific antibody is covalently attached. Only proteins with high affinity for the antibody are retained by the column; all the nonbinding proteins flow through. After the column is washed, the bound protein is eluted with an acidic solution or some other solution that disrupts the antigen-antibody complexes; the released protein then flows out of the column and is collected.

(Figure 3-40). The sample then flows down the column, driven by gravitational or hydrostatic forces alone or sometimes with the assistance of a pump. In some LC systems, the composition of the fluid flowing out of the column is monitored continuously (for example, by spectroscopy). Small aliquots of fluid flowing out of the column, called *fractions*,

are collected sequentially and can be analyzed subsequently for their contents and chemical activities (e.g., enzymatic activity). The nature of the beads in the column determines whether the separation of proteins depends on differences in their mass, charge, or other binding properties (e.g., affinity for substances attached to the beads).

**Gel Filtration Chromatography** Proteins that differ in mass can be separated on a column of porous beads made from polyacrylamide, dextran (a bacterial polysaccharide), or agarose (a seaweed derivative)—a technique called gel filtration chromatography. Although proteins flow around the beads, they spend some time within the large depressions that cover a bead's surface. Because smaller proteins can penetrate these depressions more readily than larger proteins can, they travel through a gel filtration column more slowly than larger proteins do (Figure 3-40a). (In contrast, proteins migrate *through* the pores in an electrophoretic gel; thus smaller proteins move faster than larger ones.) The total volume of liquid required to elute (or separate and remove) a protein from a gel filtration column depends on the protein's mass: the smaller its mass, the longer it is trapped on the beads, the longer it takes to traverse the column, and the greater the elution volume. If proteins of known mass are used as standards to calibrate the column, the elution volume can be used to estimate the mass of a protein in a mixture. A protein's shape as well as its mass can influence the elution volume.

**Ion-Exchange Chromatography** In ion-exchange chromatography, proteins are separated on the basis of differences in their charges. This technique makes use of specially modified beads whose surfaces are covered by amino groups or carboxyl groups and thus carry either a positive charge ( $\text{NH}_3^+$ ) or a negative charge ( $\text{COO}^-$ ) at neutral pH.

The proteins in a mixture carry various net charges at any given pH. When a solution of mixed proteins flows through a column of positively charged beads, only proteins with a net negative charge (acidic proteins) adhere to the beads; neutral and positively charged (basic) proteins flow unimpeded through the column (Figure 3-40b). The acidic proteins are then eluted selectively from the column by passing a solution of increasing concentrations of salt (a salt gradient) through the column. At low salt concentrations, protein molecules and beads are attracted by their opposite charges. At higher salt concentrations, negatively charged salt ions bind to the positively charged beads, displacing the negatively charged proteins. In a gradient of increasing salt concentrations, weakly bound proteins—those with a relatively low charge—are eluted first, and highly charged proteins are eluted last. Similarly, a negatively charged column can be used to retain and fractionate basic (positively charged) proteins.

**Affinity Chromatography** The ability of proteins to bind specifically to other molecules is the basis of affinity chromatography. In this technique, ligands or other molecules that bind to the protein of interest are covalently attached to the beads used to form the column. Ligands can be enzyme substrates, inhibitors or their analogs, or other small molecules that bind

to specific proteins. In a widely used form of this technique—*antibody-affinity*, or *immunoaffinity chromatography*—the molecule attached to the beads is an antibody specific for the desired protein (Figure 3-40c). (We discuss antibodies as tools for studying proteins next; see also Chapter 23, which describes how antibodies are made.)

In principle, an affinity column will retain only those proteins that bind the molecule attached to the beads; the remaining proteins, regardless of their charges or masses, will pass through the column because they do not bind. However, if a retained protein is in turn bound to other molecules, forming a complex, then the entire complex is retained on the column. The proteins bound to the affinity column are then eluted by adding an excess of a soluble form of the ligand, by exposure of bound materials to detergents, or by changing the salt concentration or pH such that the binding to the molecule on the column is disrupted. The ability of this technique to separate particular proteins depends on the selection of appropriate binding partners that bind more tightly to the protein of interest than to other proteins.

## Highly Specific Enzyme and Antibody Assays Can Detect Individual Proteins

The purification of a protein, or any other molecule, requires a specific *assay* that can detect the presence of that molecule as it is separated from other molecules (e.g., in column or density-gradient fractions or gel bands or spots). Such an assay capitalizes on some highly distinctive characteristic of a protein: the ability to bind a particular ligand, to catalyze a particular reaction, or to be recognized by a specific antibody. The assay must also be simple and fast to minimize errors and the possibility that the protein of interest will become denatured or degraded while the assay is being performed. The goal of any purification scheme is to isolate sufficient amounts of a given protein for study; thus a useful assay must also be sensitive enough that only a small proportion of the available material is consumed by it. Many common protein assays require just  $10^{-9}$  to  $10^{-12}$  g of material.

**Chromogenic Enzyme Reactions** Many assays are tailored to detect some functional aspect of a protein. For example, assays of enzymatic activity are based on the ability to detect the loss of substrate or the formation of product. Some enzymatic activity assays use chromogenic substrates, which change color in the course of the reaction. (Some substrates are naturally chromogenic; those that are not can be linked to a chromogenic molecule.) Because of the specificity of an enzyme for its substrate, only samples that contain the enzyme will change color in the presence of a chromogenic substrate; the rate of the change provides a measure of the quantity of enzyme present. Enzymes that catalyze chromogenic reactions can also be fused or chemically linked to an antibody and used to “report” the presence or location of an antigen to which the antibody binds (see below).

**Antibody Assays** As noted earlier, antibodies have the distinctive characteristic of binding tightly and specifically

to antigens. As a consequence, preparations of antibodies that recognize a protein antigen of interest can be generated and used to detect the presence of that protein, either in a complex mixture of other proteins (finding a needle in a haystack, as it were) or in a partially or completely purified preparation of a particular protein. The presence of the antigen can be detected by labeling the antibody with an enzyme, a fluorescent molecule, or a radioactive isotope, which can be detected using an enzyme assay, fluorescence microscopy or spectroscopy, or a radiation detector, respectively. For example, luciferase, an enzyme present in fireflies and some bacteria, can be linked to an antibody. In the presence of ATP and its substrate, luciferin, luciferase catalyzes a light-emitting reaction. In either case, after the antibody binds to the protein of interest (the antigen) and unbound antibody is washed away, substrates of the linked enzyme are added and the appearance of color or emitted light is monitored. The intensity is proportional to the amount of enzyme-linked antibody, and thus antigen, in the sample. Alternatively, after a first (or “primary”) antibody that is not otherwise labeled binds to its target protein, a second (“secondary”), labeled antibody that can recognize the first antibody is used to bind to the complex of the first antibody and its target. This combination of primary and secondary antibodies (sometimes called an antibody “sandwich”) permits very high sensitivity in the detection of a target protein because the labeled secondary antibody is often a mixture of antibodies that bind to multiple sites on the first antibody and thus results in a stronger signal than labeling of the primary antibody alone. It is important to remember that an antibody recognizes and binds to only its epitope on a target antigen. If that epitope is altered—for example, by partial unfolding or post-translational modifications—or is blocked when the antigen protein is bound to some other molecule, the ability of the antibody to bind may be reduced or completely lost. Thus the absence of antibody binding does not necessarily mean that the antigen is not present in a sample, only that the epitope portion of that antigen is not present or accessible for antibody binding.

To generate antibodies to a protein (discussed in detail in Chapter 23), the intact protein, or a fragment of the protein, is injected into an animal (usually a rabbit, mouse, or goat). Sometimes a short synthetic peptide of 10–15 residues based on the sequence of the protein of interest is used as the antigen to induce antibody formation. Such a synthetic peptide, when coupled to a large protein carrier, can induce an animal to produce antibodies that bind specifically to that part (the epitope) of the full-sized, natural protein. Biosynthetically or chemically attaching the epitope to an unrelated protein is called *epitope tagging*. As we’ll see throughout this book, antibodies generated using either synthetic peptide epitopes or intact proteins are extremely versatile reagents for isolating, detecting, and characterizing proteins.

**Detecting Proteins by Attaching Green Fluorescent Protein** An alternative to epitope tagging that is particularly useful in detecting specific proteins within live cells makes use of *green fluorescent protein (GFP)*, a naturally fluorescent

protein found in jellyfish (see Figure 4-16). A chimeric protein containing both the protein of interest and GFP, linked together in one polypeptide chain, is expressed in cells by introducing into the cells a gene encoding the combined protein. The amounts and intracellular distribution of the chimeric protein can then be determined readily. This chimeric protein approach is described in Chapter 4.

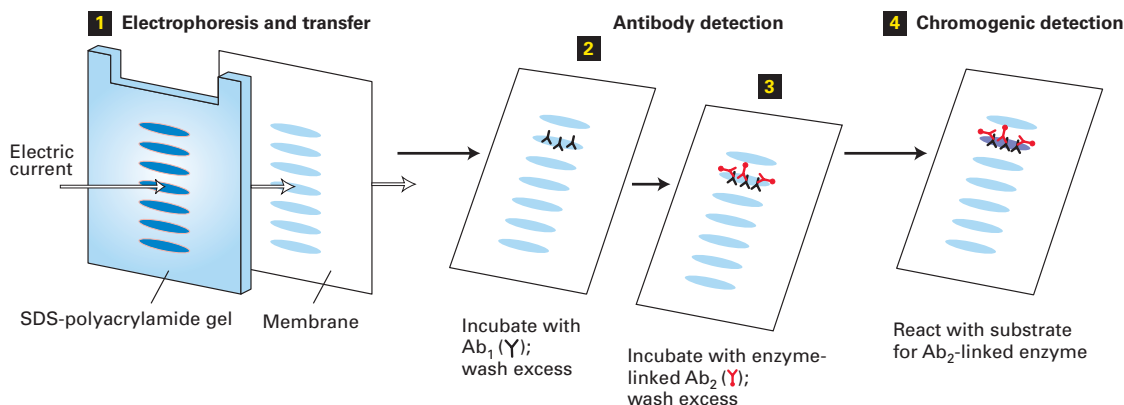

**Detecting Proteins in Gels** Proteins embedded within a gel usually are not visible. The two general approaches to detecting proteins in gels are either to label or stain the proteins while they are still within the gel or to electrophoretically transfer the proteins to a membrane made of nitrocellulose or polyvinylidene difluoride and then detect them. Proteins within gels are usually stained with an organic dye or a silver-based stain, both of which are detectable with normal visible light, or with a fluorescent dye, which requires specialized detection equipment. Coomassie blue, the most commonly used organic dye, is typically used to detect about 1000 ng of protein, with a lower limit of detection of about 4–10 ng. Silver staining and fluorescence staining are more sensitive (with a lower limit of ~1 ng). Coomassie and other stains can also be used to visualize proteins after transfer to membranes; however, the most common method of visualizing proteins in membranes is immunoblotting.

**Immunoblotting**, also called *Western blotting*, combines the resolving power of gel electrophoresis with the specificity of antibodies. This multistep procedure is commonly used to separate proteins and then identify a specific protein of interest. As shown in Figure 3-41, two different antibodies are used, one that is specific for the protein of interest (primary antibody) and a secondary antibody that binds to the first and is linked to an enzyme or other molecule that permits detection of the first antibody (and thus the protein of interest to which it binds). The enzyme to which the second antibody is attached can either generate a visible colored product or, by a process called *chemiluminescence*, produce light that can readily be recorded by film or a sensitive detector. An example of the results of an immunoblotting experiment can be seen in Figure 15-10. If an antibody to the protein of interest is not available, but the gene encoding the protein is available and can be used to express the protein, recombinant DNA methods (see Chapter 5) can incorporate a small peptide epitope into the normal sequence of the protein (epitope tagging) that can be detected by a commercially available antibody to that epitope.

**Immunoprecipitation** **Immunoprecipitation**, often abbreviated as **IP**, exploits the specificity of antibodies to separate a protein of interest from other molecules in a complex mixture—for example, all proteins extracted from a sample of cells or a sample of blood. An antibody to the protein of interest is added to a sample, and the antibody is given time to bind to epitopes on the target protein. An agent that binds to the antibody is then added to cause the antibody and its bound target to precipitate out of solution into particles that can be isolated by centrifugation. A detailed example of this technique is described in Chapter 15 (p. 684). The precipitate is then solubilized under denaturing conditions—for example, in

(a) General method of immunoblotting

(b) Immunoblotting of lysed cells to detect intracellular receptors

(c) Immunoprecipitation (IP) followed by immunoblotting (co-IP)

**EXPERIMENTAL FIGURE 3-41 Immunoblotting (IP, or Western blotting) and co-immunoprecipitation (co-IP) can detect specific proteins and their binding partners.**

(a) Immunoblotting method. Step **1**: After a protein mixture has been electrophoresed through an SDS gel, the separated bands (or spots, for two-dimensional gel electrophoresis) are transferred (blotted) from the gel onto a porous membrane from which the protein is not readily removed. Individual proteins (represented by blue ovals) are not visible at this stage. Step **2**: The membrane is flooded with a solution of an antibody ( $Ab_1$ ) specific for the protein of interest and allowed to incubate for a while.  $Ab_1$  binds to the protein of interest (second from the top), but not to any other proteins attached to the membrane, forming a layer of antibody molecules coincident with the protein (whose position still cannot be seen at this point). Then the membrane is washed to remove unbound  $Ab_1$ . Step **3**: The membrane is incubated with a second antibody ( $Ab_2$ ) that specifically recognizes and binds to the first ( $Ab_1$ ). This second antibody is covalently linked to an enzyme that catalyzes a chromogenic reaction or releases light (e.g., chemiluminescence), a radioactive isotope, or some other substance whose presence can be detected with great sensitivity. Step **4**: Finally, the location and amount of bound  $Ab_2$  are detected (e.g., by its color for a chromogenic reaction or by detectors or film that measure the light released by chemiluminescence), permitting the electrophoretic mobility (and therefore the mass) of the protein of interest to be determined as well as its quantity (based on band intensity). (b) Immunoblotting was used to detect intracellular receptors and the influence of exposure to a ligand for one of the receptors. In this experiment, cells that are precursors to red blood cells were maintained *in vitro* in petri dishes and then treated with no ligand (–, leftmost and rightmost lanes) or a ligand that binds to GR, the glucocorticoid receptor (+, center lane). The cells were then lysed in detergent, and immunoblotting (Western blotting) was performed on the total cell lysates using three different antibodies that bind to GR (anti-GR), to a receptor called PPAR $\alpha$  (anti-PPAR $\alpha$ ), or to an abundant intracellular protein, actin, whose presence and abundance was not expected to be sensitive to treatment with the ligand.

The equal intensities of the immunoblotting bands detected using the anti-actin antibody (bottom box) provided a “loading control,” which established that essentially equal amounts of cell lysate were applied (loaded) in each lane of the gel. The approximately equal intensities of the bands for both GR and PPAR $\alpha$  with or without prior incubation of the cells with the GR ligand showed that the ligand did not substantially alter the amounts of either of these proteins in the cells. Portions of the same cell lysates used for the immunoblotting in part (b) were also used for the immunoprecipitation/immunoblotting shown in part (c). (c) Immunoprecipitation (IP) followed by immunoblotting (together called co-IP) was used to determine if the GR ligand can induce formation of a stable complex that contains both GR and PPAR $\alpha$ . Portions of the cell lysates were immunoprecipitated with an antibody to GR (left and center lanes) or a control antibody (right lane) that cannot bind to either GR or PPAR $\alpha$ . The immunoprecipitates were separated from the rest of the lysates by centrifugation and then analyzed by immunoblotting with either anti-GR (top box) or anti-PPAR $\alpha$  (bottom box). As expected, the top box shows that the GR protein was detected in the immunoprecipitates generated using the  $\alpha$ -GR when the same anti-GR antibody was used for the immunoblotting, but not in the immunoprecipitates generated with the control antibody (no band observed). Strikingly, when one examines the immunoprecipitates by immunoblotting with the anti-PPAR $\alpha$  antibody (bottom box), a substantial amount of PPAR $\alpha$  is seen when the GR ligand is present (center lane), whereas little co-precipitates in the absence of the GR ligand (left lane) or in the control immunoprecipitate (right lane). These results indicate that the GR ligand induces formation of a complex containing both the glucocorticoid receptor and the PPAR $\alpha$  proteins. These results do not establish whether or not the GR and PPAR $\alpha$  proteins bind directly to each other when the GR ligand is present or if there are additional molecules in the complex that act as intermediates holding the GR and PPAR $\alpha$  tightly together when the ligand is present. [Parts (b) and (c) reprinted by permission from Macmillan Publishers Ltd, from Lee, H.Y. et al., “PPAR- $\alpha$  and glucocorticoid receptor synergize to promote erythroid progenitor self-renewal,” *Nature*, 2015, **522**:474–477.]

a detergent-containing buffer—to separate the antibody from the protein, and the immunoprecipitated target protein can then be analyzed. If the immunoprecipitated target is tightly bound to one or more other molecules, those bound molecules may be precipitated along with the protein of interest (*co-immunoprecipitation*, sometimes abbreviated as *co-IP*). The co-IP method is used frequently to identify and characterize quaternary structures and supramolecular complexes.

## Radioisotopes Are Indispensable Tools for Detecting Biological Molecules

A sensitive method for tracking a protein or other biological molecule is by detecting the radioactivity emitted from a radiolabel introduced into the molecule. In a radiolabeled molecule, at least one atom is present in a radioactive form, called a **radioisotope**.

**Radioisotopes Useful in Biological Research** Hundreds of biological molecules (e.g., amino acids, nucleosides, and numerous other small-molecule metabolites) labeled with various radioisotopes are commercially available. These preparations vary considerably in their *specific activity*, which is the amount of radioactivity per unit of material, measured in disintegrations per minute (dpm) per millimole (mmol). The specific activity of a labeled compound depends on the radioisotope's *half-life*, the time required for half the atoms to undergo radioactive decay, which releases the detectable radiation. In general, the shorter the half-life of a radioisotope, the higher its specific activity (Table 3-1). The specific activity of a labeled compound must be high enough for accurate detection of its emitted radiation.

A common approach to radiolabeling macromolecules (proteins, RNA, DNA) in cells is to add a radiolabeled biosynthetic precursor to the extracellular medium [e.g.,  $^3\text{H}$ - or  $^{35}\text{S}$ -labeled amino acids,  $^{32}\text{P}$ -labeled phosphate (precursor for  $^{32}\text{P}$ -labeled ATP), or  $^3\text{H}$ -labeled nucleic acid precursors such as deoxythymidine (also simply called thymidine) or  $^{32}\text{P}$ -labeled phosphate]. The precursor enters the cells via transporters (see Chapter 11) and is incorporated into newly synthesized macromolecules by the cells (see Chapter 5). For example, methionine and cysteine labeled

with sulfur-35 ( $^{35}\text{S}$ ) are widely used to label cellular proteins because preparations of these amino acids with high specific activities ( $>10^{15}$  dpm/mmol) are available. Kinases within cells (or used in vitro) can transfer a  $^{32}\text{P}$ -labeled phosphate from  $^{32}\text{P}$ -labeled ATP to label phosphoproteins. Likewise, commercial preparations of  $^3\text{H}$ -labeled nucleic acid precursors have much higher specific activities than those of the corresponding  $^{14}\text{C}$ -labeled preparations. In most experiments, the former are preferable because they allow RNA or DNA to be adequately labeled a shorter time after incorporation or require a smaller cell sample. Various phosphate-containing compounds in which the phosphorus atom is the radioisotope phosphorus-32 are readily available. Because of their high specific activity,  $^{32}\text{P}$ -labeled nucleotides are routinely used to label nucleic acids in cell-free systems.

Labeled compounds in which a radioisotope replaces atoms normally present in the molecule have virtually the same chemical properties as the corresponding unlabeled compounds. Enzymes, for instance, generally cannot distinguish between substrates labeled in this way and their unlabeled substrates. The presence of such radioactive atoms is indicated with the isotope in brackets (no hyphen) as a prefix (e.g., [ $^3\text{H}$ ]leucine). In contrast, labeling of almost any biomolecule (e.g., protein or nucleic acid) with the radioisotope iodine-125 ( $^{125}\text{I}$ ) requires the covalent addition of  $^{125}\text{I}$  to a molecule that normally does not have iodine as part of its structure. Because this labeling procedure modifies the chemical structure, the biological activity of the labeled molecule may differ somewhat from that of the unlabeled form. The presence of such radioactive atoms is indicated with the isotope as a prefix followed a hyphen (no bracket) (e.g.,  $^{125}\text{I}$ -trypsin). Standard methods for labeling proteins with  $^{125}\text{I}$  result in covalent attachment of the  $^{125}\text{I}$  primarily to the aromatic rings of tyrosine side chains (mono- and diiodotyrosine). Nonradioactive isotopes are finding increasing use in cell biology, especially in nuclear magnetic resonance studies and in mass spectroscopy applications, as will be explained below.

**Labeling Experiments and Detection of Radiolabeled Molecules** Whether labeled compounds are detected by **autoradiography**—exposure of the sample on a two-dimensional detector (photographic emulsion or electronic detector)—or their radioactivity is measured in an appropriate “counter,” the amount of a radiolabeled compound in a sample can be determined with great precision.

In one use of autoradiography, a tissue, cell, or cell constituent is labeled with a radioactive molecule, unassociated radioactive material is washed away, and the structure of the sample is stabilized either by chemically cross-linking the macromolecules in the sample (“fixation”) or by freezing it. The sample is then overlaid with a photographic emulsion that is sensitive to radiation. Development of the emulsion yields small silver grains whose distribution corresponds to that of the radioactive material and is usually detected by microscopy. Autoradiographic studies of whole

**TABLE 3-1** Radioisotopes Commonly Used in Biological Research

Isotope	Half-Life
Phosphorus-32	14.3 days
Iodine-125	60.4 days
Sulfur-35	87.5 days
Tritium (hydrogen-3)	12.4 years
Carbon-14	5730.4 years

cells were crucial in determining the intracellular sites where various macromolecules are synthesized and the subsequent movements of those macromolecules within cells. Various techniques employing fluorescence microscopy, which we describe in Chapter 4, have largely supplanted autoradiography for studies of this type. However, autoradiography is sometimes used in various assays for detecting specific isolated DNA or RNA sequences at specific tissue locations (see Chapter 6) in a technique referred to as *in situ* hybridization.

Quantitative measurements of the amount of radioactivity in a labeled material are performed with several different instruments. A Geiger counter measures ions produced in a gas by the  $\beta$  particles or  $\gamma$  rays emitted from a radioisotope. These instruments are mostly handheld devices used to monitor radioactivity in the laboratory to protect investigators from excess exposure. In a scintillation counter, a radiolabeled sample is mixed with a liquid containing a fluorescent compound that emits a flash of light when it absorbs the energy of the  $\beta$  particles or  $\gamma$  rays released in the decay of the radioisotope; a phototube in the instrument detects and counts these light flashes. Phosphorimagers detect radioactivity using a two-dimensional array detector, storing digital data on the number of disintegrations per minute per small pixel of surface area. These instruments, which can be thought of as a kind of reusable electronic film, are commonly used to quantify radioactive molecules separated by gel electrophoresis and are replacing photographic emulsions for this purpose.

Combinations of labeling and biochemical techniques and of visual and quantitative detection methods are often employed in labeling experiments. For instance, to identify the major proteins synthesized by a particular cell type, a sample of the cells is incubated with a radiolabeled amino acid (e.g., [ $^{35}\text{S}$ ]methionine) for a few minutes, during which time the labeled amino acid enters the cells and mixes with the cellular pool of unlabeled amino acids, and some of it is biosynthetically incorporated into newly synthesized proteins. Subsequently, unincorporated radiolabeled amino acid is washed away from the cells. The cells are harvested, and the mixture of cellular proteins is extracted from the cells (for example, by a detergent solution) and then separated by any of the methods commonly used to resolve complex protein mixtures into individual components. Gel electrophoresis in combination with autoradiography or phosphorimager analysis is often the method of choice. The radioactive bands in the gel correspond to newly synthesized proteins, which have incorporated the radiolabeled amino acid. To detect a specific protein of interest, rather than the entire ensemble of biosynthetically radiolabeled proteins, a specific protein can be isolated by immunoprecipitation. The precipitate is then solubilized, for example, in an SDS-containing buffer, and the sample is analyzed by SDS-PAGE followed by autoradiography to detect the protein that is radioactively labeled. In this type of experiment, a fluorescent compound that is activated by the radiation (“scintillator”) may be infused into the gel on completion of the electrophoretic separation so that the light emitted can be used to detect the presence of

**EXPERIMENTAL FIGURE 3-42 Pulse-chase experiments can track the pathway of protein modification within cells.** (a) To follow the fate of a specific newly synthesized protein in cells, cells were incubated with [ $^{35}\text{S}$ ]methionine for 0.5 hours (the pulse) to label all newly synthesized proteins, and any radioactive amino acid not incorporated into the cells was then washed away. The cells were further incubated (the chase) for varying times up to 24 hours, and samples from each time of chase were subjected to immunoprecipitation to isolate one specific protein (here the low-density lipoprotein receptor). SDS-PAGE of the immunoprecipitates followed by autoradiography permitted visualization of the target protein, which is initially synthesized as a small precursor (p) and then rapidly modified to a larger mature form (m) by addition of carbohydrates. About half of the labeled protein was converted from p to m during the pulse; the rest was converted after 0.5 hours of chase. The protein remained stable for 6–8 hours before it began to be degraded (as indicated by reduced band intensity). (b) The same experiment was performed in cells in which a mutant form of the protein is made. The mutant p form cannot be properly converted to the m form, and it is more quickly degraded than the normal protein. [© Kozarsky et al., *The Journal of Cell Biology*, **102**: 1567–1575. doi:10.1083/jcb.102.5.1567]

the labeled protein, using either film or a two-dimensional electronic detector. An example is shown in the experiment described below (Figure 3-42). This method is particularly useful for weak  $\beta$  emitters such as  $^3\text{H}$ .

**Pulse-chase** experiments are particularly useful for tracing changes in the intracellular location of proteins or the modification of a protein or metabolite over time. In this experimental protocol, a cell sample is exposed to a radiolabeled compound that can be incorporated into or otherwise attached to a cellular molecule of interest—the “pulse”—for a brief period. The pulse ends when the unincorporated radiolabeled molecules are washed away and the cells are exposed to a vast excess of the identical, but unlabeled, compound to dilute the radioactivity of any remaining, but unincorporated, radiolabeled compound. This procedure prevents any incorporation of significant amounts of radiolabel after the “pulse” period and initiates the “chase” period (see Figure 3-42). Samples taken periodically during the chase period are assayed to determine the location or chemical form of the radiolabel as a function of time. Pulse-chase

experiments in which the radiolabeled protein is detected by autoradiography after immunoprecipitation and SDS-PAGE are often used to follow the rate of synthesis, modification, and degradation of proteins. In these experiments, radiolabeled amino acid precursors are added during the pulse, and the amounts and characteristics of the radiolabeled target protein are detected during the chase. One can thus observe postsynthetic modifications of the protein, such as the covalent addition of sugars (see Chapters 13 and 14) or proteolytic cleavage, that change its electrophoretic mobility, as well as the rate of degradation of the protein, which is detected as the loss of signal with increasing time of chase. A classic use of the pulse-chase technique with autoradiography was in studies that elucidated the pathway traversed by secreted proteins from their site of synthesis in the endoplasmic reticulum to the cell surface (see Chapter 14).

## Mass Spectrometry Can Determine the Mass and Sequence of Proteins

Mass spectrometry (MS) is a powerful technique for characterizing proteins, especially for determining the mass of a protein or fragments of a protein. With such information in hand, it is also possible to determine part or all of the protein's sequence. This method permits the accurate direct determination of the ratio of the mass ( $m$ ) of a charged molecule (molecular ion) to its charge ( $z$ ), or  $m/z$ . Additional techniques are then used to deduce the absolute mass of the molecular ion.

All mass spectrometers have four key features. The first is an ion source, from which charge, usually in the form of protons, is transferred to the peptide or protein molecules under study (ionization). Their conversion to ions occurs in the presence of a high electric field, which then directs the charged molecular ions into the second key component, the mass analyzer. The mass analyzer, which is always in a high vacuum chamber, physically separates the ions on the basis of their differing mass-to-charge ( $m/z$ ) ratios. The separated ions are subsequently directed to strike a detector, the third key component, which provides a measure of the relative abundances of each of the ions in the sample. The fourth essential component is a computerized data system that is used to calibrate the instrument; to acquire, store, and process the resulting data; and often to direct the instrument to automatically collect additional specific types of data from the sample, based on the initial observations. This type of automated feedback is used for the tandem MS (MS/MS) peptide-sequencing methods described below.

The two most frequently used methods of generating ions of proteins and protein fragments are (1) matrix-assisted laser desorption/ionization (MALDI) and (2) electrospray (ES). In MALDI (Figure 3-43), the peptide or protein sample is mixed with a low-molecular-weight, UV-absorbing organic acid (the matrix) and then dried on a metal target. Energy from a laser ionizes and vaporizes the sample, producing singly charged molecular ions from the constituent molecules. In ES (Figure 3-44a), a sample of peptides or

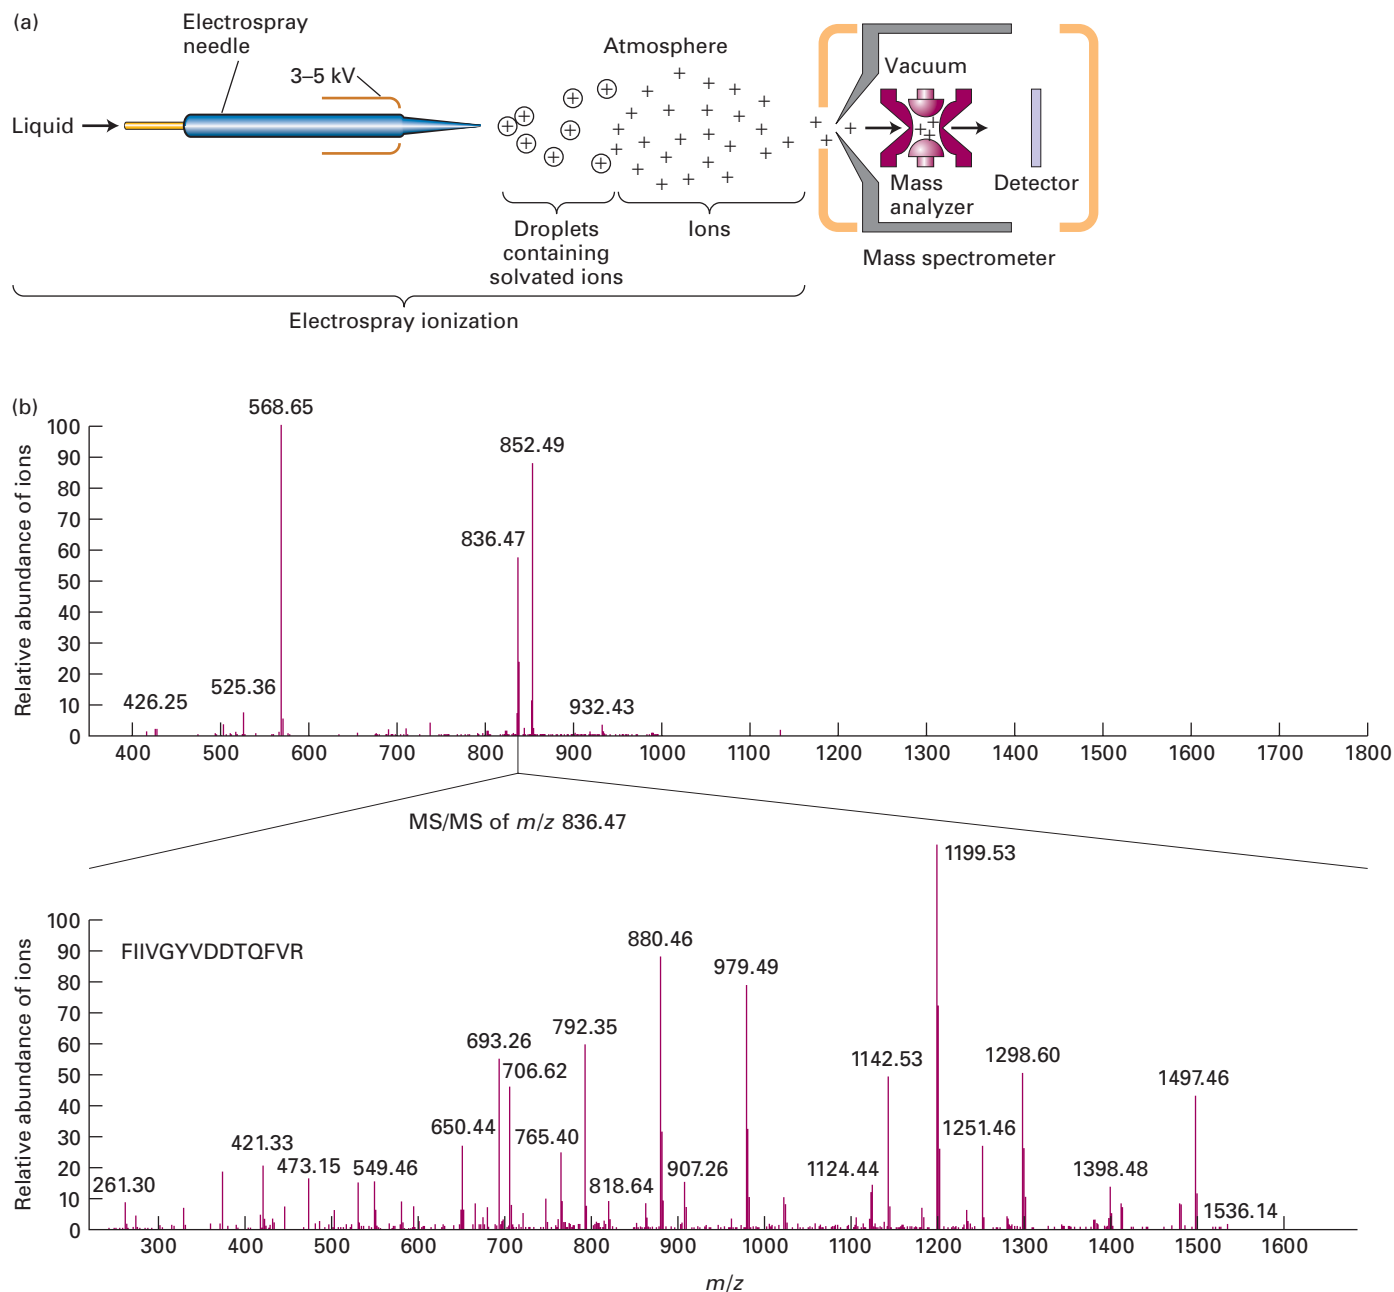

**EXPERIMENTAL FIGURE 3-43 Molecular mass can be determined by matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) mass spectrometry.** In a MALDI-TOF mass spectrometer, pulses of light from a laser ionize a protein or peptide mixture that is absorbed on a metal target (step **1**). An electric field in the mass analyzer accelerates the ions in the sample toward the detector (steps **2** and **3**). The time it takes an ion to reach the detector is proportional to the square root of the mass-to-charge ( $m/z$ ) ratio. Among ions having the same charge, the smaller ions move faster (shorter time to the detector). The molecular weight of each ion from the sample is calculated using the time of flight of a standard.

proteins in solution is converted into a fine mist of tiny droplets by spraying through a narrow capillary at atmospheric pressure. The droplets are formed in the presence of a high electric field, which renders them highly charged. The solvent evaporates from the droplets in their short flight (mm) to the entrance of the mass spectrometer's mass analyzer, forming multiply charged ions from the peptides and proteins. The gaseous ions are transferred into the mass analyzer region of the MS, where they are then accelerated by electric fields and separated by the mass analyzer on the basis of their  $m/z$ .

The two most frequently used types of mass analyzers are time-of-flight (TOF) instruments and ion traps. TOF instruments exploit the fact that the time it takes an ion to pass through the length of the mass analyzer before reaching the detector is proportional to the square root of  $m/z$  (smaller ions move faster than larger ones with the same charge; see Figure 3-43). In ion-trap analyzers, tunable electric fields are used to capture, or "trap," ions with a specific  $m/z$  and to sequentially pass the trapped ions out of the mass analyzer onto the detector (see Figure 3-44a). By varying the electric fields, researchers can examine ions with a wide range of  $m/z$  values one by one, producing a mass spectrum, which is a graph of  $m/z$  ( $x$  axis) versus relative abundance, determined by the intensity of the signal measured by the detector ( $y$  axis) (Figure 3-44b, *top panel*).

In tandem, or MS/MS, instruments, any given parent ion in the original mass spectrum (see Figure 3-44b, *top panel*) can be chosen (mass-selected) for further analysis. The chosen ions are transferred into a second chamber in which

**EXPERIMENTAL FIGURE 3-44 Molecular mass of proteins and peptides can be determined by electrospray ionization ion-trap mass spectrometry.** (a) Electrospray (ES) ionization converts proteins and peptides in a solution into highly charged gaseous ions by passing the solution through a needle (forming the droplets) that has a high voltage across it (charging the droplets). Evaporation of the solvent produces gaseous ions that enter a mass spectrometer. The ions are analyzed by an ion-trap mass analyzer that then directs ions to the detector. (b) *Top panel:* Mass spectrum of a mixture of three major and several minor peptides from the mouse H-2 class I histocompatibility antigen Q10  $\alpha$  chain is presented as the relative abundance of the ions striking the detector (y axis) as a function of the mass-to-charge ( $m/z$ ) ratio (x axis). *Bottom panel:* In an MS/MS instrument such as the ion trap

shown in part (a), a specific peptide ion can be selected for fragmentation into smaller ions that are then analyzed and detected. The MS/MS spectrum (also called the product-ion spectrum) provides detailed structural information about the parent ion, including sequence information for peptides. Here the ion with an  $m/z$  of 836.47 was selected and fragmented and the  $m/z$  mass spectrum of the product ions measured. Note there is no longer an ion with an  $m/z$  of 836.47 present because it was fragmented. From the varying sizes of the product ions, the understanding that peptide bonds are often broken in such experiments, the known  $m/z$  values for individual amino acid fragments, and database information, the sequence of the peptide, FIIVGYVDDTQFVR, can be deduced. [Part (b), unpublished data from S. Carr.]

they are broken into smaller fragment ions by collision with an inert gas, and then the  $m/z$  and relative abundances of the resulting fragment ions are measured in a second MS analyzer (Figure 3-44b, *bottom panel*, see also Figure 3-47 later in this chapter). These multiple mass analysis and fragmentation steps all take place within the same machine in about 0.1 seconds per selected parent ion. The fragmentation and subsequent mass analysis permit the sequences of short peptides (<25 amino acids) to be determined because collisional fragmentation occurs primarily at peptide bonds, so the differences in masses between the multiple ion fragments generated correspond to the in-chain masses of the individual amino acids, permitting deduction of the sequence in conjunction with database sequence information (see Figure 3-44b, *bottom panel*).

Mass spectrometry is highly sensitive, able to detect as little as  $1 \times 10^{-16}$  mol (100 attomoles) of a peptide or  $10 \times 10^{-15}$  mol (10 femtomoles) of a protein of 200,000 MW. Errors in mass measurement accuracy are dependent on the specific mass analyzer used, but are typically about 0.01 percent for peptides and 0.05–0.1 percent for proteins. As described in Section 3.6 below, it is possible to use MS to analyze complex mixtures of proteins as well as purified proteins. MS can readily distinguish between two chemically identical peptides that differ only in that one of the peptides contains “heavy” stable (nonradioactive) isotopic forms of one or more elements (e.g., the isotopes  $^2\text{H}$ ,  $^{13}\text{C}$ ,  $^{15}\text{N}$ ) whereas the other contains the most common, “light” isotopes (e.g.,  $^1\text{H}$ ,  $^{12}\text{C}$ ,  $^{14}\text{N}$ ) because the masses of these peptides differ. Most commonly, protein samples are digested by proteases and the peptide digestion products are subjected to analysis. An especially powerful application of MS is to take a complex mixture of proteins from a biological specimen, digest it with trypsin or other proteases, partially separate the components using liquid chromatography, and then transfer the solution flowing out of the chromatographic column directly into an ES tandem mass spectrometer. This technique, called LC-MS/MS, which permits the nearly continuous analysis of a very complex mixture of proteins, will be described in more detail below.

The abundances of ions determined by mass spectrometry in any given sample are relative, not absolute, values. Therefore, if one wants to use MS to compare the amounts of a particular protein in two different samples (e.g., from a normal versus a mutant organism), it is necessary to have an internal standard in the samples—a molecule whose amounts do not differ between the two samples. One then determines the amounts of the protein of interest relative to that of the standard in each sample. This approach permits quantitatively accurate inter-sample comparisons of protein levels. An alternative approach involves simultaneously comparing in a single MS analysis the amounts of proteins from two different cell or tissue samples that are mixed together. This mixing approach is possible provided the proteins in one of the samples contain different stable isotopes than those in the other. The masses of the otherwise chemically identical peptides from the two samples

will then differ (heavy vs. light) and can thus be distinguished by MS. Several methods can be used to chemically or enzymatically incorporate heavy or light isotopes into proteins isolated from cells for such analysis. Alternatively, cells or organisms can first be grown in the presence of amino acids containing either “heavy” or “light” isotope atoms so that these amino acids are biosynthetically incorporated into all the proteins of that sample. Cells are typically incubated with the heavy or light amino acids for five or more cell divisions to ensure that all proteins are thoroughly labeled. Proteins from the two samples are then mixed together, digested into peptides, and the peptides analyzed by mass spectrometry. Proteins and peptides derived from the “heavy” sample can be distinguished in the mass spectrometer from those from the other, “light,” sample because of their higher masses. Thus a direct comparison can be made of the relative amounts of the equivalent proteins in each sample—for example, in tumor versus normal cells or in cells treated with and without a drug. When the samples are cells grown in the laboratory, the method is called stable isotope labeling with amino acids in cell culture (SILAC).

### Protein Primary Structure Can Be Determined by Chemical Methods and from Gene Sequences

The classic method for determining the amino acid sequence of a protein is Edman degradation. In this procedure, the free amino group of the N-terminal amino acid of a polypeptide is labeled, and the labeled amino acid is then cleaved from the polypeptide and identified by high-pressure liquid chromatography. The polypeptide is left one residue shorter, with a new amino acid at the N-terminus. The cycle is repeated on the ever-shortening polypeptide until all the residues have been identified.

Before about 1985, biologists commonly used Edman degradation for determining protein sequences. Now, however, complete protein sequences usually are determined primarily by analysis of genome and messenger RNA sequences. The complete genomes of many organisms have already been sequenced, and the database of genome sequences from humans and numerous model organisms is expanding rapidly. As discussed in Chapter 6, the sequences of proteins can be deduced from DNA sequences that are predicted to encode proteins.

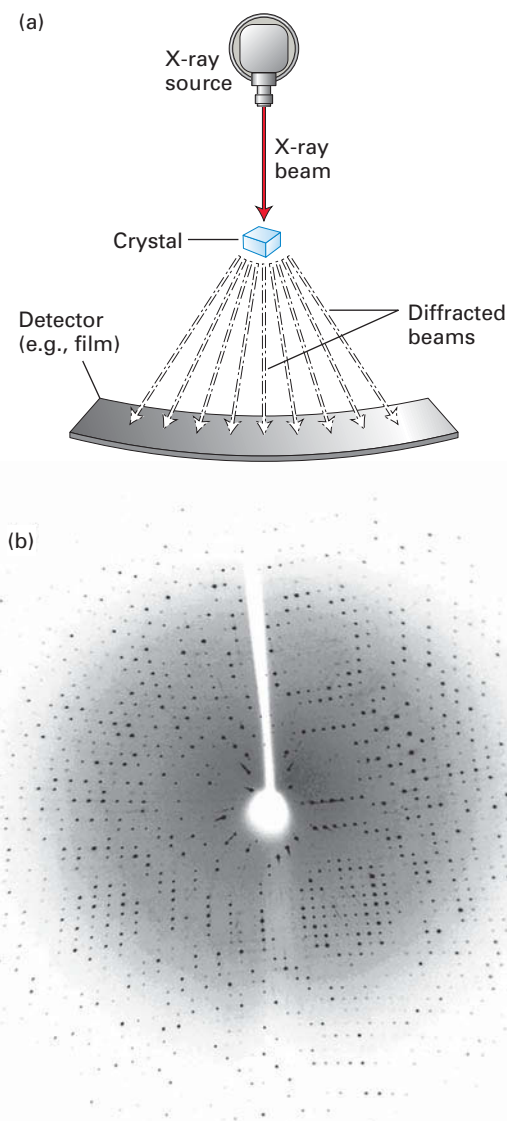

A powerful approach for determining the primary structure of an isolated protein combines MS and the use of sequence databases. First, the peptide mass fingerprint of the protein is obtained by MS. A *peptide mass fingerprint* is the list of the molecular weights of peptides that are generated from the protein by digestion with a specific protease, such as trypsin. The molecular weights of the parent protein and its proteolytic fragments are then used to search genome databases for any similar-sized protein with identical or similar peptide mass fingerprints. Mass spectrometry can also be used to directly sequence peptides using MS/MS, as described above.

## Protein Conformation Is Determined by Sophisticated Physical Methods

In this chapter, we have emphasized that protein function is dependent on protein structure. Thus, to figure out exactly how a protein works, its three-dimensional structure must be determined. Determining a protein's conformation requires sophisticated physical methods and complex analyses of the experimental data. Here we briefly describe three methods used to generate three-dimensional models of proteins.

**X-ray Crystallography** The use of x-ray crystallography to determine the three-dimensional structures of proteins was pioneered by Max Perutz and John Kendrew in the 1950s. In this technique, beams of x-rays are passed through a protein crystal, in which millions of protein molecules are precisely aligned with one another in a rigid crystalline array. The wavelengths of x-rays are about 0.1–0.2 nm, short enough to determine the positions of individual atoms in the protein. The electrons in the atoms of the crystal scatter the x-rays, which produce a diffraction pattern of discrete spots when they are intercepted by photographic film or an electronic detector (Figure 3-45). Such patterns are extremely complex—composed of as many as 25,000 diffraction spots, or reflections, whose measured intensities vary depending on the distribution of the electrons in the sample, which is, in turn, determined by the atomic structure and three-dimensional conformation of the protein. Elaborate calculations and modifications of the protein (such as the binding of heavy metals) must be made to interpret the diffraction pattern and calculate the distribution of electrons (called the *electron density map*). A portion of an electron density map of a protein can be seen in Figure 2-9. With the three-dimensional electron density map in hand, one then “fits” a molecular model of the protein to match the electron density, and it is these models that one sees in the various diagrams of proteins throughout this book (e.g., Figure 3-9). The process is analogous to reconstructing the precise shape of a rock from the ripples that it creates when thrown into a pond. Although sometimes the structures of parts of the protein cannot be clearly defined, using x-ray crystallography, researchers are systematically determining the structures of representative types of most proteins. To date, more than 90,000 detailed three-dimensional structures, including more than 35,000 distinct protein sequences, have been established using x-ray crystallography. These structures can be found in the Research Collaboratory for Structural Bioinformatics Protein Data Bank (<http://www.rcsb.org/pdb/home/home.do>), each with its own “PDB” entry.

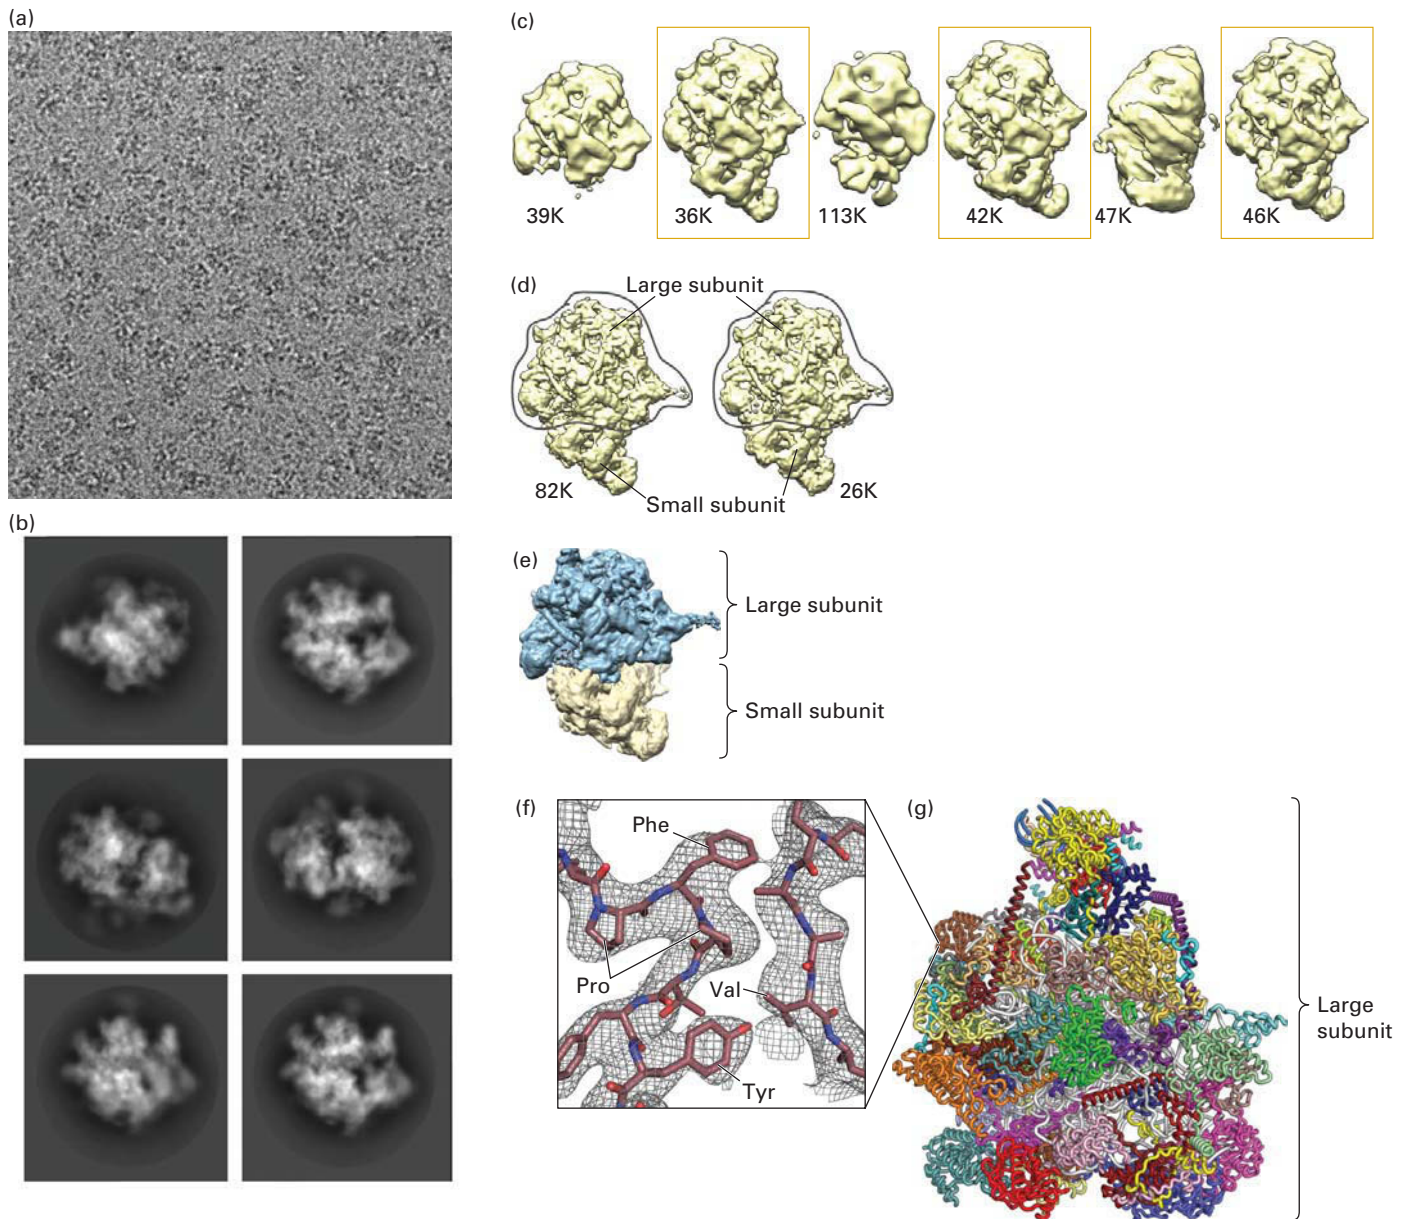

**Cryoelectron Microscopy** Although some proteins readily crystallize, obtaining crystals of others—particularly large multisubunit proteins and membrane-associated proteins—requires a time-consuming, often robot-assisted trial-and-error effort to find just the right conditions, if they can be found at all. (Growing crystals suitable for structural studies is as much an art as a science.) There are several ways to

**EXPERIMENTAL FIGURE 3-45** X-ray crystallography provides diffraction data from which the three-dimensional structure of a protein can be determined. (a) Basic components of an x-ray crystallographic determination. When a narrow beam of x-rays strikes a crystal, part of it passes straight through and the rest is scattered (diffracted) in various directions. The intensity of the diffracted waves, which form periodic arrangements of diffraction spots, is recorded on an x-ray film or with a solid-state electronic detector. (b) X-ray diffraction pattern for a protein crystal collected on a solid-state detector. From complex analyses of patterns of spots like this one, the locations of the atoms in a protein can be determined. See J. M. Berg, J. L. Tymoczko, G. J. Gatto, and L. Stryer, 2015, *Biochemistry*, 8th ed., Macmillan. [Part (b) courtesy James M. Berger]

determine the structures of such difficult-to-crystallize proteins. One is cryoelectron microscopy (Figure 3-46). In this technique, a dilute protein sample in an aqueous solution is applied in a thin layer to an electron microscope sample holder (a “grid”) and rapidly frozen in liquid helium to preserve its structure. It is then examined in the frozen, hydrated state in a cryoelectron microscope. Images of the protein are

### EXPERIMENTAL FIGURE 3-46 Cryoelectron microscopy analysis of the structure of the human mitochondrial ribosome.

The mitochondrion is a complex, multifunctional intracellular organelle best known for its ability to synthesize the energy carrier ATP (see Chapter 12). Human mitochondria can synthesize proteins encoded by mitochondrial DNA using large (1.7 MDa), multi-protein (at least 78) and multi-RNA complexes called mitochondrial ribosomes that differ somewhat from cytoplasmic ribosomes. (a) Cryoelectron micrograph of isolated human mitochondrial ribosomes. The low contrast between the ribosomes and the buffer solution makes it difficult to clearly see individual, frozen ribosome particles, which are oriented randomly in the image. (b) Automated image processing of 323,292 individual particles permits their grouping into classes based on orientation and averaging of the images within each class to generate clearer images of the ribosome. (c) Additional computational analysis generates distinct structures, each based on tens of thousands of individual particles (the number of particles analyzed for each structure in thousands [K] is shown beneath each). The structures enclosed in boxes were selected for

additional analysis, which produced the two very similar models shown in (d) containing virtually identical large subunits. (e) Color-coded, low-resolution model of the electron density of the large (blue) and small (yellow) subunits. The conformational heterogeneity of the small subunit prevented its high-resolution structure determination from the data shown here. (f) High-magnification view of the experimentally determined electron density (meshwork) from a portion of one of the proteins in the large subunit illustrates how the electron density is used to build the superimposed molecular model of polypeptide chains. In this very small portion of one protein within the large subunit, the side chains of proline (Pro), phenylalanine (Phe), valine (Val), and tyrosine (Tyr) residues are easily seen and demonstrate the power of cryoelectron microscopy to determine protein structures at very high resolutions. (g) Model of the 48 protein subunits (different colors) in the large subunit determined at 3.4 Å resolution. [Republished with permission of American Association for the Advancement of Science, from Brown, A., et al, "Structure of the large ribosomal subunit from human mitochondria." *Science*, 2014, **346** (6210): 718-722; permission conveyed through Copyright Clearance Center, Inc.]

recorded on a very sensitive camera using a low dose of electrons to prevent radiation-induced damage to the structure. Since the individual proteins are in different orientations in the frozen sample, sophisticated computer algorithms analyze the images to sort them into groups with the same orientation. The average image of each orientation is calculated from images of the thousands of different molecules in each group, and then the computer assembles the average images, each of which show views of the protein from different orientations, to reconstruct the protein's structure in three dimensions. Recent advances in this technology have produced structures in which the polypeptide backbone and amino acid side chains can be discerned. These structures help provide insight into the mechanisms underlying the protein's function. The use of cryoelectron microscopy and other types of electron microscopy for visualizing cell structures is discussed in Chapter 4.

**NMR Spectroscopy** The three-dimensional structures of small proteins containing as many as 200 amino acids can be studied routinely with nuclear magnetic resonance (NMR) spectroscopy, and specialized approaches can be used to extend the size range to somewhat larger proteins. In this technique, a concentrated protein solution is placed in a magnetic field, and the effects of different radio frequencies on the nuclear spin states of different atoms are measured. The spin state of any atom is influenced by neighboring atoms in adjacent residues, with closely spaced residues having a greater effect than distant residues. From the magnitude of the effect, the distances between residues can be calculated by a triangulation-like process; these distances are then used to generate a model of the three-dimensional structure of the protein. An important distinction between x-ray crystallography and NMR spectroscopy is that the former method directly determines the locations of the atoms, while the latter directly determines the distances between the atoms, from which the structure is deduced.

Although NMR does not require the crystallization of a protein—a definite advantage—this technique is usually limited to proteins smaller than about 50 kDa (although new techniques permit analysis of the dynamics in much larger proteins). However, NMR analysis can provide information about the ability of a protein to adopt a set of closely related, but not exactly identical, conformations and to move between those conformations (protein dynamics). This is a common feature of proteins, which are not absolutely rigid structures, but can “breathe” or exhibit slight variations in the relative positions of their constituent atoms. In some cases, these variations can have functional significance; for example, they may influence how proteins bind to one another. NMR structural analysis has been particularly useful in studying isolated protein domains, which can often be obtained as stable structures and tend to be small enough for this technique. To date, there are more than 10,000 NMR-determined structures available in the Protein Data Bank.

Another powerful approach to studying protein dynamics and protein-protein interactions is hydrogen/deuterium

exchange mass spectrometry (HXMS). When a protein is placed in a deuterated water ( $D_2O$ ) solution, the rate at which deuterium is exchanged for hydrogen in the amides in the peptide bonds depends on the accessibility of an amide to the solvent. Those amides exposed on the protein's surface are highly accessible and exhibit rapid proton/deuterium exchange. Those amides buried in the center of the protein or in a protein-to-protein interface, as well as those participating in hydrogen bonds with other parts of the protein, exhibit slower proton/deuterium exchange rates. A change in protein conformation or binding to other molecules has the potential to alter the rate of hydrogen/deuterium exchange of one or more amides of a protein. MS analysis permits a hypersensitive assay of such conformational changes, allowing the identification of those parts of the protein that directly bind to other molecules or undergo such conformational changes.

## KEY CONCEPTS OF SECTION 3.5

### Purifying, Detecting, and Characterizing Proteins

- Proteins can be separated from other cell components and from one another on the basis of differences in their physical and chemical properties.
- Centrifugation separates proteins on the basis of their rates of sedimentation, which are influenced by their masses and shapes (see Figure 3-37).
- Electrophoresis separates proteins on the basis of their rates of movement in an applied electric field. SDS-polyacrylamide gel electrophoresis (SDS-PAGE) can resolve polypeptide chains differing in molecular weight by 10 percent or less (see Figure 3-38). Two-dimensional gel electrophoresis provides additional resolution by separating proteins first by charge (first dimension) and then by mass (second dimension).
- Liquid chromatography separates proteins on the basis of their rates of movement through a column packed with spherical beads. Proteins differing in mass are resolved on gel filtration columns; those differing in charge, on ion-exchange columns; and those differing in ligand-binding properties, on affinity columns (see Figure 3-40).
- Various assays are used to detect and quantify proteins. Some assays use a light-producing reaction to generate a readily detected signal. Other assays produce an amplified colored signal with enzymes and chromogenic substrates.
- Antibodies are powerful reagents used to detect, quantify, and isolate proteins.
- Immunoblotting, also called Western blotting, is a frequently used method to study specific proteins that exploits the high specificity and sensitivity of protein detection by

antibodies and the high-resolution separation of proteins by SDS-PAGE (see Figure 3-41).

- Immunoprecipitation, often abbreviated as IP, permits the separation of a protein of interest from other proteins in a complex mixture using antibodies specific for the protein of interest. The antibodies are used to precipitate their target protein out of solution for subsequent analysis. Molecules tightly bound to the target protein can precipitate with it (co-immunoprecipitation).
- Isotopes, both radioactive and nonradioactive, play a key role in the study of proteins and other biomolecules. They can be incorporated into molecules without changing the chemical composition of the molecule or as add-on tags. They can be used to help detect the synthesis, location, processing, and stability of proteins.
- Autoradiography is a technique for detecting radioactively labeled molecules in cells, tissues, or electrophoretic gels using two-dimensional detectors (photographic emulsion or electronic detectors).
- Pulse-chase experiments can determine the intracellular fate of proteins and other metabolites (see Figure 3-42).
- Mass spectrometry is a very sensitive and highly precise method of detecting, identifying, and characterizing proteins and peptides.
- Three-dimensional structures of proteins are obtained by x-ray crystallography, cryoelectron microscopy, and NMR spectroscopy. X-ray crystallography provides the most detailed structures but requires protein crystallization. Cryoelectron microscopy is most useful for large protein complexes, which are difficult to crystallize. Only relatively small proteins are amenable to NMR three-dimensional structural analysis.

## 3.6 Proteomics

For most of the twentieth century, the study of proteins was restricted primarily to the analysis of individual proteins. For example, one would study an enzyme by determining its enzymatic activity (its substrates, products, rate of reaction, requirement for cofactors, pH, etc.), its structure, and its mechanism of action. In some cases, the relationships between a few enzymes that participate in a metabolic pathway might also be studied. On a broader scale, the localization and activity of an enzyme would be examined in the context of a cell or tissue. The effects of mutations, diseases, or drugs on the expression and activity of the enzyme might also be the subject of investigation. This multipronged approach provided deep insight into the function and mechanisms of action of individual proteins or relatively small numbers of interacting proteins. However, such a one-by-one approach to studying proteins does not readily provide a global picture of what is happening in the proteome of a cell, tissue, or entire organism.

## Proteomics Is the Study of All or a Large Subset of Proteins in a Biological System

The advent of genomics (sequencing of genomic DNA and its associated technologies, such as simultaneous analysis of the levels of all mRNAs in cells and tissues) clearly showed that a global, or systems, approach to biology could provide unique and highly valuable insights. Many scientists recognized that a global analysis of the proteins in biological systems had the potential for equally valuable contributions to our understanding. Thus a new field was born—**proteomics**. Proteomics is the systematic study of the amounts, modifications, interactions, localization, and functions of all or subsets of proteins at the whole-organism, tissue, cellular, and subcellular levels.

A number of broad questions are addressed in proteomic studies:

- In a given sample (whole organism, tissue, cell, subcellular compartment), what fraction of the whole proteome is expressed (i.e., which proteins are present)?
- Of those proteins present in the sample, what are their relative abundances?
- What are the relative amounts of the different splice forms and chemically modified forms (e.g., phosphorylated, methylated, fatty acylated) of the proteins?
- Which proteins are present in large multiprotein complexes, and which proteins are in each complex? What are the functions of these complexes, and how do they interact?
- When the state (e.g., growth rate, stage of cell cycle, differentiation, stress level) of a cell changes, do the proteins in the cell, or those secreted from the cell, change in a characteristic (*fingerprint*-like) pattern? Which proteins change, and how (relative amounts, modifications, splice forms, etc.)? [Answering these questions requires a form of *protein expression profiling* that complements the *transcriptional (mRNA) profiling* discussed in Chapter 9.]
- Can such fingerprint-like changes be used for diagnostic purposes? For example, do certain cancers or heart disease cause characteristic changes in blood proteins? Can the proteomic fingerprint help determine if a given cancer is resistant or sensitive to a particular chemotherapeutic drug? [Proteomic fingerprints can also be the starting point for studies of the mechanisms underlying the change of state. Proteins (and other biomolecules) that show changes that are diagnostic of a particular state are called *biomarkers*.]
- Can changes in the proteome help define targets for drugs or suggest mechanisms by which a drug might induce toxic side effects? (If so, it might be possible to engineer modified versions of the drug with fewer side effects.)

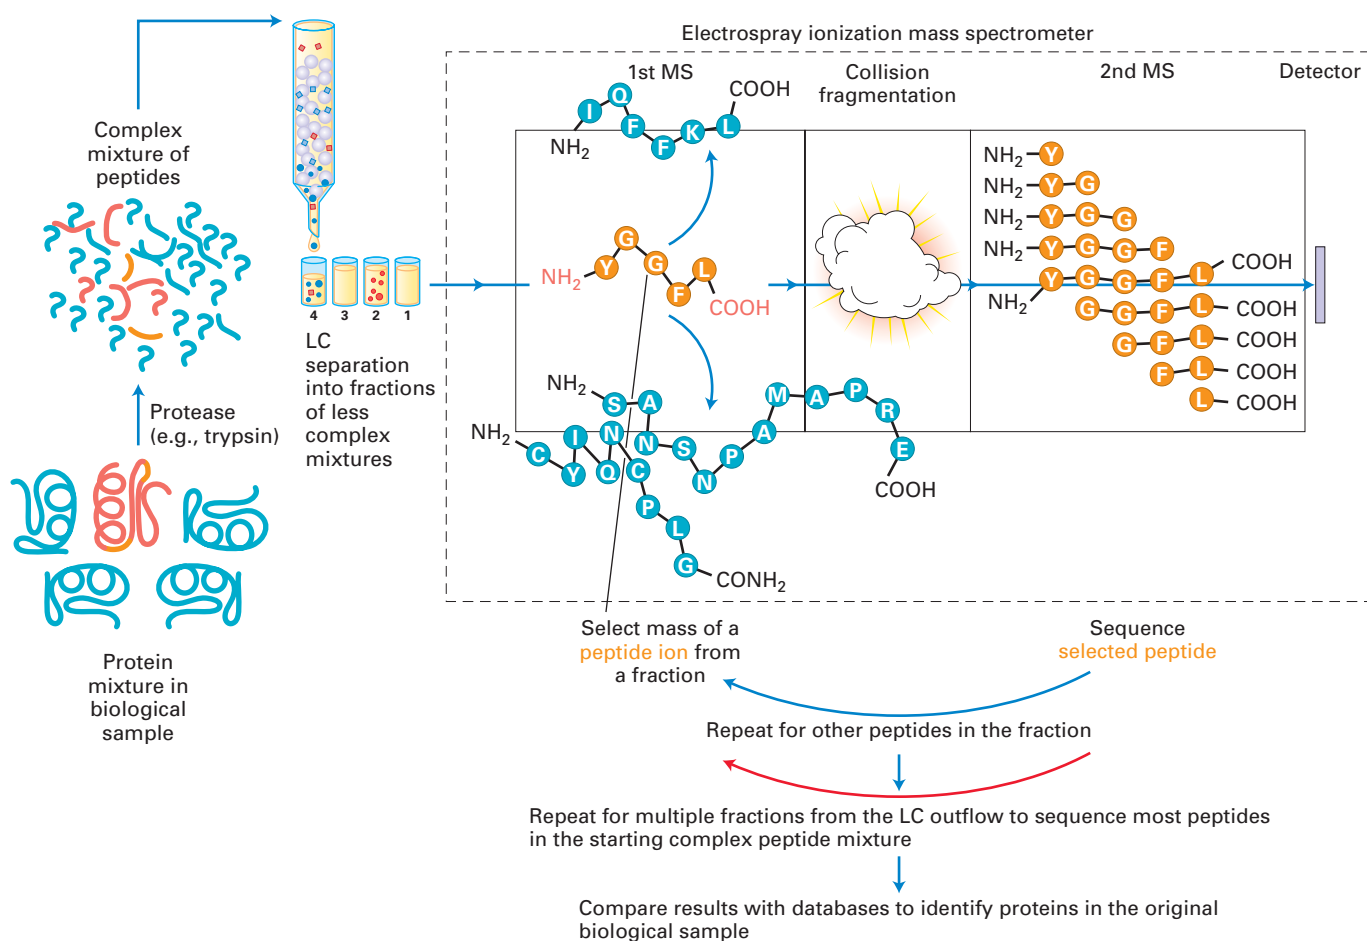

These are just a few of the questions that can be addressed using proteomics. The methods used to answer these questions are as diverse as the questions themselves, and their numbers are growing rapidly.

## Advanced Techniques in Mass Spectrometry Are Critical to Proteomic Analysis

Advances in proteomics technologies (e.g., mass spectrometry) profoundly affect the types of questions that can be practically studied. For many years, two-dimensional gel electrophoresis allowed researchers to separate, display, and characterize complex mixtures of proteins (see Figure 3-39). The spots on a two-dimensional electrophoresis gel could be excised, the protein fragmented by proteolysis (e.g., by trypsin digestion), and the fragments identified by MS. An alternative to this two-dimensional gel electrophoresis method is *high-throughput LC-MS/MS*. Figure 3-47 outlines the general LC-MS/MS approach, in which a complex mixture of proteins is digested with a protease; the myriad resulting peptides are fractionated by LC into multiple, less complex fractions, which are slowly but continuously injected by electrospray ionization into a tandem mass spectrometer. The fractions are then sequentially subjected to multiple

cycles of MS/MS until the sequences of many of the peptides have been determined and used to identify the proteins in the original biological sample. Detection of a substantial fraction of the proteins in whole cells or tissues currently requires samples containing more than 50  $\mu\text{g}$  of protein, an amount equivalent to the protein content of some 70,000–200,000 mammalian cells. Efforts are under way to increase the sensitivity of the method so that eventually one might be able to analyze the proteome of an individual cell.

An example of the use of LC-MS/MS to identify many of the proteins in each organelle is seen in Figure 3-48. Cells from murine (mouse) liver tissue were mechanically broken to release the organelles, and the organelles were partially separated by density-gradient centrifugation. The locations of the organelles in the gradient were determined using immunoblotting with antibodies that recognized previously identified, organelle-specific proteins. Fractions from the gradient were then subjected to LC-MS/MS to identify the proteins in each fraction, and the distributions in the gradient of many

### EXPERIMENTAL FIGURE 3-47 LC-MS/MS is used to identify the proteins in a complex biological sample.

A complex mixture of proteins in a biological sample (e.g., an isolated preparation of Golgi organelles) is digested with a protease. The mixture of resulting peptides is fractionated by liquid chromatography (LC) into multiple, less complex, fractions, which are slowly but continuously injected by

electrospray ionization into a tandem mass spectrometer. The fractions are then sequentially subjected to multiple cycles of MS/MS until the masses and sequences of many of the peptides have been determined and used to identify the proteins in the original biological sample through comparison with protein databases.

**EXPERIMENTAL FIGURE 3-48 Density-gradient centrifugation and LC-MS/MS can be used to identify many of the proteins in organelles.** (a) The cells in liver tissue were mechanically broken to release the organelles, and the organelles were partially separated by density-gradient centrifugation. The locations of the organelles—which were spread out through the gradient and somewhat overlapped with one another—were determined using immunoblotting with antibodies that recognized previously identified, organelle-specific proteins. Fractions from the gradient were

individual proteins were compared with the distributions of the organelles. This strategy permitted the assignment of many individual proteins to one or more organelles (organelle proteome profiling). More recently, a combination of organelle purification, MS, biochemical localization, and computational methods has been used to show that at least a thousand distinct proteins are localized in the mitochondria of humans and mice.

Proteomics methods combined with molecular genetics methods are currently being used to identify all the protein complexes in eukaryotic cells. For example, in the yeast *Saccharomyces cerevisiae*, approximately 500 complexes, with an average of 4.9 distinct proteins per complex, have been identified. These complexes, in turn, are involved in at least 400 complex-to-complex interactions. Such systematic proteomic studies are providing new insights into the organization of proteins within cells and into how proteins work together to permit cells to live and function.

Phosphoproteomics, the identification and quantification of phosphorylation sites on the proteins in a complex

subjected to proteolysis and LC-MS/MS to identify the peptides, and hence the proteins, in each fraction. Comparisons with the locations of the organelles in the gradient (called protein correlation profiling) permitted assignment of many individual proteins to one or more organelles (organelle proteome identification). (b) The hierarchical breakdown of data derived from the procedures in part (a). Note that not all proteins identified could be assigned to organelles and that some proteins were assigned to more than one organelle. [Data from L. J. Foster et al., 2006, *Cell* **125**:187–199.]

mixture, is playing a growing role in the analysis of cell metabolism and regulation. As we have already learned, the reversible phosphorylation of proteins by kinases and phosphatases is a key mechanism for regulating proteins in cells. Phosphoproteomics permits the simultaneous determination of the phosphorylation states of many proteins and thus provides an important tool for analyzing complex cellular regulatory networks. Only a fraction—in some cases, only a small fraction—of a particular protein might be phosphorylated. Thus phosphoproteomic analysis can require 50–100 times more initial cell or tissue sample material (from about 2.5 to more than 20 mg of total cellular protein per sample) than does standard proteomic analysis. As a consequence, investigators usually use affinity chromatography methods with either metal-containing (e.g.,  $\text{Fe}^{3+}$  or  $\text{TiO}_2$ ) or antibody-containing columns to separate phosphopeptides from nonphosphorylated peptides (phosphopeptide enrichment) prior to subjecting the phosphopeptides to LC-MS/MS analysis.

## KEY CONCEPTS OF SECTION 3.6

### Proteomics

- Proteomics is the systematic study of the amounts (and changes in the amounts), modifications, interactions, localization, and functions of all or subsets of all proteins in biological systems at the whole-organism, tissue, cellular, and subcellular levels.
- Proteomics provides insights into the fundamental organization of proteins within cells and how that organization is influenced by the state of the cells (e.g., differentiation into distinct cell types; responses to stress, disease, and drugs).
- A wide variety of methods are used for proteomic analyses, including two-dimensional gel electrophoresis, density-gradient centrifugation, and mass spectrometry (particularly LC-MS/MS).
- Proteomics has helped begin to identify the proteomes of organelles (“organelle proteome profiling”) as well as the organization of individual proteins into multiprotein complexes (see Figure 3-48).
- Phosphoproteomics is a specialized application of proteomics that identifies the collection of phosphorylated proteins (phosphoproteome) in cells and characterizes how the level of phosphorylation of these proteins varies as the state of the cells changes.

peptide bond	69	tertiary structure	72
phosphorylation	103	ubiquitin	99
polypeptide	70	$V_{max}$	91
primary structure	70	Western blotting	112
proteasome	97	x-ray	
protein	70	crystallography	119

### Review the Concepts

1. The three-dimensional structure of a protein is determined by its primary, secondary, and tertiary structures. Define the *primary*, *secondary*, and *tertiary structures*. What are some of the common secondary structures? What are the forces that hold together the secondary and tertiary structures?
2. Proper folding of proteins is essential for their biological activity. In general, the functional conformation of a protein is the conformation with lowest energy. This means that if an unfolded protein is allowed to reach equilibrium, it should assemble automatically into its native, functioning folded state. Why then is there a need for molecular chaperones and chaperonins in cells? What different roles do molecular chaperones and chaperonins play in the folding of proteins?
3. Enzymes catalyze chemical reactions. What constitutes the active site of an enzyme? What are the turnover number ( $k_{cat}$ ), the Michaelis constant ( $K_m$ ), and the maximal velocity ( $V_{max}$ ) of an enzyme? The  $k_{cat}$  (catalytic rate constant) for carbonic anhydrase is  $5 \times 10^5$  molecules per second. This is a “rate constant,” but not a “rate.” What is the difference? By what concentration would you multiply this rate constant in order to determine an actual rate of product formation ( $V$ )? Under what circumstances would this rate become equal to the maximal velocity ( $V_{max}$ ) of the enzyme?
4. The following reaction coordinate diagram charts the energy of a substrate molecule (S) as it passes through a transition state ( $X^\ddagger$ ) on its way to becoming a stable product (P) alone or in the presence of one of two different enzymes (E1 and E2). How does the addition of either enzyme affect the change in Gibbs free energy ( $\Delta G$ ) for the reaction? Which of the two enzymes binds with greater affinity to the substrate? Which enzyme better stabilizes the transition state? Which enzyme functions as a better catalyst?

5. A healthy immune system can raise antibodies that recognize and bind with high affinity to almost any stable molecule. The molecule to which an antibody binds is known as an antigen. Antibodies have been exploited by enterprising scientists to generate valuable tools for research, diagnosis, and therapy. One clever application is the generation of antibodies that function like enzymes to catalyze complicated chemical reactions. If you wished to produce such a “catalytic” antibody, what would you suggest using as the antigen? Should it be the substrate of the reaction? The product? Something else?

6. Proteins are degraded in cells. What is ubiquitin, and what role does it play in tagging proteins for degradation? What is the role of proteasomes in protein degradation? How might proteasome inhibitors serve as chemotherapeutic (cancer-treating) agents?

7. The function of proteins can be regulated in a number of ways. What is cooperativity, and how does it influence protein function? Describe how protein phosphorylation and proteolytic cleavage can modulate protein function.

8. A number of techniques can separate proteins on the basis of their differences in mass. Describe the use of two of these techniques, centrifugation and gel electrophoresis. The blood proteins transferrin (MW 76 kDa) and lysozyme (MW 15 kDa) can be separated by rate-zonal centrifugation or SDS-polyacrylamide gel electrophoresis. Which of the two proteins will sediment faster during centrifugation? Which will migrate faster during electrophoresis?

9. Liquid chromatography is an analytical method used to separate proteins. Describe the principles for separating proteins by gel filtration, ion-exchange, and affinity chromatography.

10. Various methods have been developed for detecting proteins. Describe how radioisotopes and autoradiography can be used for labeling and detecting proteins. How does Western blotting detect proteins?

11. Physical methods are often used to determine protein conformation. Describe how x-ray crystallography, cryo-electron microscopy, and NMR spectroscopy can be used to determine the shapes of proteins. What are the advantages

and disadvantages of each method? Which is better for small proteins? Large proteins? Huge macromolecular assemblies?

12. Mass spectrometry is a powerful tool in proteomics. What are the four key features of a mass spectrometer? Describe briefly how MALDI and two-dimensional polyacrylamide gel electrophoresis could be used to identify a protein expressed in cancer cells but not in normal healthy cells.

Fluorescence microscopy showing the locations of DNA (green), microtubules (yellow), and microfilaments (purple) in two cultured cells. The cells were chemically fixed and then rendered permeable to antibodies using a gentle detergent. Microtubules were stained with an antibody to tubulin; microfilaments were stained with a labeled toxin, phalloidin, that binds selectively to F-actin; and DNA was visualized with a DNA-binding dye. [Torsten Wittman, University of California, San Francisco.]

**It is difficult to believe** that just 200 years ago it was not yet appreciated that all living things are made of cells. In 1655, Robert Hooke used a primitive microscope to examine a piece of cork and saw an orderly arrangement of rectangles—the walls of the dead plant cells—that reminded him of monks' cells in a monastery, so he coined the term *cell*. Shortly after this, Antoni van Leeuwenhoek's observations of the microorganisms he saw in his simple microscope became the first description of live cells. Two hundred years later, Matthias Schleiden and Theodore Schwann proposed that cells constitute the fundamental unit of life in plants, animals, and single-celled organisms. Collectively, these discoveries were some of the greatest in biology and posed the question of how cells are organized and function.

Even today, many technical constraints hamper studies of cells in intact animals and plants. One alternative is the use of intact organs that are removed from animals and treated

# Culturing and Visualizing Cells

to maintain their physiological integrity and function. However, the organization of organs, even isolated ones, is sufficiently complex to pose numerous problems for research. Thus molecular cell biologists often conduct experimental studies on cells isolated from an organism. In Section 4.1, we learn how to maintain and grow diverse cell types and how to isolate specific types of cells from complex mixtures.

In many cases, isolated cells can be maintained in the laboratory under conditions that permit their survival and growth, a procedure known as *culturing*. Cultured cells have several advantages over intact organisms for cell biology research. Cells of a single specific type can be grown in culture, experimental conditions can be better controlled, and in many cases a single cell can be readily grown into a colony of many identical cells. The resulting strain of cells, which is genetically homogeneous, is called a **clone**. However, cultured cells are not in their native setting, so researchers are

## OUTLINE

### 4.2 Light Microscopy: Exploring Cell Structure and Visualizing Proteins Within Cells

### 4.3 Electron Microscopy: High-Resolution Imaging

### 4.4 Isolation of Cell Organelles

now growing and examining cells in three-dimensional environments to more closely mimic their situation in an animal.

Discoveries about cellular organization have been intimately tied to developments in microscopy. This is as true today as it was 400 years ago. Light microscopy initially revealed the beautiful internal organization of cells, and today highly sophisticated microscopes are continually being improved to probe deeper and deeper into the molecular mechanisms by which cells function. In Section 4.2, we discuss light microscopy and the long-standing but still valuable techniques that are available, and then examine several clever methods that have been developed more recently, culminating with the newest, cutting-edge technologies. A major advance came in the 1960s and 1970s with the development of *immunofluorescence microscopy*, which allows the localization of specific proteins within fixed cells, thus providing a static image of their location, as illustrated in the chapter-opening figure. Such studies led to the important understanding that the membranes and interior spaces of each type of organelle contain a distinctive group of proteins that are necessary for the organelle to carry out its unique functions. Another major advance came in the mid-1990s with the simple idea of expressing *chimeric proteins*—consisting of a protein of interest covalently linked to a naturally fluorescent protein—which enabled biologists to visualize the movements of individual proteins in live cells. Suddenly, the dynamic nature of cells could be appreciated, which changed the view of cells from the previously available static images. In addition, it presented a technological challenge: the more sensitive a microscope could be made to detect the fluorescent protein, the more information the investigator could glean from the data. It also opened up the development of fluorescent techniques to monitor protein-protein interactions in live cells, as well as a myriad of other sophisticated molecular technologies, some of which we also discuss in this section. For decades, light microscopy was constrained by the resolution of the light microscope—to about 200 nm—due to the limitations imposed by the wavelength of visible light. We discuss methods that have been developed over the last few years to “beat” this resolution barrier with the development of *super-resolution microscopy*.

Despite the amazing developments in light microscopy, visible light still provides too low a resolution to examine cells in fine ultrastructural detail. The electron microscope gives a much higher resolution, but the technology generally requires that the cell be fixed and sectioned, and therefore all cell movements are frozen in time. Electron microscopy also allows investigators to examine the structure of macromolecular complexes or single macromolecules. In Section 4.3, we outline the various approaches for preparing specimens for observation in the electron microscope and describe the types of information that can be derived from them.

Light and electron microscopy revealed that all eukaryotic cells—whether of fungal, plant, or animal origin—contain a similar repertoire of membrane-limited compartments termed organelles. In parallel with the developments in microscopy,

subcellular fractionation methods were developed that have enabled cell biologists to isolate individual organelles to a high degree of purity. These techniques, detailed in Section 4.4, continue to provide important information about the protein composition and biochemical function of organelles.

## 4.1 Growing and Studying Cells in Culture

The study of cells is greatly facilitated by growing them in culture, so that they can be examined by microscopy and subjected to specific treatments under controlled conditions. It is generally quite easy to grow unicellular bacteria, fungi, or protists, for example, by placing them in a rich medium that supports their growth. However, animal cells come from multicellular organisms, which makes it more difficult to culture single cells or small groups of cells. In this section, we discuss how animal cells are grown in culture and how different cell types can be purified for study.

### Culture of Animal Cells Requires Nutrient-Rich Media and Special Solid Surfaces

To permit the survival and normal function of cultured tissues or cells, the temperature, pH, ionic strength, and access to essential nutrients must simulate as closely as possible the conditions within an intact organism. Isolated animal cells are typically placed in a nutrient-rich liquid, called the culture medium, within specially coated plastic dishes or flasks. The cultures are kept in incubators in which the temperature, atmosphere, and humidity can be controlled. To reduce the chances of bacterial or fungal contamination, antibiotics are often added to the culture medium. To further guard against contamination, investigators usually transfer cells between dishes, add reagents to the culture medium, and otherwise manipulate the specimens within special sterile cabinets containing circulating air that is filtered to remove microorganisms and other airborne contaminants.

Media for culturing animal cells must supply the nine amino acids (phenylalanine, valine, threonine, tryptophan, isoleucine, methionine, leucine, lysine, and histidine) that cannot be synthesized by adult vertebrate animal cells. In addition, most cultured cells require three other amino acids (cysteine, tyrosine, and arginine) that are synthesized only by specialized cells in intact animals, as well as glutamine, which serves as a nitrogen source. The other necessary components of a medium for culturing animal cells are vitamins, various salts, fatty acids, glucose, and serum—the fluid remaining after the noncellular part of blood (plasma) has been allowed to clot. Serum contains various protein factors that are needed for the proliferation of mammalian cells in culture, including the polypeptide hormone insulin; transferrin, which supplies iron in a bioaccessible form; and numerous growth factors. In addition, certain cell types require specialized protein growth factors not present in

serum. For instance, progenitors of red blood cells require erythropoietin, and T lymphocytes require interleukin 2 (see Chapter 16). A few mammalian cell types can be grown in a chemically defined, serum-free medium containing amino acids, glucose, vitamins, and salts plus certain trace minerals, specific protein growth factors, and other components.

Unlike bacterial and yeast cells, which can be grown in suspension, most animal cell types will grow only when attached to a solid surface. This requirement highlights the importance of the cell-surface proteins, called **cell-adhesion molecules (CAMs)**, that cells use to bind to adjacent cells and to components of the extracellular matrix such as collagen, laminin, or fibronectin (see Chapter 20). The solid growth surface (usually glass or plastic) is either pre-coated with these extracellular-matrix proteins, or they come from the serum or are secreted by the cells in culture. A single cell cultured on a glass or plastic dish proliferates to form a visible mass, or *colony*, containing thousands of genetically identical cells in 4 to 14 days, depending on the growth rate. Although most normal animal cells require a surface to grow on, some specialized blood cells, and especially tumor cells, can be grown in suspension as single cells.

## Primary Cell Cultures and Cell Strains Have a Finite Life Span

*Primary cells* are cells isolated directly from tissues. Normal animal tissues (e.g., skin, kidney, liver) or whole embryos are commonly used to establish *primary cell cultures*. To prepare individual tissue cells for a primary culture, the cell-cell and cell-matrix interactions must be broken. To do so, tissue fragments are treated with a combination of a protease (e.g., trypsin, the collagen-hydrolyzing enzyme collagenase, or both) and a divalent cation chelator (e.g., EDTA) that depletes the medium of free calcium ( $\text{Ca}^{2+}$ ). Many CAMs require calcium and are thus inactivated when calcium is removed; other CAMs that are not calcium dependent need to be cleaved by a protease for the cells to separate. The released cells are then placed in a nutrient-rich, serum-supplemented medium in dishes, where they can adhere to the surface and to one another. The same protease-chelator solution is used to remove adherent cells from a culture dish for biochemical studies or subculturing (transfer to another dish).

**Fibroblasts** are the predominant cells in connective tissue and normally produce extracellular-matrix components such as collagen that bind to CAMs, thereby anchoring cells to a surface. In culture, fibroblasts usually divide more rapidly than other cells from a tissue, eventually becoming the predominant cell type in a primary culture unless special precautions are taken to remove them when isolating other types of cells.

When cells removed from an embryo or an adult animal are cultured, most of the adherent cells will divide a finite number of times and then cease growing (a phenomenon called cell senescence). For instance, human fetal fibroblasts divide about 50 times before they cease growth (Figure 4-1a). Starting with  $10^6$  cells, 50 doublings has the potential to

produce  $10^6 \times 2^{50}$ , or more than  $10^{20}$ , cells, whose weight would be equivalent to that of about a thousand people. Normally, only a very small fraction of these cells are used in any one experiment. Thus, even though its lifetime is limited, a single culture, if carefully maintained, can be studied through many cell generations. Such a lineage of cells originating from one initial primary culture is called a **cell strain**.

One important exception to the finite life span of normal cells is the *embryonic stem cell*, which, as its name implies, is derived from an embryo and will divide and give rise to all tissues during development. As we discuss in Chapter 21, embryonic stem cells can be cultured indefinitely under the appropriate conditions.

**FIGURE 4-1 Stages in the establishment of a cell culture.**

(a) When cells isolated from human tissue are initially cultured, some cells die and others (mainly fibroblasts) start to grow; overall, the growth rate increases (phase I). If the remaining cells are harvested, diluted, and replated into dishes again and again, the cell strain continues to divide at a constant rate for about 50 cell generations (phase II), after which the growth rate falls rapidly. In the ensuing period (phase III), all the cells in the culture stop growing (senescence). (b) In a culture prepared from mouse or other rodent cells, initial cell death (not shown) is coupled with the emergence of healthy, growing cells. As these dividing cells are diluted and allowed to continue growth, they soon begin to lose growth potential, and most stop growing (i.e., the culture goes into senescence). Very rare cells undergo oncogenic mutations that allow them to survive and continue dividing until their progeny overgrow the culture. These cells constitute a cell line, which will grow indefinitely if it is appropriately diluted and fed with nutrients. Such cells are said to be immortal.

Research with cell strains is simplified by our ability to freeze them and successfully thaw them at a later time for experimental analysis. Cell strains can be frozen in a state of suspended animation and stored for extended periods at liquid nitrogen temperature, provided that a preservative that prevents the formation of damaging ice crystals is used. Although not all cells survive thawing, many do survive and resume growth.

## Transformed Cells Can Grow Indefinitely in Culture

To be able to clone individual cells, modify cell behavior, or select mutants, biologists often want to maintain cell cultures for many more than 50 doublings. Such prolonged growth is exhibited by cells derived from some tumors. In addition, rare cells in a population of primary cells may undergo spontaneous oncogenic mutations, leading to *oncogenic transformation* (see Chapter 24). Such cells, said to be oncogenically transformed, or simply *transformed*, are able to grow indefinitely. A culture of cells with an indefinite life span is considered immortal and is called a **cell line**.

Primary cultures of normal rodent cells commonly undergo spontaneous transformation into a cell line. After rodent cells are grown in culture for several generations, the culture goes into senescence (Figure 4-1b). During this period, most of the cells stop growing, but often a rapidly dividing transformed cell arises spontaneously and takes over, or overgrows, the culture. A cell line derived from such a transformed variant will grow indefinitely if provided with the necessary nutrients. In contrast to rodent cells, normal human cells rarely undergo spontaneous transformation into a cell line. The HeLa cell line, the first human cell line established, was originally obtained in 1952 from a malignant tumor (carcinoma) of the uterine cervix and is still used extensively today. Many other human cell lines are derived from cancers, and biologists have rendered others immortal by transforming them to express oncogenes.

Regardless of their source, cells in immortal lines often have chromosomes with abnormal DNA sequences. In addition, the number of chromosomes in such cells is usually greater than that in the normal cell from which they arose, and the chromosome number changes as the cells continue to divide in culture. A noteworthy exception, and exciting development, is a recently described human cell line of hematopoietic origin that is haploid for all chromosomes except chromosome 8. Since inactivation of one of the two copies of a gene in a diploid cell generally does not generate a phenotype, a line with a single copy of most genes should be very useful for genetic analysis, making possible the types of genetic screens employed in model organisms (see Chapter 6). Cells with an abnormal number of chromosomes are said to be *aneuploid*.

## Flow Cytometry Separates Different Cell Types

Some cell types differ sufficiently in density that they can be separated on the basis of this physical property. White blood cells (leukocytes) and red blood cells (erythrocytes),

for instance, have very different densities because erythrocytes have no nucleus; thus these cells can be separated by equilibrium density-gradient centrifugation (described in Section 4.4). Most cell types cannot be differentiated so easily, so other techniques, such as flow cytometry, must be used to separate them.

To separate one type of cell from a complex mixture, it is necessary to have some way to mark and then sort out the desired cells. As we will see below, it is possible to mark cells by expressing a fluorescent protein in them, but if only a few cells in the population express the protein, how can we sort them from the nonfluorescent ones? The cells can be analyzed in a *flow cytometer*. This machine flows cells past a laser beam that measures the light that they scatter and the fluorescence that they emit; thus it can quantify the cells expressing the fluorescent protein in a mixture. A *fluorescence-activated cell sorter* (FACS), which is based on flow cytometry, can both analyze the cells and select the few fluorescent cells from thousands of others and sort them into a separate culture dish (Figure 4-2). To achieve this, the cells are mixed with a buffer and forced through a vibrating nozzle to generate tiny droplets. The concentration of cells is adjusted so that most of the droplets do not contain cells, and the ones that do contain only one. Just before the nozzle, the stream of cells passes through a laser beam so that the presence and size of a cell can be recorded from the scattered light using one detector, and the amount of fluorescent light emitted can be quantified using a second, fluorescent light detector. If a cell is present in a droplet, the droplet is given a negative electric charge as it emerges from the nozzle. The stream of droplets then passes through two plates that generate an electric field proportional to the fluorescence detected from the cell in the droplet. This field generates a force that moves charged droplets out of the stream of uncharged droplets and into a collection tube. Since the amount of force applied is proportional to the fluorescence emitted by the cell in the droplet, cells with different levels of fluorescence can be collected. Having been sorted from other cells, the selected cells can be grown in culture.

The FACS procedure is commonly used to purify the different types of white blood cells, each of which bears on its surface one or more distinctive proteins and so will bind monoclonal antibodies specific for its proteins. If a cell mixture is incubated with a fluorescent dye linked to the antibody to a specific cell-surface protein, only the desired cells will be fluorescent. Only the T cells of the immune system, for instance, have both CD3 and Thy1.2 proteins on their surfaces. The presence of these surface proteins allows T cells to be separated easily from other types of blood cells or spleen cells (Figure 4-3).

Other uses of flow cytometry include the measurement of a cell's DNA and RNA content and the determination of its general shape and size. The FACS can make simultaneous measurements of the size of a cell (from the amount of scattered light) and the amount of DNA that it contains (from the amount of fluorescence emitted from a DNA-binding dye). Measurements of the DNA content of individual cells

**FIGURE 4-2 A fluorescence-activated cell sorter (FACS) separates cells having different levels of fluorescence.** Step **1**: A concentrated suspension of labeled cells is mixed with a buffer (the sheath fluid) so that the cells pass single file through a laser light beam. Step **2**: Both the fluorescent light emitted and the light scattered by each cell are measured; from measurements of the scattered light, the size and shape of the cell can be determined. Step **3**: The suspension is then forced through a nozzle, which forms tiny droplets containing at most a single cell. At the time of formation at the nozzle tip, each droplet containing a cell is given a negative electric charge proportional to the fluorescence of that cell determined from the earlier measurement. Step **4**: Droplets now pass through an electric field, so that those with no charge are discarded, whereas those with different electric charges are separated and collected. Because it takes only milliseconds to sort each droplet, as many as 10 million cells per hour can pass through the machine.

are used to follow replication of DNA as the cells progress through the cell cycle (see Chapter 19).

An alternative method for separating specific types of cells uses small magnetic beads coupled to antibodies to a specific cell-surface molecule. For example, to isolate T cells, the beads are coated with a monoclonal antibody specific for a surface protein such as CD3 or Thy1.2. Only cells with these proteins will stick to the beads, which can be recovered from the preparation by adhesion to a small magnet on the side of a test tube.

## Growth of Cells in Two-Dimensional and Three-Dimensional Culture Mimics the In Vivo Environment

While much has been learned using cells grown on plastic or glass surfaces, these surfaces are far removed from cells' normal tissue environment. As detailed in Chapter 20, many cell types function only when closely linked to other cells. Key examples are the sheet-like layers of epithelial tissue, called **epithelia** (singular, **epithelium**), that cover the external

**EXPERIMENTAL FIGURE 4-3 T cells bound to fluorescence-tagged antibodies to two cell-surface proteins are separated from other white blood cells by FACS.** Spleen cells from a mouse were treated with a red fluorescent monoclonal antibody specific for the CD3 cell-surface protein and with a green fluorescent monoclonal antibody specific for a second cell-surface protein, Thy1.2. As the cells were passed through a FACS, the intensity of the green and red fluorescence emitted by each cell was recorded. Each dot represents a single cell. This plot of green fluorescence (vertical axis) versus red fluorescence (horizontal axis) for thousands of spleen cells shows that about half of them—the T cells—express both CD3 and Thy1.2 proteins on their surfaces (upper-right quadrant). The remaining cells, which exhibit low fluorescence (lower-left quadrant), express only background levels of these proteins and are other types of white blood cells. Note the logarithmic scale on both axes. [Data from Chengcheng Zhang, Whitehead Institute.]

**FIGURE 4-4 Madin-Darby canine kidney (MDCK) cells grown in specialized containers provide a useful experimental system for studying epithelial cells.** MDCK cells form a polarized epithelium when grown on a porous membrane filter coated on one side with collagen and other components of the basal lamina. With the use of the special culture dish shown here, the medium on each side of the filter (apical and basal sides of the monolayer) can be experimentally manipulated and the movement of molecules across the layer monitored. Several cell junctions that interconnect the cells form only if the growth medium contains sufficient calcium.

and internal surfaces of organs. Typically, epithelial cells have distinct surfaces, called the *apical* (top), *basal* (base or bottom), and *lateral* (side) surfaces (see Figure 20–11).

The basal surface usually contacts an underlying extracellular matrix called the *basal lamina*, whose composition and function are discussed in Section 20.3. Epithelial cells often function to transport specific classes of molecules across the epithelial sheet; for example, the epithelial lining of the intestine transports nutrients into the cell through the apical surface and out toward the bloodstream across the basolateral surface. When grown on plastic or glass, epithelial cells cannot easily perform this function. Therefore, special containers have been designed with a porous surface that acts as a basal lamina to which epithelial cells attach and form a uniform two-dimensional sheet (Figure 4-4). A commonly used cultured cell line derived from dog kidney epithelium, called the *Madin-Darby canine kidney* (MDCK) cell line, is often used to study the formation and function of epithelial sheets.

However, even a two-dimensional sheet often does not allow cells to fully mimic behavior in their normal environment. Methods have now been developed to grow cells in three dimensions by providing a support infiltrated with appropriate components of the extracellular matrix (discussed in Chapter 20). If MDCK cells are cultured under appropriate conditions, they will form a tubular sheet mimicking a tubular organ or the duct of a secretory gland. In these three-dimensional structures, the apical side of the epithelial sheet lines the lumen, whereas the basal side of each cell is in contact with the extracellular matrix (Figure 4-5).

**EXPERIMENTAL FIGURE 4-5 MDCK cells can form cysts in culture.** (a) MDCK cells grown on a supported extracellular matrix will form groups of cells that polarize to form a tubular single layer of cells with a lumen in the middle, called a cyst. (b) By examining the localization of proteins found in the apical (red) and basolateral membranes

(green), we can see that these cells are fully polarized, with the apical side facing the lumen, which recapitulates their organization in the kidney tubules from which they are derived. The nuclear DNA is stained blue. [Institute of Cancer Sciences/CRUK Beatson Institute, University of Glasgow, Garscube Estate, Switchback Road.]

If we can grow an epithelial tube in culture, can we grow a whole organ that could be transplanted into a patient? Recent advances in biomedical engineering are developing promising strategies to do this, initially in experimental animals. In an example of one approach, a 3-D printer is used to help make a replacement ear. First, an exact computer image of an ear is generated. This image is used to program a 3-D printer to assemble a pliable matrix—containing support material that is biodegradable, together with appropriate components of the extracellular matrix—in the precise shape of an ear. This matrix provides support for the growth of skin cells, either in culture or after transplantation under the skin, so that ultimately the synthetic organ can be surgically attached to a living animal. Other approaches make use of 3-D printers to assemble the matrix and seed it with appropriate cells. An exciting and ambitious goal of this technology is to generate synthetic organs containing many different types of cells by printing each of several layers with appropriate matrix and cells to generate complex three-dimensional organs that might one day be used to replace defective ones in patients. Many hurdles still need to be overcome, but the ability to generate stem cells from patients and then induce differentiation in culture (described in Chapter 21) is overcoming the major obstacle of immunological rejection and will probably be key to providing cells for the assembly of synthetic organs. ■

## Hybridomas Produce Abundant Monoclonal Antibodies

In addition to serving as research models for studies of cell function, cultured cells can be converted into “factories” for producing specific proteins. For example, special cultured cells can be used to generate monoclonal antibodies, which are experimental tools widely used in many aspects of cell biological research. They are also used for diagnostic and therapeutic purposes in medicine, as we discuss in later chapters.

To understand the challenge of generating monoclonal antibodies, we must briefly review how mammals produce antibodies; more detail is provided in Chapter 23. Recall that antibodies are proteins secreted by white blood cells that bind with high affinity to their antigen (see Figure 3-19). Each normal antibody-producing B lymphocyte in a mammal is capable of producing a single type of antibody that can bind to a particular determinant, or **epitope**, on an antigen molecule. An epitope is generally a small region on the antigen, consisting, for example, of just a few amino acids. If an animal is injected with an antigen, the B lymphocytes that make antibodies recognizing that antigen are stimulated to grow and secrete those antibodies. Each antigen-activated B lymphocyte forms a clone of cells in the spleen or lymph nodes, with each cell producing the identical antibody—that is, a *monoclonal antibody*. Because most natural antigens contain multiple epitopes, exposure of an animal to an antigen usually stimulates the formation of multiple B-lymphocyte clones, each producing a different antibody. The resulting mixture of antibodies from the many B-lymphocyte clones that recognize different epitopes on the antigen is said to be

*polyclonal*. Such polyclonal antibodies circulate in the blood and can be isolated as a group.

Although polyclonal antibodies are very useful, monoclonal antibodies are more suitable for the many types of experiments and medical applications in which we need a reagent that binds to just one site on a protein; for example, one that competes with a ligand on a cell-surface receptor. Unfortunately, the biochemical purification of any one type of monoclonal antibody from blood is not feasible for two main reasons: the concentration of any given antibody is quite low, and all antibodies have the same basic molecular architecture (see Figure 3-19).

To produce and then purify monoclonal antibodies, one first needs to be able to grow the appropriate B-lymphocyte clone. However, primary cultures of normal B lymphocytes are of limited usefulness for the production of monoclonal antibodies because they have a limited life span. Thus the first step in producing a monoclonal antibody is to generate immortal antibody-producing cells (Figure 4-6). Immortality is achieved by fusing normal B lymphocytes from an immunized animal with transformed, immortal lymphocytes called *myeloma cells* that themselves do not synthesize antibodies (see Figure 3-19). Treatment with certain viral glycoproteins or the chemical polyethylene glycol encourages the plasma membranes of two cells to fuse, allowing their cytosols and organelles to intermingle. Some of the fused cells undergo division, and their nuclei eventually coalesce, producing viable *hybrid cells* with a single nucleus that contains chromosomes from both parent cells. The fusion of two cells that are genetically different can yield a hybrid cell with novel characteristics. For instance, the fusion of a myeloma cell with a normal antibody-producing cell from a rat or mouse spleen yields a hybrid that proliferates into a clone called a **hybridoma**. Like myeloma cells, hybridoma cells grow rapidly and are immortal. Each hybridoma produces the monoclonal antibody encoded by its B-lymphocyte parent.

The second step in this procedure for producing a monoclonal antibody is to separate, or select, the hybridoma cells from the unfused parent cells and the cells fused with another of the same type. This selection is usually performed by incubating the mixture of cells in a special culture medium, called a *selection medium*, that permits the growth of only the hybridoma cells because of their novel characteristics. The myeloma cells used for the fusion carry a mutation that blocks a metabolic pathway, so a selection medium can be used that is lethal to them and not to their B-lymphocyte fusion partners that do not have the mutation. In the immortal hybrid cells, the functional gene from the lymphocyte can supply the missing gene product. The lymphocytes used in the fusion are not immortal and will not be able to grow in the selection medium either. Thus the hybridoma cells will be the only ones able to proliferate rapidly in the selection medium and so can be readily isolated from the initial mixture of cells. Finally, each selected hybridoma clone is tested for the production of the desired antibody; any clone producing that antibody is then grown in large cultures, from which a substantial quantity of pure monoclonal antibody can be obtained.

**FIGURE 4-6 Use of cell fusion and selection to obtain hybridomas producing a monoclonal antibody to a specific protein.**

**Step 1:** Immortal myeloma cells that cannot synthesize purines under special conditions because they lack thymidine kinase are fused with normal antibody-producing spleen cells from an animal that was immunized with antigen X. **Step 2:** When cultured in a special selective medium, unfused and self-fused cells do not grow: the myeloma cells do not grow because the selective medium does not contain purines, and the spleen cells do not grow because they have a limited life span in culture. Thus only fused cells formed from a myeloma cell and a spleen cell survive in the selective medium, proliferating into clones called hybridomas. Each hybridoma produces a single antibody. **Step 3:** Testing of individual clones identifies those that recognize antigen X. After a hybridoma that produces a desired antibody has been identified, the clone can be cultured to yield large amounts of that antibody.

Monoclonal antibodies have become very valuable as specific research tools. They are commonly employed in affinity chromatography to isolate and purify proteins from complex mixtures (see Figure 3-38c). As we discuss later in this chapter, they can also be employed in immunofluorescence microscopy to bind to and so locate a particular protein within cells. They can also be used to identify specific proteins in cell fractions with the use of immunoblotting (see Figure 3-39). Monoclonal antibodies have become important diagnostic and therapeutic tools in medicine as well; for example, monoclonal antibodies that bind to and inactivate toxins secreted by bacterial pathogens are used to treat diseases. Other monoclonal antibodies are specific for cell-surface proteins expressed by certain types of tumor cells. Several of these anti-tumor antibodies are widely used in cancer therapy, including a monoclonal antibody against a mutant form of the Her2 receptor that is overexpressed in some breast cancers.

## A Wide Variety of Cell Biological Processes Can Be Studied with Cultured Cells

As we discussed in the introduction to this chapter, studying animal cells in culture is much easier than studying cells in intact animals, partly because they can easily be subjected to a variety of manipulations. Cultured cells are particularly useful for the elucidation of fundamental processes. One way to understand a biological process is to interfere with a specific constituent in the cell and assess the outcome—this approach is like trying to understand how a car works by removing components and seeing what goes wrong. In some cases, human diseases associated with genetic defects in specific cell components can be analyzed using cells cultured from the patients. For example, analysis of cultured cells from patients with a genetic defect resulting in hypercholesterolemia—who have elevated blood cholesterol leading to heart disease and stroke—was critical in elucidating the basic steps of receptor-mediated endocytosis (see Chapter 14). In addition to relying on naturally occurring genetic lesions, we can manipulate cultured cells to interfere with expression of specific components. As we will see in Chapter 6, it is possible to decrease the expression of a specific protein in cultured cells by selectively “knocking down” the corresponding mRNA and then assess what effect this change has on particular processes in the cell. Chapter 6 also describes very recently developed techniques that can be used to inactivate specific genes in the genomes of cultured cells and thereby assess how the complete loss of specific RNAs and proteins affects cell functions.

## Drugs Are Commonly Used in Cell Biological Research

Another powerful way to analyze biological processes is to treat cells with drugs that bind to specific cell components and inactivate or activate them. In this section, we discuss some of the common drugs used for this purpose and how new drugs affecting specific cell processes can be developed.

Naturally occurring drugs have been used for centuries, but how they worked was often unknown. For example, extracts of meadow saffron were used to treat gout, a painful disease resulting from inflammation of joints. Today we know that this plant contains colchicine, a drug that depolymerizes microtubules and interferes with the ability of white blood cells to move to sites of inflammation (see Chapter 18). Alexander Fleming discovered that certain fungi secrete compounds that kill bacteria (antibiotics), and his discovery resulted in the development of penicillin. Only later was it discovered that penicillin inhibits cell division by blocking the assembly of the cell walls of certain bacteria.

Discoveries like these have resulted in a wide range of drugs that can inhibit specific and essential processes of cells. In most cases, researchers have eventually been able to identify the molecular targets of these drugs. For example, there are many antibiotic drugs that affect aspects of prokaryotic protein synthesis. A selection of some of the drugs most commonly used in cell biological research are listed in Table 4-1, grouped according to the process they inhibit.

How does one discover a new drug? One widely used approach is to search *chemical libraries*, consisting of tens of thousands to hundreds of thousands of different compounds, for chemicals that inhibit a specific process. The screening

**TABLE 4-1** Selected Drugs Used in Cell Biological Research

DNA replication inhibitors	Aphidicolin (eukaryotic DNA polymerase inhibitor); camptothecin, etoposide (eukaryotic topoisomerase inhibitors)
Transcription inhibitors	$\alpha$ -Amanitin (eukaryotic RNA polymerase II inhibitor); actinomycin D, 5,6-Dichloro-1- $\beta$ -D-ribofuranosylbenzimidazole (DRB) (eukaryotic transcription elongation inhibitor); rifampicin (bacterial RNA polymerase inhibitor); thiolutin (bacterial and yeast RNA polymerase inhibitor)
Protein synthesis inhibitors: block general protein production; toxic after extended exposure	Cycloheximide, anisomycin (translation inhibitors in eukaryotes); geneticin/G418, hygromycin, puromycin (translation inhibitors in bacteria and eukaryotes); chloramphenicol (translation inhibitor in bacteria and mitochondria); tetracycline (translation inhibitor in bacteria)
Protease inhibitors: block protein degradation	MG-132, lactacystin (proteasome inhibitors); E-64, leupeptin (serine and/or cysteine protease inhibitors); phenylmethanesulfonylfluoride (PMSF) (serine protease inhibitor); tosyl-L-lysine chloromethyl ketone (TLCK) (trypsin-like serine protease inhibitor)
Compounds affecting the cytoskeleton	Phalloidin, jasplakinolide (F-actin stabilizer); latrunculin, cytochalasin (F-actin polymerization inhibitors); taxol (microtubule stabilizer); colchicine, nocodazole, vinblastine, podophyllotoxin (microtubule polymerization inhibitors); monastrol (kinesin-5 inhibitor)
Compounds affecting membrane traffic, intracellular movement, and the secretory pathway, protein glycosylation	Brefeldin A (secretion inhibitor); leptomycin B (nuclear protein export inhibitor); dynasore (dynamin inhibitor); tunicamycin (N-linked glycosylation inhibitor)
Kinase inhibitors	Genistein, rapamycin, gleevec (tyrosine kinase inhibitors with various specificities); wortmannin, LY294002 (PI3 kinase inhibitors); staurosporine (protein kinase inhibitor); roscovitine (cell cycle CDK1 and CDK2 inhibitors); U0126 (MEK inhibitor)
Phosphatase inhibitors	Cyclosporine A, FK506, calyculin (protein phosphatase inhibitors with various specificities); okadaic acid (general inhibitor of serine/threonine phosphatases); phenylarsine oxide, sodium orthovanadate (tyrosine phosphatase inhibitors)
Compounds affecting intracellular cAMP levels	Forskolin (adenylate cyclase activator)
Compounds affecting ions (e.g., $K^+$ , $Ca^{2+}$ )	A23187 ( $Ca^{2+}$ ionophore); valinomycin ( $K^+$ ionophore); BAPTA (divalent cation (e.g., $Ca^{2+}$ ) binding/sequestering agent); thapsigargin (endoplasmic reticulum $Ca^{2+}$ ATPase inhibitor); ouabain ( $Na^+/K^+$ ATPase inhibitor)
Some drugs used in medicine	Propranolol ( $\beta$ -adrenergic receptor antagonist), statins (HMG-CoA reductase inhibitors, block cholesterol synthesis); omeprazole (a gastric proton pump inhibitor)

Note: Some of these molecules have broad specificity, whereas others are highly specific. More information about many of these compounds can be found in the relevant chapters in this text.

**FIGURE 4-7 Screening for drugs that affect specific biological processes.**

(a) In this example, a chemical library of 16,320 different chemicals was subjected to a series of screens for inhibitors of mitosis. Since such an inhibitor is expected to arrest cells at the mitotic stage of the cell cycle, the first screen (step 1) was to see if any of the chemicals enhanced the level of a marker specific for mitotic cells; this screen yielded 139 candidates. Microtubules make up the structure of the mitotic spindle, and the researchers were not interested in new drugs that target microtubules, so in the second screen (step 2) they tested the 139 compounds for their ability to affect microtubule assembly; this test eliminated 53 candidates. Immunofluorescence microscopy with antibodies to tubulin (the major subunit of microtubules), together with a stain for DNA, was then used in the third screen (step 3) to identify compounds that disrupt the structure of the spindle. (b) Localization of tubulin (green) and DNA (blue) for an untreated mitotic spindle (top) and one treated with one of the recovered compounds, now called monastrol. Monastrol inhibits a microtubule-based motor protein called kinesin-5, discussed in Chapter 18, that is necessary to separate the poles of the mitotic spindle. When kinesin-5 is inhibited, the two poles remain associated to give a monopolar spindle.

[Part (b) T. U. Mayer et al., 1999, *Science* 286:971–974.]

of chemical libraries in conjunction with high-throughput microscopic techniques has now become one of the major routes for new leads in drug discovery. Here we give just one case to illustrate how this type of approach works.

In our example (Figure 4-7a), researchers wanted to identify compounds that inhibit mitosis, the process by which duplicated chromosomes are accurately segregated by a microtubule-based machine called the mitotic spindle (discussed in Chapter 18). It was known that if spindle assembly is compromised, cells are arrested in mitosis. Therefore, the screen first used an automated robotic method to look for compounds that arrest cells in mitosis. The basis for the inhibition of mitosis by the candidate compounds was then explored to see if they affected assembly of the microtubules. Since inhibition of microtubule assembly was not of interest, the effect of the remaining candidate compounds on the structure of the spindle was determined by immunofluorescence microscopy using antibodies to tubulin, the major protein of microtubules. Over 16,000 compounds were screened, and a compound was identified that resulted in cells with abnormal spindles—instead of having two asters, they had a single aster, resulting in what is called a mono-astral array (Figure 4-7b). This drug, now called *monastrol*, was found to interfere with the assembly of the spindle by inhibiting a microtubule-based motor protein called kinesin-5. (See Chapter 18 for more details about the mitotic spindle.) Derivatives of monastrol are now being tested as anti-tumor agents for the treatment of certain cancers.

## KEY CONCEPTS OF SECTION 4.1

### Growing and Studying Cells in Culture

- Animal cells have to be grown in culture under conditions that mimic their natural environment, which generally requires them to be supplied with necessary amino acids and growth factors.
- Most animal cells need to adhere to a solid surface to grow.
- Primary cells—those isolated directly from tissue—have a finite life span.
- Transformed cells, such as cells derived from tumors, can grow indefinitely in culture.
- Cells that can be grown indefinitely are called a cell line.
- Many cell lines are aneuploid, having a different number of chromosomes than the parent cell from which they were derived.
- Cells expressing a fluorescent protein can be sorted on a machine called a fluorescence-activated cell sorter (FACS).
- Different cell types express different marker proteins on their cell surfaces, which can be labeled with fluorescent markers, allowing them to be sorted on a FACS machine.

- Epithelial cells are often grown in special containers to mimic their functional polarity. Cells can also be grown on three-dimensional matrices to more accurately reflect their normal environment.
- Monoclonal antibodies, which bind one epitope on an antigen, can be secreted by cultured cells called hybridomas. These hybrid cells are made by fusing antibody-producing B lymphocytes with immortal myeloma cells and then identifying those clones that produce the desired antibody. Monoclonal antibodies are important for basic research and as therapeutic agents.
- Cells in culture can be much more easily manipulated than cells in an intact animal.
- Basic biological processes can be studied by interfering with specific cell components, either through genetic mechanisms or by the application of specific drugs.
- Large chemical libraries can be screened for compounds that target specific processes to study those processes and to identify new drugs.

## 4.2 Light Microscopy: Exploring Cell Structure and Visualizing Proteins Within Cells

The cellular basis of life was first appreciated using primitive light microscopes. Since then, progress in cell biology has paralleled, and has often been driven by, technological advances in light microscopy (Figure 4-8). Here we discuss each of these major developments and how they advanced the study of cellular processes. First we describe basic uses

of a light microscope to observe unstained cells and structures. Next we describe the development of fluorescence microscopy and its use to localize specific proteins in fixed cells. By using molecular genetic techniques to fuse a protein of interest with a naturally fluorescent protein and express the resulting chimeric protein in cells, it is possible to follow the movement of specific proteins in live cells—an ability that has revealed how dynamic the organization of live cells is. In parallel with these advances in specimen preparation, optical advances were being made to enhance and sharpen the images provided by fluorescence microscopy to reveal cellular structure with unprecedented clarity. Many specialized technologies have emerged from these advances, and we describe some of the more important ones.

Many of the techniques we describe allow one to examine live cells in a microscope. These advances not only permit *video microscopy*, but also allow one to examine the responses of live cells or their components to specific stimuli or their interactions with other cells. As we discuss in this section, they have provided scientists with the ability to probe the functioning of individual components in live cells.

### The Resolution of the Conventional Light Microscope Is About 0.2 $\mu\text{m}$

All microscopes produce a magnified image of a small object, but the nature of the image depends on the type of microscope employed and on the way the specimen is prepared. The compound microscope, used in conventional *bright-field light microscopy*, contains several lenses that magnify the image of a specimen under study (Figure 4-9a, b). The total magnification is a product of the magnification of the individual lenses: if the *objective lens*, the lens closest to the specimen, magnifies 100-fold (a 100 $\times$  lens, the maximum usually employed), and the *projection lens* that focuses the

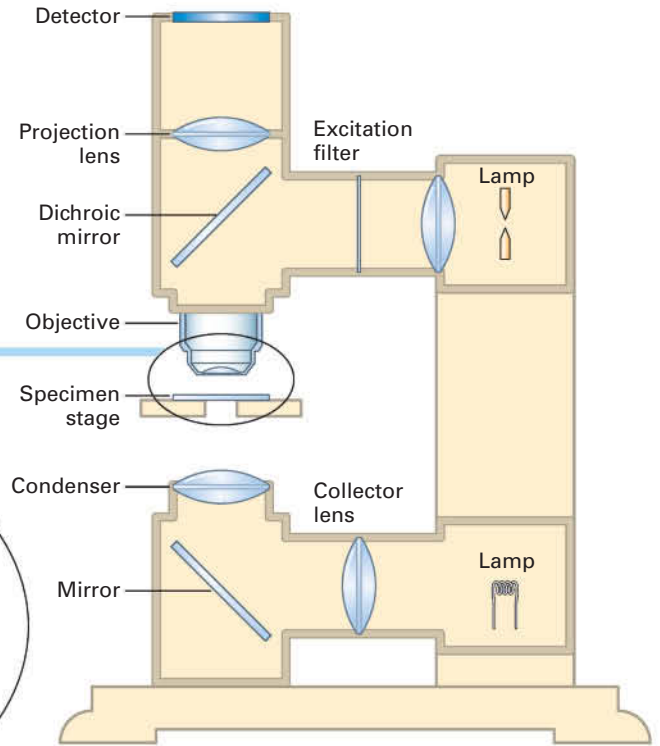

**FIGURE 4-8 Development of the light microscope.** (a) Early microscopes, like the ones used by Robert Hooke in the 1660s, used lenses or a mirror to illuminate the specimen. (b) Optics in general, and light microscopes in particular, developed enormously during the nineteenth century. By the middle of the twentieth century, highly

sophisticated microscopes limited only by the resolution of light were common. (c) In the second half of the twentieth century, fluorescence microscopy and digital imaging, together with confocal techniques, were developed to yield the versatile microscopes of today. [Part (a) SSPL/Getty Images; parts (b) and (c) courtesy of A. Bretscher.]

(a)

### Optical microscope

### (b) Bright-field

### (c) Phase-contrast

### (d) Fluorescence

**FIGURE 4-9 Optical microscopes are commonly configured for bright-field, phase-contrast, or fluorescence microscopy.** (a) In a typical light microscope, the specimen is usually mounted on a transparent glass slide and positioned on the movable specimen stage. (b) In bright-field light microscopy, light from a tungsten lamp is focused on the specimen by a condenser lens below the stage; the light travels the pathway shown in yellow. (c) In phase-contrast microscopy, incident light passes through an annular diaphragm, which focuses a circular annulus (ring) of light on the specimen. Light that passes unobstructed through the specimen is focused by the objective lens onto the thicker gray ring of the phase plate, which absorbs some of the direct light and alters its phase by one-quarter of a wavelength. If a specimen refracts (bends) or diffracts the light, the phase of some light waves is altered (green lines), and the light waves pass through the clear region of the phase plate. The refracted and unrefracted light is recombined at the image plane to form the image. (d) In fluorescence microscopy, a beam of light from a mercury lamp (gray lines) is directed to the excitation filter, which allows only the correct wavelength of light to pass through (green lines). The light is then reflected off a dichroic mirror and through the objective lens, which focuses it on the specimen. The fluorescent light emitted by the specimen (red lines) passes up through the objective lens, then through the dichroic mirror, and is focused and recorded on the detector at the image plane.

image on a camera magnifies 10-fold, the final magnification will be 1000-fold. Alternatively, if the light is directed to an ocular or *eyepiece* lens that magnifies 10-fold, the final magnification recorded by the human eye will also be 1000-fold.

The most important property of any microscope, however, is not its magnification, but its resolving power, or **resolution**: the ability to distinguish between two very closely positioned objects. Merely enlarging the image of a specimen accomplishes nothing if the image is blurred. The resolution of a microscope lens is numerically equivalent to  $D$ , the minimum distance between two distinguishable objects. The smaller the value of  $D$ , the better the resolution. The value of  $D$  is given by the equation

$$D = \frac{0.61\lambda}{N \sin \alpha} \quad (4-1)$$

where  $\alpha$  is the angular aperture, or half-angle, of the cone of light entering the objective lens from the specimen (Figure 4-9a),  $N$  is the refractive index of the medium between the specimen and the objective lens (i.e., the relative velocity of light in the medium compared with the velocity in air), and  $\lambda$  is the wavelength of the incident light. Resolution is improved by using shorter wavelengths of light (decreasing the value of  $\lambda$ ) or by gathering more light (increasing either  $N$  or  $\alpha$ ). Lenses for high-resolution microscopy are designed to work with oil between the lens and the specimen since oil has a higher refractive index (1.56, compared with 1.0 for air and 1.3 for water). To maximize the angle  $\alpha$ , and hence  $\sin \alpha$ , the lenses are also designed to focus very close to the thin coverslip covering the specimen. The term  $N \sin \alpha$  is known as the *numerical aperture* (NA) and is usually marked on the objective lens. A good high-magnification lens has an NA of about 1.4, and the very best lenses—which cost as much as

a medium-sized car—have a value approaching 1.5. Notice that the magnification is not part of this equation.

Owing to limitations in the values of  $\alpha$ ,  $\lambda$ , and  $N$  based on the physical properties of light, the *limit of resolution* of a light microscope using visible light is about 0.2  $\mu\text{m}$  (200 nm). No matter how many times the image is magnified, a conventional light microscope can never resolve objects that are closer than about 0.2  $\mu\text{m}$  apart or reveal details smaller than about 0.2  $\mu\text{m}$  in size. However, some new and sophisticated technologies devised to “beat” this resolution barrier can resolve objects just a few nanometers apart; we discuss such super-resolution microscopes in a later section.

Despite its lack of resolution, a conventional microscope can track a single object to within a few nanometers. If we know the precise size and shape of an object—say, a 5-nm sphere of gold that is attached to an antibody that is in turn bound to a cell-surface protein on a live cell—and if we use a camera to rapidly take multiple digital images, then a computer can calculate the average position to reveal the center of the object to within a few nanometers. In this way, computer algorithms can be used to track a single object—in this case, the location and movement with time of a cell-surface protein labeled with the gold-tagged antibody—more precisely than would be possible based on the light microscope’s resolution alone. This technique has been used to measure nanometer-sized steps as molecules and vesicles move along cytoskeletal filaments (see Figures 17-28 and 17-29).

### Phase-Contrast and Differential-Interference-Contrast Microscopy Visualize Unstained Live Cells

Cells are about 70 percent water, 15 percent protein, 6 percent RNA, and contain smaller amounts of lipids, DNA, and small molecules. Since none of these major classes of molecules are colored, and since they hardly impede the transmission of light, special methods must be used to see cells in a microscope. For example, the simplest microscopes view cells under *bright-field* optics (Figure 4-9b), and little detail can be seen (Figure 4-10). Two common methods for imaging live cells and unstained tissues to generate contrast take advantage of differences in the refractive index and thickness of cellular materials. These methods, called *phase-contrast microscopy* and *differential-interference-contrast (DIC) microscopy* (or Nomarski interference microscopy), produce images that differ in appearance and reveal different features of cell architecture. Figure 4-10 compares images of live, cultured cells obtained with these two methods and with standard bright-field microscopy. Since optical microscopes are expensive, they are often set up to perform many different types of microscopy on the same microscope stand (see Figure 4-9a–d).

Phase-contrast microscopy generates an image in which the degree of darkness or brightness of a region of a specimen depends on the *refractive index* of that region. Light moves more slowly in a medium with a higher refractive index. Thus

**FIGURE 4-10 Live cells can be visualized by microscopy techniques that generate contrast by interference.** These micrographs show live, cultured macrophage cells viewed by bright-field microscopy (*left*), phase-contrast microscopy (*middle*), and differential-interference-contrast (DIC) microscopy (*right*). In a phase-contrast

image, cells are surrounded by alternating dark and light bands; in-focus and out-of-focus details are simultaneously imaged in a phase-contrast microscope. In a DIC image, cells appear in pseudorelief. Because only a narrow in-focus region is imaged, a DIC image is an optical slice through the object. [Courtesy of N. Watson and James Evans.]

a beam of light is refracted (bent) once as it passes from the medium into a transparent object and again when it departs. In a phase-contrast microscope, a cone of light generated by an annular diaphragm in the condenser lens illuminates the specimen (see Figure 4-9c). The light passes through the specimen into the objective lens, and the unobstructed direct light passes through a region of the phase plate that both transmits only a small percentage of the light and changes its phase slightly. The part of a light wave that passes through a specimen will be refracted and will be out of phase (out of synchrony) with the part of the wave that does not pass through the specimen. How much their phases differ depends on the difference in refractive index along the two paths and on the thickness of the specimen. The refracted and unrefracted light is recombined at the image plane to form the image. If the two parts of the light wave are recombined, the resultant light will be brighter if they are in phase and less bright if they are out of phase. Phase-contrast microscopy is suitable for observing single cells or thin cell layers, but not thick tissues. It is particularly useful for examining the location and movement of larger organelles in live cells.

DIC microscopy, which is based on splitting the light into two perpendicular components before passing them through the specimen and then recombining them to observe their interference pattern, is the method of choice for visualizing extremely small details and thick objects. Contrast is generated by differences in the refractive index of the object and of its surrounding medium. In DIC images, objects appear to cast a shadow to one side. The “shadow” primarily represents a difference in the refractive index of a specimen rather than its topography. DIC microscopy easily defines the outlines of large organelles, such as the nucleus and vacuole. In addition to having a “relief”-like appearance, a DIC image is a thin *optical section*, or slice, through the object (Figure 4-10, *right*). Thus details of the nucleus in thick specimens (e.g., an intact *Caenorhabditis elegans* roundworm; see Figure 21-25d) can be observed in a series of such optical sections, and the three-dimensional structure of the object can be reconstructed by combining the individual DIC images.

Both phase-contrast and DIC microscopy can be used in *time-lapse microscopy*, in which the same cell is photographed at regular intervals over time to generate a movie. This procedure allows the observer to study cell movement, provided the microscope’s stage can control the temperature of the specimen and the appropriate environment.

### Imaging Subcellular Details Often Requires That Specimens Be Fixed, Sectioned, and Stained

As we have seen, live cells and tissues generally do not absorb light, so they are nearly invisible in a light microscope. Although cells can be visualized by the special techniques we have just discussed, these methods do not reveal the fine details of structure.

Specimens for light microscopy are commonly fixed with a solution containing chemicals that cross-link most proteins and nucleic acids. Formaldehyde, a common fixative, cross-links amino groups on adjacent molecules; these covalent bonds stabilize protein-protein and protein–nucleic acid interactions and render the molecules insoluble and stable for subsequent procedures. After fixation, a tissue sample for examination by light microscopy is usually embedded in paraffin and cut into sections about 50  $\mu\text{m}$  thick (Figure 4-11a). Cultured cells growing on glass coverslips, as described above, are thin enough so they can be fixed *in situ* and visualized by light microscopy without the need for sectioning.

A final step in preparing a specimen for light microscopy is to stain it so as to visualize the main structural features of the cell or tissue. Many chemical stains bind to molecules that have specific features. For example, histological samples are often stained with *hematoxylin* and *eosin* (“H&E stain”). Hematoxylin binds to basic amino acids (lysine and arginine) on many different kinds of proteins, whereas eosin binds to acidic molecules (such as DNA and side chains of the amino acids aspartate and glutamate). Because of their different binding properties, these dyes stain various cell types sufficiently differently that they are distinguishable

**FIGURE 4-11 Tissues for light microscopy are commonly fixed, embedded in a solid medium, and cut into thin sections.** (a) A fixed tissue is dehydrated by soaking in a series of alcohol-water solutions, ending with an organic solvent compatible with the embedding medium. To embed the tissue for sectioning, the tissue is placed in liquid paraffin. After the block containing the specimen has hardened, it is mounted on the arm of a microtome, and slices are cut with a knife. Typical sections cut for light microscopy are 0.5 to 50  $\mu\text{m}$  thick. The sections are collected on microscope slides and stained with an appropriate agent. (b) Sections of normal (top) and cancerous (adenocarcinoma, bottom) human colon stained with H&E stain. Notice the disorganization of the cells in the cancer tissue. visually (Figure 4-11b). If an enzyme catalyzes a reaction that produces a colored or otherwise visible precipitate from a colorless precursor, that enzyme can be detected in cell sections by their colored reaction products. Such staining techniques, although once quite common, have been largely replaced by other techniques for visualizing particular proteins, as we discuss next.

## Fluorescence Microscopy Can Localize and Quantify Specific Molecules in Live Cells

Perhaps the most versatile and powerful technique for localizing molecules within a cell by light microscopy is **fluorescent staining** of cells and observation by *fluorescence microscopy*. A chemical is said to be *fluorescent* if it absorbs light at one wavelength (the excitation wavelength) and emits light (fluoresces) at a specific longer wavelength. Modern microscopes used for observing fluorescent samples are configured to pass the excitation light through the objective lens into the sample and then selectively observe the emitted fluorescent light coming back through the objective lens from the sample. This is achieved by reflecting the excitation light with a special type of filter, called a dichroic mirror, into the sample and allowing the light emitted at the longer wavelength to pass through to the observer (see Figure 4-9d). Here we discuss several ways in which fluorescence microscopy can be used to examine specific molecules in cells.

## Intracellular Ion Concentrations Can Be Determined with Ion-Sensitive Fluorescent Dyes

The concentration of  $\text{Ca}^{2+}$  or  $\text{H}^{+}$  within live cells can be measured with the aid of fluorescent dyes, or *fluorochromes*, whose fluorescence depends on the concentration of these ions. As discussed in later chapters, intracellular  $\text{Ca}^{2+}$  and  $\text{H}^{+}$  concentrations have pronounced effects on many cellular processes. For instance, many hormones and other stimuli cause a rise in cytosolic  $\text{Ca}^{2+}$  from the resting level of about  $10^{-7}$  M to  $10^{-6}$  M, which induces various cellular responses such as the contraction of muscle.

The fluorochrome *fura-2*, which is sensitive to  $\text{Ca}^{2+}$ , contains five carboxylate groups that form ester linkages with ethanol. The resulting fura-2 ester is lipophilic and can diffuse from the medium across the plasma membrane into cells. Within the cytosol, esterases hydrolyze the fura-2 ester, yielding fura-2, whose free carboxylate groups render the molecule nonlipophilic and thus unable to cross cellular membranes, so it remains in the cytosol. Inside cells, each fura-2 molecule can bind a single  $\text{Ca}^{2+}$  ion, but no other cellular cation. This binding, which is proportional to the cytosolic  $\text{Ca}^{2+}$  concentration over a certain range, increases the fluorescence of fura-2 at one particular wavelength. At a second wavelength, the fluorescence of fura-2 is the same whether or not  $\text{Ca}^{2+}$  is bound and thus provides a measure of the total amount of fura-2 in a region of the cell. By examining cells continuously in the fluorescence microscope and measuring rapid changes in the ratio of fura-2 fluorescence

**EXPERIMENTAL FIGURE 4-12** Fura-2, a  $\text{Ca}^{2+}$ -sensitive fluorochrome, can be used to monitor the relative concentrations of cytosolic  $\text{Ca}^{2+}$  in different regions of live cells. (Left) In a moving leukocyte, a  $\text{Ca}^{2+}$  gradient is established. The highest concentrations (green) are at the rear of the cell, where cortical contractions take place, and the lowest concentrations (blue) are at the cell front, where actin undergoes polymerization. (Right) When a pipette filled with chemotactic molecules placed to the side of the cell induces the cell to turn, the  $\text{Ca}^{2+}$  concentration momentarily increases throughout the cytoplasm, and a new gradient is established. The gradient is oriented such that the region of lowest  $\text{Ca}^{2+}$  (blue) lies in the direction that the cell will turn, whereas a region of high  $\text{Ca}^{2+}$  (yellow) always forms at the site that will become the rear of the cell. [From R. A. Brundage et al., 1991, *Science* **254**:703; courtesy of F. Fay.]

at the two wavelengths, one can quantify rapid changes in the fraction of fura-2 that has bound a  $\text{Ca}^{2+}$  ion, and thus in the concentration of cytosolic  $\text{Ca}^{2+}$  (Figure 4-12).

Fluorescent dyes (e.g., SNARF-1) that are sensitive to  $\text{H}^+$  concentrations can be used similarly to monitor the cytosolic pH of live cells. Other useful probes consist of a fluorochrome linked to a weak base that is only partially protonated at neutral pH and thus can freely permeate cellular membranes. In acidic organelles, however, these probes become protonated; because the protonated probes cannot recross the organelle membrane, they accumulate in the lumen at concentrations much greater than in the cytosol. Thus this type of fluorescent dye can be used to specifically stain particular organelles in live cells (Figure 4-13).

### Immunofluorescence Microscopy Can Detect Specific Proteins in Fixed Cells

The common chemical dyes mentioned above stain nucleic acids or broad classes of proteins, but it is much more informative to detect the presence and location of specific proteins. *Immunofluorescence microscopy*, the most widely used method of detecting specific proteins, uses an antibody to which a fluorescent dye has been covalently attached. To use this method, one must first generate antibodies to the specific protein of interest. As discussed briefly in Section 4.1 and in detail in Chapter 23, as part of the response to infection, the vertebrate immune system generates proteins called antibodies that bind specifically to the infectious agent. Cell

biologists have made use of this immunological response to generate antibodies to specific proteins. Consider you have purified protein X and then inject it into an experimental animal so that it responds to the protein as a foreign molecule. Over a period of weeks, the animal will mount an immune response and make antibodies to protein X (the “antigen”). If you collect the blood from the animal, it will have antibodies to protein X mixed in with antibodies to many other different antigens, together with all the other blood proteins. You can now covalently bind protein X to a resin and, using affinity chromatography, bind and selectively retain just those antibodies specific to protein X. The antibodies can be eluted from the resin, and now you have a reagent that binds specifically to protein X. This approach generates *polyclonal antibodies* since many different cells in the animal have contributed the antibodies, and the antibodies are likely to bind to many different epitopes on protein X. Alternatively, as we described earlier in this chapter, it is possible to generate a clonal cell line that secretes antibodies to a specific epitope on protein X; these are called *monoclonal antibodies*.

To use either type of antibody to localize a protein, the cells or tissue must first be fixed to ensure that all components remain in place, and the cell must be permeabilized to allow entry of the antibody, which is commonly done by incubating the cells with a non-ionic detergent or by

**EXPERIMENTAL FIGURE 4-13** Location of lysosomes and mitochondria in a cultured living bovine pulmonary artery endothelial cell. The cell was stained with a green-fluorescing dye that is specifically bound to mitochondria and a red-fluorescing dye that is specifically incorporated into lysosomes. The image was sharpened using a deconvolution computer program discussed later in the chapter. N, nucleus. [© 2015 Thermo Fisher Scientific, Inc. Used under permission.]

extracting the lipids with an organic solvent. In one version of immunofluorescence microscopy, the antibody is covalently linked to a fluorochrome. Classically used fluorochromes include rhodamine and Texas red, which emit red light; Cy3, which emits orange light; and fluorescein, which emits green light; but newer and more photostable fluorochromes, with emission wavelengths from blue to far-red, have now been developed. When a fluorochrome-antibody complex is added to a permeabilized cell or tissue section, the complex will bind to the corresponding antigen, then light up when illuminated at the excitation wavelength. Staining a specimen with different dyes that fluoresce at different wavelengths allows multiple proteins as well as DNA to be localized within the same cell (see the chapter-opening figure).

The most commonly used variation of this technique is called *indirect immunofluorescence microscopy* because the antibody specific to the protein of interest is detected indirectly. In this technique, an unlabeled monoclonal or polyclonal antibody is applied to the specimen, followed by a second, fluorochrome-tagged antibody that binds to the constant (Fc) segment of the first antibody. For example, a “secondary” antibody can be generated by immunizing a goat with the Fc segment that is common to all rabbit IgG antibodies; when coupled to a fluorochrome, this second antibody preparation (called “goat anti-rabbit”) will detect any rabbit antibody used to stain a tissue or cell (Figure 4-14). Because several

goat anti-rabbit antibody molecules can bind to a single rabbit antibody molecule in a specimen, the fluorescence is generally much brighter than if a single fluorochrome-tagged antibody were used. This approach is often extended to do *double-label fluorescence microscopy*, in which two proteins can be visualized simultaneously. For example, two proteins can be visualized by indirect immunofluorescence microscopy using primary antibodies made in different animals (e.g., rabbit and chicken) and secondary antibodies (e.g., goat–anti-rabbit and sheep–anti-chicken) labeled with different fluorochromes. In another variation, one protein can be visualized by indirect immunofluorescence microscopy and the second protein by a dye that specifically binds to it. Once the individual images are taken on the fluorescence microscope, they can be merged electronically (Figure 4-15).

In another widely used version of this technology, molecular genetic techniques are used to make a cDNA encoding a recombinant protein to which is fused a short sequence of amino acids called an *epitope tag*. When expressed in cells, this cDNA will generate the protein linked to the specific tag. Two commonly used epitope tags are FLAG, which encodes the amino acid sequence DYKDDDDK (single-letter amino acid code), and myc, which encodes the sequence EQKLI-SEEDL. Commercial fluorochrome-coupled monoclonal antibodies to the FLAG or myc epitopes can then be used to detect the recombinant protein in the cell. In an extension of this technology to allow the simultaneous visualization

**FIGURE 4-14 A specific protein can be localized in fixed tissue sections by indirect immunofluorescence microscopy.** (a) To localize a protein by immunofluorescence microscopy, a tissue section, or sample of cells, must be chemically fixed and made permeable to antibodies (step **1**). The sample is then incubated with a primary antibody that binds specifically to the antigen of interest, and unbound antibody is then removed by washing (step **2**). The sample is next incubated with a fluorochrome-labeled secondary antibody that specifically binds to the primary antibody, and again, excess secondary antibody is removed by washing (step **3**). The sample is then mounted in specialized mounting

medium and examined in a fluorescence microscope (step **4**). (b) In this example, a section of the rat intestinal wall was stained with Evans blue, which generates a nonspecific red fluorescence, and GLUT2, a glucose transport protein, was localized by indirect immunofluorescence microscopy. GLUT2 (yellow) is seen to be present in the basal and lateral sides of the intestinal cells, but is absent from the brush border, composed of closely packed microvilli on the apical surface facing the intestinal lumen. Capillaries run through the lamina propria, a loose connective tissue beneath the epithelial layer. [Part (b) from B. Thorens et al., 1990, *Am. J. Physiol.* **259**:C279; courtesy of B. Thorens.]

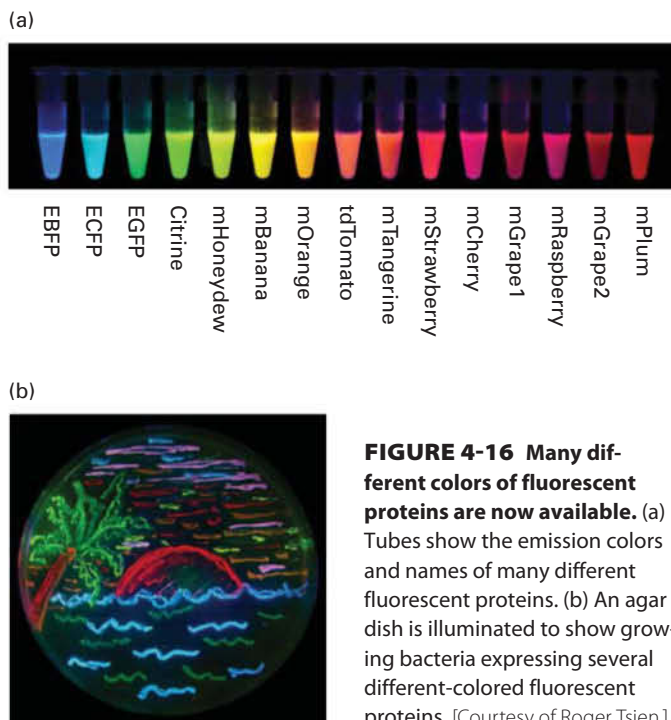

**EXPERIMENTAL FIGURE 4-15 Double-label fluorescence microscopy can visualize the relative distributions of two proteins.** In double-label fluorescence microscopy, each protein must be labeled with a different fluorochrome. (a) A cultured cell was fixed and permeabilized and then incubated with Rhodamine-labeled phalloidin, a reagent that specifically binds to filamentous actin. It was also incubated with rabbit antibodies to tubulin, the major component of microtubules, followed by a fluorescein-labeled secondary goat-anti-rabbit antibody. (b) The upper panels show the fluorescein-stained tubulin (*left*) and Rhodamine-stained actin (*right*), and the lower panel shows the electronically merged images. [Part (b) courtesy of A. Bretscher.]

of two proteins, one protein can be tagged with FLAG and a different protein with myc. Each tagged protein is then visualized with a different color, for example, with an Alexa-488-labeled antibody (emitting green light) to the myc epitope and an Alexa-568-labeled antibody (emitting red light) to the FLAG epitope.

## Tagging with Fluorescent Proteins Allows the Visualization of Specific Proteins in Live Cells

The jellyfish *Aequorea victoria* expresses a naturally fluorescent protein, called *green fluorescent protein* (GFP, ~27 kDa). GFP contains a serine, tyrosine, and glycine sequence whose side chains spontaneously cyclize to form a green-fluorescing fluorochrome when illuminated with blue light. Using recombinant DNA technology, it is possible to make a DNA construct in which the coding sequence of GFP is fused to the coding sequence of a protein of interest. When this construct is introduced into and expressed in cells, a GFP-“tagged” protein is made in which the protein of interest is covalently linked to GFP as part of the same polypeptide. Although GFP is a medium-sized protein, the function of the protein of interest is often not changed by fusing it to GFP. This technique allows one to visualize GFP—and hence the protein of interest. One can not only see the location of the GFP-tagged protein immediately, but can also view its distribution in a live cell over time and thereby assess its dynamics or track its localization following various cell treatments. The simple idea of tagging specific proteins with GFP has revolutionized cell biology and has led to the development of many different fluorescent proteins (Figure 4-16). Use of this colorful variety of fluorescent proteins allows one to visualize two

**FIGURE 4-16 Many different colors of fluorescent proteins are now available.** (a) Tubes show the emission colors and names of many different fluorescent proteins. (b) An agar dish is illuminated to show growing bacteria expressing several different-colored fluorescent proteins. [Courtesy of Roger Tsien.]

or more proteins simultaneously if they are each tagged with a different-colored fluorescent protein. We describe additional techniques that exploit fluorescent proteins in the following sections.

### Deconvolution and Confocal Microscopy Enhance Visualization of Three-Dimensional Fluorescent Objects

Conventional fluorescence microscopy has two major limitations. First, the fluorescent light emitted by a sample comes not only from the plane of focus, but also from molecules above and below it; thus the observer sees a blurred image caused by the superposition of fluorescent images from molecules at many depths in the cell. The blurring effect makes it difficult to determine the actual spatial arrangements. Second, to visualize thick specimens, consecutive (serial) images at various depths throughout the sample must be collected and then aligned to reconstruct structures in the original thick tissue. Two general approaches have been developed to obtain high-resolution three-dimensional information. Both of these methods require that the image be collected electronically so that it can then be computationally manipulated as necessary.

The first approach, called *deconvolution microscopy*, uses computational methods to remove fluorescence contributed by out-of-focus parts of the sample. Consider a three-dimensional sample in which images from three different focal planes are recorded. Since the whole sample is illuminated, the image from plane 2 will contain out-of-focus fluorescence from planes 1 and 3. If we knew exactly how out-of-focus fluorescence from planes 1 and 3 contributed to the light collected in plane 2, we could computationally remove it. To obtain this information for a particular microscope, we can make a series of images of focal planes from a test slide containing tiny fluorescent beads. Each bead represents a pinpoint of light that becomes a blurred object outside its focal plane; from these images we can determine a *point spread function* that enables us to calculate the distribution of fluorescent point sources that contributed to the “blur” when out of focus. Once we have calibrated the microscope in this manner, the experimental series of images can be computationally deconvolved. Microscopes with automated stages to collect the images, and associated software programs to deconvolve the images, are available commercially. Images restored by deconvolution display impressive detail without any blurring, as illustrated in Figure 4-17.

The second approach to obtaining better three-dimensional information is called *confocal microscopy* because it uses optical methods to obtain images from a specific focal plane and exclude light from other planes. Confocal microscopes collect a series of images focused through the vertical depth of the sample, from which an accurate three-dimensional representation can be computationally generated. Two types of confocal microscopes are in common use today, a *point-scanning* confocal

(a)

(b)

**EXPERIMENTAL FIGURE 4-17 Deconvolution fluorescence microscopy yields high-resolution optical sections that can be reconstructed to create one three-dimensional image.** A macrophage cell was stained with fluorochrome-labeled reagents specific for DNA (blue), microtubules (green), and actin microfilaments (red). The series of fluorescent images obtained at consecutive focal planes (optical sections) through the cell were recombined in three dimensions. (a) In this three-dimensional reconstruction of the raw images, the DNA, microtubules, and actin appear as diffuse zones in the cell. (b) After application of the deconvolution algorithm to the images, the fibrillar organization of microtubules and the localization of actin to adhesions are readily visible in the reconstruction. [Courtesy of James Evans, PhenoVista Biosciences.]

microscope (also known as a *laser-scanning confocal microscope*, or *LSCM*) and a *spinning disk* confocal microscope. The idea behind each microscope is to both illuminate and

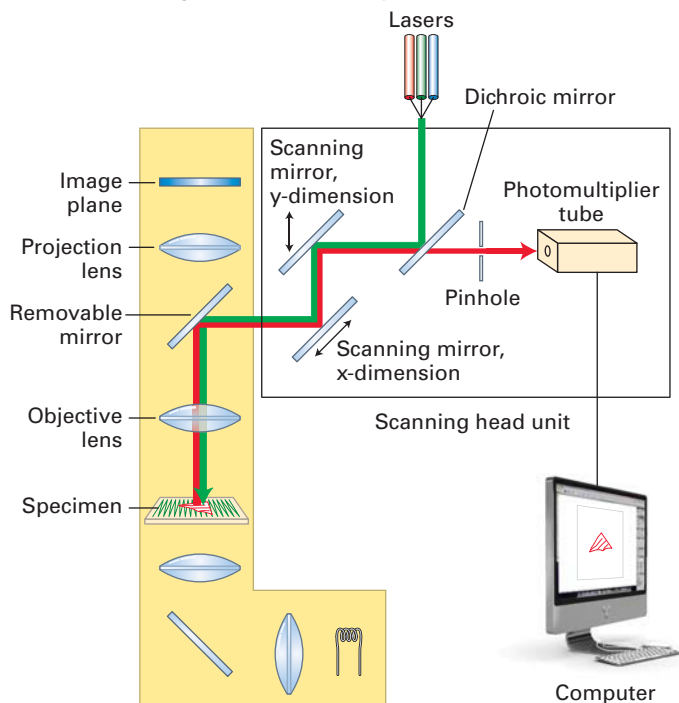

collect emitted fluorescent light from just one small area of a focal plane at a time in such a way that out-of-focus light is excluded. This can be achieved by collecting the emitted light through a pinhole before it reaches the detector—light from the illuminated focal plane passes through, whereas light from other focal planes is largely excluded. The illuminated area is then moved across the whole focal plane to build up the image electronically. The two types of microscopes differ in how they cover the image. The point-scanning microscope uses a point laser light source at the excitation wavelength to rapidly scan the focal plane in a raster pattern, collects the emitted fluorescence in a photomultiplier tube, and thereby builds up an image (Figure 4-18a). It can then take a series of images at different depths in the sample to generate a three-dimensional reconstruction. A point-scanning confocal microscope can provide exceptionally high-resolution images in both two and three dimensions (Figure 4-19), although it has two minor limitations. First, it can take significant time to

scan each focal plane, so if a very dynamic process is being imaged, the microscope may not be able to collect images fast enough to follow the dynamics. Second, it illuminates each spot with intense laser light, which can bleach the fluorochrome being imaged and damage live cells by phototoxicity, thereby limiting the number of images that can be collected.

The spinning disk microscope circumvents these two problems (Figure 4-18b). The excitation light from a laser is spread out and illuminates a small part of a disk spinning at high speed; for example, at 3000 rpm. The disk in fact consists of two linked disks: one with 20,000 lenses that precisely focuses the laser light on 20,000 pinholes of the second disk. The pinholes are arranged in such a way that they completely scan the focal plane of the sample several times with each turn of the disk. The emitted fluorescent light returns through the pinholes of the second disk and is reflected by a dichroic mirror and focused onto a highly sensitive digital camera. In this way, the sample is scanned

(a) Point-scanning confocal microscope

(b) Spinning disk confocal microscope

**FIGURE 4-18 Light paths for two types of confocal microscopy.** Both types of microscopy are assembled around a conventional fluorescence microscope (yellow shading). (a) Light path in a point-scanning confocal microscope. A single-wavelength point of light from an appropriate laser is reflected off a dichroic mirror and bounces off two scanning mirrors and from there passes through the objective lens to illuminate a spot in the specimen. The scanning mirrors rock back and forth in such a way that the light scans the specimen in a raster fashion (see green lines in the specimen). The fluorescence emitted by the specimen passes back through the objective lens and is bounced off the scanning mirrors onto the dichroic mirror. This allows the light to pass through toward the pinhole. This pinhole excludes light from out-of-focus focal planes, so the light reaching the photomultiplier tube

comes almost exclusively from the illuminated spot in the focal plane. A computer then takes these signals and reconstructs the image. (b) Light path in a spinning disk confocal microscope. Here, instead of using two scanning mirrors, the beam from the laser is spread to illuminate pinholes on the coupled spinning disks, the first consisting of micro-lenses to focus the light on pinholes in the second disk. The excitation light passes through the objective lens to provide point illumination of a number of spots in the specimen. The fluorescence emitted passes back through the objective lens and through the holes in the spinning disk, and is then bounced off a dichroic mirror into a sensitive digital camera. The pinholes in the disk are arranged so that as it spins, it rapidly illuminates all parts of the specimen several times. As the disk spins as fast as 3000 rpm, very dynamic events in live cells can be recorded.

(a) Conventional fluorescence microscopy

**FIGURE 4-19 Confocal microscopy produces an in-focus optical section through thick cells.** A mitotic fertilized egg from a sea urchin (*Psammechinus*) was lysed with a detergent, exposed to a tubulin antibody, and then exposed to a fluorescein-tagged antibody that binds to the anti-tubulin antibody. (a) When viewed by conventional fluorescence microscopy, the mitotic spindle is blurred. This blurring occurs

(b) Confocal fluorescence microscopy

because background fluorescence is detected from tubulin above and below the focal plane as depicted in the sketch. (b) The confocal microscopic image is sharp, particularly in the center of the mitotic spindle. In this case, fluorescence is detected only from molecules in the focal plane, generating a very thin optical section. [Micrographs © 1987 White et al., 1987, *The Journal of Cell Biology* **105**:41–48. doi10.1083/jcb.105.1.41]

in less than a millisecond, so the real-time location of a fluorescent reporter can be captured even if it is highly dynamic (Figure 4-20). A current limitation of the spinning disk microscope is that the pinhole size is generally fixed and has to be matched to the magnification of the objective lens, so it is generally configured for use with a 63 $\times$  or 100 $\times$  objective and is less useful for the lower-magnification imaging that might be required in tissue sections. However, within the last year, spinning disk head units have become available in which the pinhole size can be changed. Thus the point-scanning and spinning disk confocal microscopes have overlapping and complementary strengths.

### Two-Photon Excitation Microscopy Allows Imaging Deep into Tissue Samples

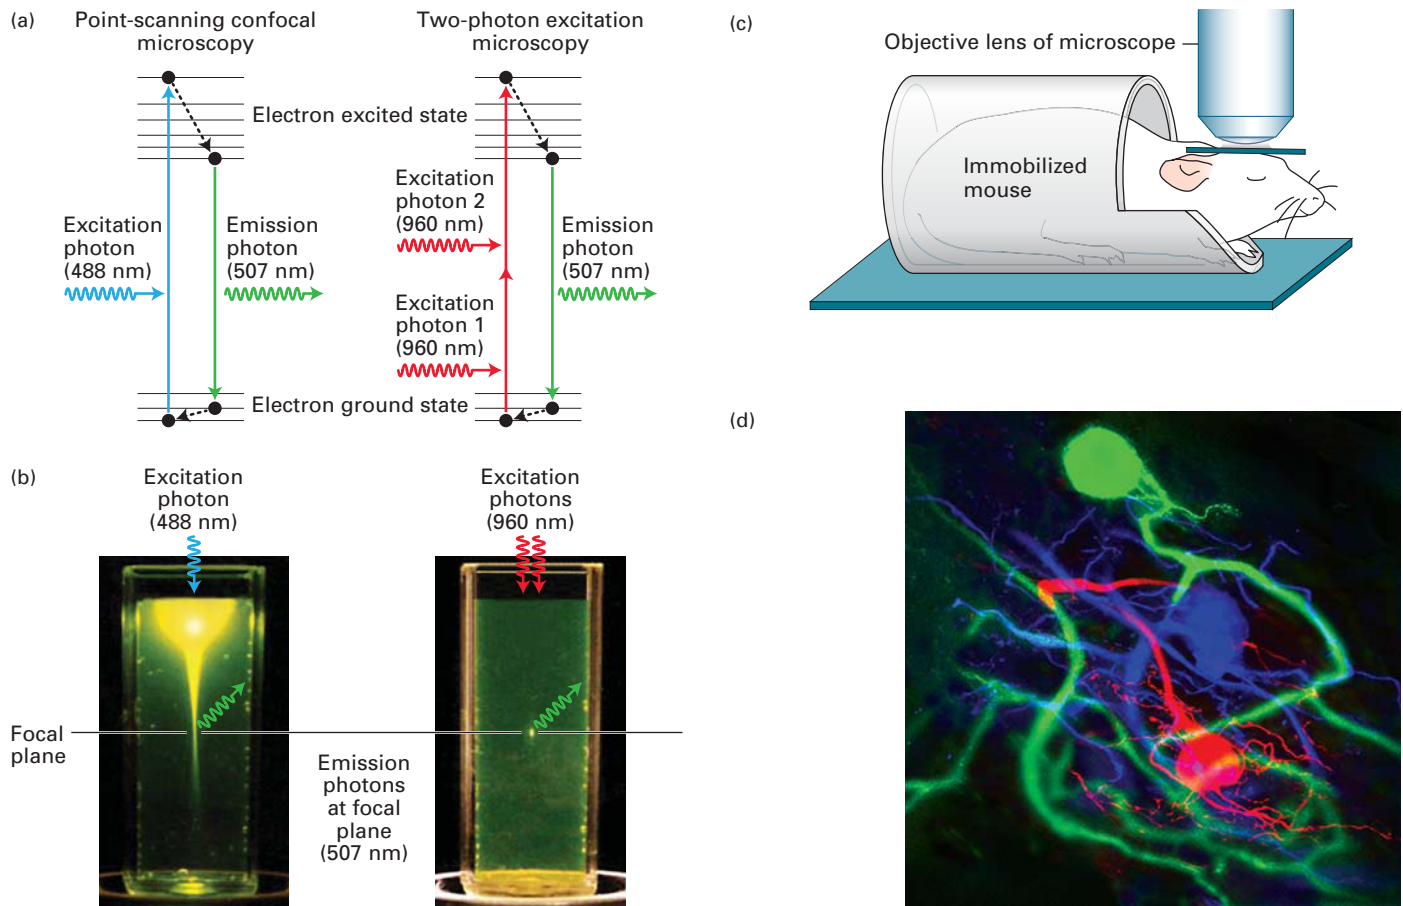

We have just seen how point-scanning confocal microscopy can help reduce fluorescence from out-of-focus planes. To achieve this, it focuses a cone of laser light on a spot that scans across the focal plane. Regions above and below the focal plane are also illuminated by this cone of light,

generating out-of-focus signal that must be removed by collecting the light through a pinhole. This intense cone of light can also lead to photobleaching (rendering the fluorescent protein inactive) or damage to the sample by phototoxicity. If the sample is very thin, these are not significant problems, but as the sample gets thicker, they become more relevant. To circumvent these problems, use was made of the finding that a fluorochrome can be excited either by a single photon—for example, at 488 nm—or by two photons of half the energy at 960 nm, either of which will generate the same emission wavelength (Figure 4-21a). Thus if a 960-nm cone of laser light is focused on a spot in one plane so that only at the focal point is there sufficient density of photons to excite the fluorochrome (Figure 4-21b), no out-of-focus signal will be obtained and less photobleaching or phototoxicity will occur. Because only fluorochromes in the focal plane are excited, two-photon microscopy can be used to explore much thicker samples, and there is no need for a pinhole to exclude out-of-focus light. However, very high laser intensity is required for two-photon excitation microscopy, as the two photons must arrive within about a femtosecond

**EXPERIMENTAL FIGURE 4-20** The dynamics of microtubules can be imaged on the spinning disk confocal microscope. Six

frames from a movie of GFP-tubulin in two rod-shaped cells of fission yeast are shown. [Courtesy of Fred Chang.]

**FIGURE 4-21 Two-photon excitation microscopy restricts illumination to the focal plane to allow deep penetration for intravital imaging.** (a) A diagram illustrating the different excitation methods used for conventional point-scanning confocal microscopy and for two-photon excitation microscopy. In the conventional system, absorption of a single photon of the appropriate wavelength (here at 488 nm, shown by the blue arrow) results in an electron jumping to the excited state. After undergoing vibrational relaxation (black dashed arrow), the electron falls back to the ground state with emission of one photon at a longer (lower-energy) wavelength, in this case 507 nm (green arrow). In two-photon excitation, when two photons of the appropriate wavelength (shown here at 960 nm, red arrows) arrive almost instantaneously, they can both be absorbed and induce the electron to jump to the excited state. As in the previous case, the electron undergoes some vibrational relaxation (black dashed arrow) and falls back to the

ground state with the emission of a photon (507 nm). (b) A cuvette of fluorescent material is illuminated with 488-nm light (left), as in conventional confocal microscopy, or with intense 960-nm light, as in two-photon microscopy. Notice that the conventional system produces a bright cone of excitation outside the focal plane, whereas two-photon excitation illuminates just one spot in the focal plane. (c) Because two-photon microscopy does not excite fluorochromes outside the plane of focus, it can be used to observe cells up to 1 mm deep within a living animal ("intravital imaging"). To image a living animal, it has to be immobilized on the microscope stage and access given for the objective lens to come close to the region being imaged. (d) An example of intravital imaging in which labeled neurons in a lobster were imaged. [Part (b) from W. Zipfel et al. 2003, Macmillan Publishers Ltd: *Nature Biotechnol.* **21**:1369, courtesy Warren R. Zipfel; part (d) unpublished data from Peter Kloppeburg and Warren R. Zipfel.]

of each other, which is achieved using rapid laser pulses. If individual cells in an animal express different color variants of fluorescent proteins, two-photon microscopy can be used to observe events in living animals (called *intravital imaging*) within about 1 mm of the surface (Figure 4-21c,d).

### TIRF Microscopy Provides Exceptional Imaging in One Focal Plane

The confocal microscopes we have just described provide amazing and informative images, but they are not perfect. Scientists continue to develop systems that are optimized

for special circumstances. Some experimental situations call for fluorescence imaging in a thin focal plane adjacent to a surface, where it would be optimal to minimize out-of-focus background. For example, confocal imaging is not ideal for exploring the details of proteins at adhesion sites between a cell and a coverslip, or for following the kinetics of assembly of microtubules attached to a coverslip. Both of these situations can be imaged at high sensitivity using *total internal reflection fluorescence (TIRF)* microscopy, in which only the portion of the specimen immediately adjacent to the coverslip is illuminated. In the most common configuration of TIRF microscopy, the

**EXPERIMENTAL FIGURE 4-22** Fluorescent samples in a restricted focal plane can be imaged by total internal reflection fluorescence (TIRF) microscopy. (a) In TIRF microscopy, only about 50–100 nm of the specimen adjacent to the coverslip is illuminated, so that fluorescent molecules in the rest of the sample are not excited. This limited illumination is achieved by directing the illuminating light at an angle at which it is reflected from the glass-water interface of the coverslip rather than passing through it. Whereas most of the light is reflected, it also generates a very small region of illumination called the evanescent wave (depicted in light green). (b) Immunofluorescence microscopy with tubulin antibody was used to visualize microtubules viewed by conventional fluorescence microscopy (*top*) and by TIRF (*middle*), and a merged image was created from the two views (*bottom*). The two images were collected and false-colored red and green so that the merge could highlight those microtubules that are close to the coverslip (green). [Part (b) © 2010 J. B. Manneville et al., 2010, *The Journal of Cell Biology* 191:585–598. doi: 10.1083/jcb.201002151.]

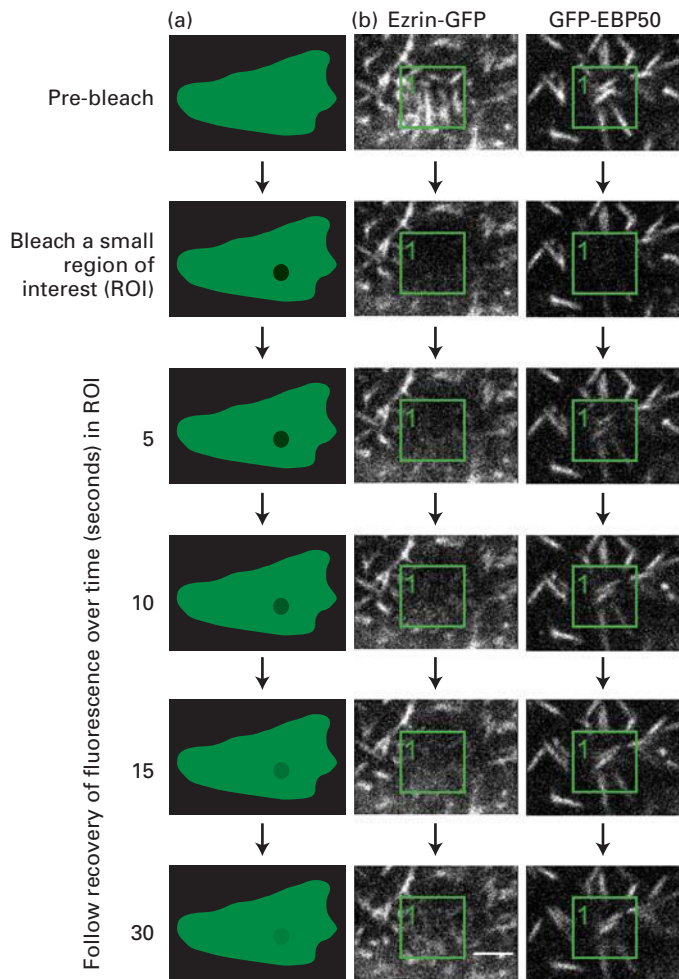

excitation light comes through the objective lens (Figure 4-22a). However, the angle at which the light arrives at the coverslip is adjusted so that the light is reflected off the coverslip and returns up through the objective. This generates a narrow band of light, called an *evanescent wave*, that illuminates only about 50–100 nm of the sample adjacent to the coverslip (2–4 times the thickness of a microtubule), with no illumination of the rest of the sample. Thus if you have a complex mixture of fluorescent structures in a specimen, the TIRF microscope will show you only those that are within 50–100 nm of the coverslip. TIRF has been exceptionally useful in identifying structures on the bottoms of cells grown on a coverslip (Figure 4-22b) and for measuring the kinetics of assembly and disassembly of structures such as microtubules and actin filaments (see Chapters 17 and 18).

### FRAP Reveals the Dynamics of Cellular Components

Live cell fluorescence imaging reveals the locations and bulk dynamics of populations of fluorescent molecules, but it doesn't tell you how dynamic individual molecules are. For example, if we see that a GFP-labeled protein forms a patch at the surface of a cell, does this represent a stable collection of fluorescent protein molecules or a dynamic equilibrium, with fluorescent proteins coming in and out of the patch? We can investigate this question by observing the dynamics of the molecules in the patch (Figure 4-23).

If we use a high-intensity light to permanently bleach the fluorochrome (e.g., GFP) in the patch, there will initially be no fluorescence coming from it, and it will look dark in the fluorescence microscope. However, if the components in the patch are in dynamic equilibrium with unbleached molecules elsewhere in the cell, the bleached molecules will be replaced by unbleached ones, and the fluorescence will begin to come back. The rate of fluorescence recovery is a measure of the dynamics of the molecules. This technique, known as *fluorescence recovery after photobleaching* (FRAP), has revealed how very dynamic many components of cells are. For example, it has been used to determine the diffusion coefficient of membrane proteins (see Figure 7-10) and the dynamics of specific components of the secretory pathway. In another approach to measuring the dynamics of tagged proteins, variants of fluorescent proteins have been developed that can be switched, using a laser of an appropriate wavelength, from emitting green light to emitting red light. In this way, the dynamics of the switched population of red-emitting molecules can be imaged in live cells.

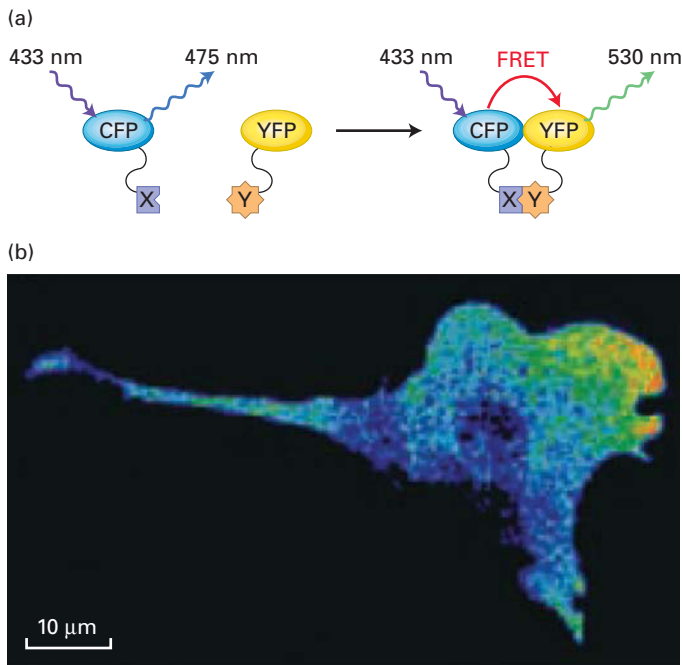

**EXPERIMENTAL FIGURE 4-23 Fluorescence recovery after photobleaching (FRAP) reveals the dynamics of molecules.** In a live cell, following the distribution of a GFP-labeled protein provides a view of the overall distribution of the protein, but it doesn't tell us how dynamic populations of individual molecules might be. (a) In FRAP, the GFP fluorochrome is bleached by a short burst of strong laser light focused on the region of interest (ROI). The light rapidly bleaches the molecules irreversibly, so they are not detected again. Restoration of fluorescence in the region tells us that unbleached molecules have moved into the ROI. (b) FRAP was used to determine the exchange rate of EBP50 and ezrin, two components of microvilli (seen as white lines), on the apical surface of epithelial cells. In cells expressing either GFP-EBP50 or ezrin-GFP, the GFP in a small region indicated by the green box was bleached, and recovery by exchange with unbleached protein was followed. The fluorescence of GFP-EBP50 returns very fast, indicating it has a fast exchange rate, whereas the fluorescence of ezrin-GFP returns slowly, indicating a slower exchange rate. (c) By quantifying the recovery, the dynamic properties of EBP50 and ezrin can be established. [Parts (b) and (c) © 2012 Garbett et al., 2012, *The Journal of Cell Biology* **198**:195–203. doi: 10.1083/jcb.201204008.]

## FRET Measures Distance Between Fluorochromes

Fluorescence microscopy can also be used to determine if two proteins interact *in vivo* by taking advantage of a phenomenon called *Förster resonance energy transfer* (FRET). This technique uses a pair of fluorescent proteins in which the emission wavelength of the first is close to the excitation wavelength of the second (Figure 4-24). For example, when cyan fluorescent protein (CFP) is excited with 433-nm light, it fluoresces and emits light at 475 nm. If yellow fluorescent protein (YFP) is close by, however, instead of emitting 475-nm light, CFP transfers energy to YFP by FRET, and YFP emits light at 530 nm. The efficiency of FRET is proportional to  $R^{-6}$ , where  $R$  is the distance between the fluorochromes; it is therefore very sensitive to small changes in distance and in practice is not detectable at distances greater than 10 nm. Thus, by illuminating an appropriately prepared sample with 433-nm light and observing at 530 nm, one can tell if proteins separately tagged with CFP and YFP are in very close proximity. For example, FRET sensors have been developed to determine where signaling between a small GTP-binding regulatory protein and its effector occurs in the cell (Figure 4-24b).

A clever application of FRET, called a *FRET biosensor*, can be used to sense local biochemical environments in live cells. The idea is to express a single polypeptide containing both CFP and YFP separated by a region that undergoes a conformational change when it senses a biochemical signal. In the absence of the signal, CFP and YFP are too far apart to undergo significant FRET. However, when the signal is detected, the conformational change brings CFP and YFP close enough together to generate FRET. A version of this technique can be used to measure the local activity of a specific protein kinase. In this case, between the CFP and YFP lies a region of polypeptide containing the substrate for the protein kinase—the *sensor domain*—and a domain that binds specifically to the phosphorylated substrate—the *ligand domain* (Figure 4-25a). When the sensor domain is phosphorylated by the kinase, the ligand domain binds to it and brings the CFP and YFP sufficiently close to undergo FRET. Since protein phosphorylation is a dynamic process, dephosphorylation of the sensor domain by the appropriate phosphatase will deactivate the FRET biosensor. Thus the FRET signal will reflect the regions of the cell where there is excess kinase over phosphatase activity. As an example, scientists have developed a FRET biosensor for protein kinase A activity, which is activated by

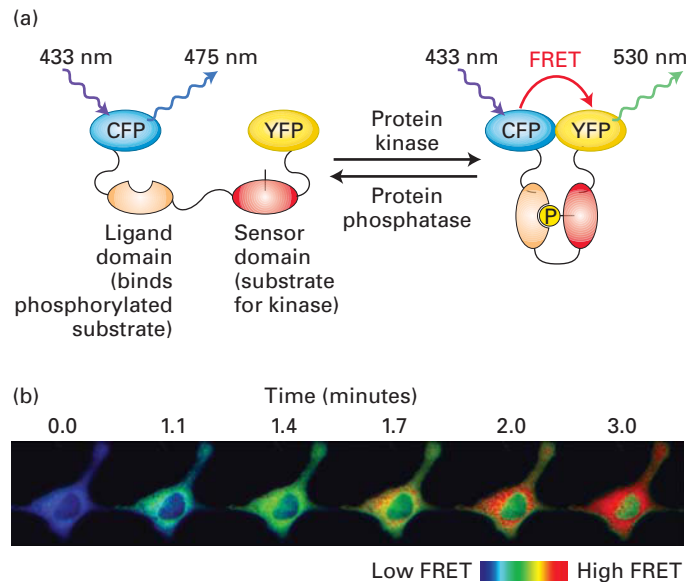

**FIGURE 4-24 Protein-protein interactions can be visualized by FRET.** The idea behind FRET is to use two different fluorescent proteins so that when one is excited, energy will be transferred to the second one by FRET, provided that they are sufficiently close. (a) In this example, cyan fluorescent protein (CFP) is fused to protein X, yellow fluorescent protein (YFP) is fused to protein Y, and both proteins are expressed in a live cell. If the cell is now illuminated with 433-nm light, the CFP will emit a fluorescent signal at 475 nm. If YFP is not close by (*left*), energy transfer will not occur, and no 530-nm light will be emitted. However, if protein X interacts with protein Y (*right*), it will bring CFP close to YFP, energy will be transferred to YFP by FRET, and YFP will emit light at 530 nm. (b) In this mouse fibroblast, FRET has been used to reveal that the interaction between an active regulatory protein (Rac) and its binding partner is localized to the front of the migrating cell. [Part (b) © 2003 R. B. Sekar, A. Periasamy, et al. 2003, *The Journal of Cell Biology* 160:629–633. doi: 10.1083/jcb.200210140.]

elevation of the signaling molecule cAMP (see Section 15.1). In cells expressing the protein kinase A biosensor, pharmacological elevation of cAMP induces rapid FRET (Figure 4-25b). Creative researchers are developing FRET biosensors to illuminate many different types of local environments; for example, FRET biosensors exist to measure the concentration and location of  $\text{Ca}^{2+}$  and the activation state of GTPase switch proteins (see Figure 3-32).

### Super-Resolution Microscopy Can Localize Proteins to Nanometer Accuracy

As we discussed earlier, the theoretical resolution limit of the fluorescence microscope is about  $0.2 \mu\text{m}$  (200 nm). Two new general approaches, collectively known as *super-resolution microscopy*, have been developed to get around this limitation. In the first type of approach, the illuminating light is patterned in such a way that higher-resolution images are obtained. In *structured illumination microscopy (SIM)*, the specimen is illuminated with a pattern of light and

**EXPERIMENTAL FIGURE 4-25 FRET biosensors can detect local biochemical environments.** (a) A FRET biosensor is a fusion protein containing two fluorescent proteins linked by a region sensitive to the environment under study. In this example, a protein construct consists of CFP linked to YFP by a region that contains a particular sequence that can be phosphorylated by a specific kinase (the “sensor domain”) and a region (the “ligand domain”) that binds the sensor domain when it is phosphorylated. In the absence of kinase activity, the two fluorescent proteins are too far apart to undergo FRET, whereas when locally phosphorylated by the active kinase, the sensor domain becomes phosphorylated, the ligand domain binds to it, and CFP and YFP are brought sufficiently close to undergo FRET. The sensor can also be deactivated when it encounters the appropriate phosphatase that removes the added phosphate. Thus the biosensor reports on the ratio of kinase to phosphatase activity in the local environment. (b) An example of the use of a FRET biosensor for protein kinase A, which is activated by elevation of cAMP. In this example, forskolin, a drug that induces the generation of cAMP, was added to cells at  $t = 0$  and the images collected at various times thereafter. Imaging shows both the rate of activation and localization of the active kinase. [Part (b) from J. Zhang et al., 2001, *Proc. Natl. Acad. Sci. USA* 98:14997–15005. © 2001 National Academy of Sciences, U.S.A.]

dark stripes, and several images are taken as the illuminating pattern is rotated to generate Moiré fringes. Computational analysis of the images gives a resolution of about 100 nm, twice that of a conventional confocal microscope, as can be seen in a micrograph of part of the nuclear envelope (Figure 4-26a). SIM is especially good for live cell imaging, as three-dimensional images can be collected every 4 seconds. In *stimulated emission depletion (STED)* microscopy, the sample is scanned just as in point-scanning microscopy, but with an important difference: the focused excitation laser point is surrounded by a donut-shaped “depletion beam,” which effectively makes the area excited much smaller. Since the computer records the precise position of the spot excited and can record the emission from it, it can build up an impressive image, optimally yielding a resolution of 30 nm, greatly enhancing the detail one can see, for example, in an image of actin fibers (Figure 4-26b).

Point-scanning image

PALM image

#### EXPERIMENTAL FIGURE 4-26 Super-resolution microscopy can generate light-microscope images with up to nanometer resolution.

The theoretical resolution of the light microscope can be circumvented by super-resolution microscopy. (a) In structured illumination microscopy (SIM), the sample is illuminated by a pattern of light and dark stripes and several images are taken as the illumination is rotated. This technique generates interference patterns that can be mathematically reconstructed to generate a higher-resolution image. The images on the right show the similar fields of the nucleus (lamin, green; DNA, magenta) imaged by conventional point-scanning confocal microscopy and by SIM, which improves resolution about twofold. (b) In stimulated emission depletion microscopy (STED), the sample is scanned as in point-scanning microscopy, but with a very small point of light, generated by an emission laser and confined by a donut-shaped stimulated emission depletion zone. The sample at

the right shows part of a cell stained for actin fibers after imaging by point-scanning microscopy and by STED. (c) In photoactivated localization microscopy (PALM), use is made of a variant of GFP that can be photoactivated by a wavelength different from its excitation wavelength. When a small number of GFP molecules are activated, and then excited, each will emit thousands of photons that can be collected. This generates a Gaussian curve centered on the location of the emitting GFP; the center provides the location of the GFP to nanometer accuracy. This process is reiterated hundreds of times to excite other GFP molecules, and a high-resolution image emerges. At the right, a confocal image of microtubules is compared with a corresponding super-resolution image in which the three-dimensional arrangement of the microtubules is color coded. [Micrographs in (a) from Schermelleh et al., 2008, *Science* **320**:1332–1336.; in (b) from Dr. Elise Stanley, Toronto Western Research Institute; (c) from B. Huang et al., 2008, *Science* **319**:810–813.]

The second general approach uses single-molecule detection and localization. To understand how this works, consider two fluorescent spots separated by 75 nm. When you try to image them, they each generate a Gaussian distribution of fluorescence, which overlap so much that they look like one spot. However, if you could image each spot individually and find the center of each Gaussian curve, you could “beat” the resolution limit and detect the two spots 75 nm apart. One way to do this, called *photoactivated localization microscopy* (PALM), relies on the ability of a variant of GFP to be photoactivated; that is, it can become fluorescent only after being activated by a specific wavelength of light, different from its excitation wavelength. Consider what happens when we activate just one such GFP molecule. When we then excite the sample, the one activated GFP emits many hundreds of photons, giving rise to a Gaussian distribution (Figure 4-26c). Although analysis of each photon does not tell us precisely where the GFP is, the center of the distribution can tell us where the GFP is located with nanometer accuracy. If we now activate another GFP, we can localize it individually with the same precision. In PALM, a small percentage of GFPs are activated and each localized with high precision, and then another set is activated and localized, and as additional cycles of activation and localization are

recorded, a high-resolution image emerges. For example, the three-dimensional distribution of microtubules can be seen with much greater clarity than with conventional fluorescence microscopy (see Figure 4-26c). These types of images can take significant time to generate, so their use on samples of live cells is so far restricted. Nevertheless, because of the tremendous benefits of super-resolution microscopy, enormous efforts are being made to improve its sensitivity, speed, and spatial resolution, and we can expect rapid progress in the development of these approaches.

## Light-Sheet Microscopy Can Rapidly Image Cells in Living Tissue

Most of the confocal imaging approaches we have discussed above illuminate and detect fluorochromes through the same objective lens; this ensures that the excitation of the sample and the imaging of the emitted fluorescence occur in the same focal plane. As a result of this approach, there are limitations on the depth of sample that can be imaged. Very recently, a new technology has been developed to get around this limitation. In *light-sheet microscopy*, the sample is illuminated from the side and then viewed in an orthogonal direction (Figure 4-27a). A focused laser beam sweeps back and forth across the sample,

**FIGURE 4-27 Light-sheet microscopy can image rapid events in living tissue.** (a) In light-sheet microscopy, a tissue sample is illuminated from the side by a focused laser beam that scans the sample to generate a sheet of light. The sample is observed in the orthogonal direction through the detection objective. To get a three-dimensional image, the illuminating and detection objectives are moved coordinately, taking images throughout the depth of the sample. (b) The  $\text{Ca}^{2+}$  biosensor known as GCaMP. This biosensor is made using recombinant DNA techniques to generate a polypeptide to which the N- and C-termini of GFP are fused, and the middle interrupted. On one side of the interruption is the sensor domain, consisting of the  $\text{Ca}^{2+}$ -binding protein calmodulin. On the other side is the ligand domain, consisting of a target sequence to which calmodulin will bind in the presence of  $\text{Ca}^{2+}$ . In the absence of  $\text{Ca}^{2+}$ , the GFP is not functional due to the interruption. In the presence of  $\text{Ca}^{2+}$ , calmodulin binds four  $\text{Ca}^{2+}$  ions and undergoes a conformational change that allows it to bind the ligand domain. This conformational change brings the two parts of GFP into close proximity so that the fluorescent protein is functional. (c)  $\text{Ca}^{2+}$  transients, false-colored red, in cells of the brain of a living zebrafish. [Part (c) from M. B. Ahrens et al., 2013, *Nature Methods* 10:413–420.]

illuminating a single plane. A detection objective, at right angles to the illuminated plane, then images the sample. To generate a three-dimensional image, all the planes in the sample have to be imaged. This is achieved by coordinately stepping the illuminating sheet and detection objective through the sample to generate a stack of images, which can then be assembled computationally into a three-dimensional rendering.

In one example of the use of this technology, scientists have imaged concentrations of  $\text{Ca}^{2+}$  in the cells of a living zebrafish brain. The neurons in the brain of the zebrafish were made to express a  $\text{Ca}^{2+}$  biosensor, called GCaMP, which is based on GFP that does not fluoresce in the absence of  $\text{Ca}^{2+}$ , but is designed to fluoresce in its presence (Figure 4-27b). This biosensor consists of GFP in which the N- and C-terminal domains are connected, but the middle of the protein is interrupted, and a  $\text{Ca}^{2+}$  sensor domain is attached to one end and a ligand domain to the other. Because the structure of GFP is interrupted, the protein no longer fluoresces when excited by the appropriate illuminating light. The sensor domain is derived from the small  $\text{Ca}^{2+}$ -binding protein calmodulin (see Figure 3-31), which changes its conformation when it binds four  $\text{Ca}^{2+}$  ions. The ligand domain is a target sequence to which calmodulin binds only when it is activated by binding  $\text{Ca}^{2+}$ . When active calmodulin binds the ligand domain, it changes the conformation of the interrupted GFP in such a way that it can now be excited and fluoresce. In this way, a fluorescent signal is reported whenever  $\text{Ca}^{2+}$  levels rise sufficiently to activate calmodulin. As we discuss in Chapter 22, when neurons communicate, part of this communication involves an elevation in  $\text{Ca}^{2+}$  levels. This neuronal communication can be nicely imaged by light-sheet microscopy *in vivo* in the brain of a zebrafish expressing the GCaMP biosensor (Figure 4-27c).

## KEY CONCEPTS OF SECTION 4.2

### Light Microscopy: Exploring Cell Structure and Visualizing Proteins Within Cells

- The resolution of the light microscope, about  $0.2\ \mu\text{m}$ , is limited by the wavelength of light.
- Differences in refractive index can be used to observe parts of single cells by employing phase-contrast and direct-interference-contrast microscopy.
- Tissues generally have to be fixed, sectioned, and stained for cells and subcellular structures to be observed.
- Fluorescence microscopy makes use of compounds that absorb light at one wavelength and emit it at a longer wavelength.
- Ion-sensitive fluorescent dyes can measure intracellular concentrations of ions, such as  $\text{Ca}^{2+}$ .
- Immunofluorescence microscopy makes use of antibodies to localize specific components in fixed and permeabilized cells.

- Indirect immunofluorescence microscopy uses an unlabeled primary antibody, followed by a fluorescently labeled secondary antibody that recognizes the primary one and allows it to be localized.
- Short sequences encoding epitope tags can be appended to protein-coding sequences to allow localization of the expressed protein using an antibody to the epitope tag.
- Green fluorescence protein (GFP) and its derivatives are naturally occurring fluorescent proteins.
- Fusing GFP to a protein of interest allows its localization and dynamics to be explored in a live cell.
- Deconvolution and confocal microscopy provide greatly improved clarity in fluorescent images by removing out-of-focus fluorescent light.
- Total internal reflection fluorescence (TIRF) microscopy allows fluorescent samples adjacent to a coverslip to be seen with great clarity.
- Fluorescence recovery after photobleaching (FRAP) allows the dynamics of a population of molecules to be analyzed.
- Förster resonance energy transfer (FRET) is a technique in which light energy is transferred from one fluorescent protein to another when the proteins are very close, thereby revealing when two molecules are close in the cell.
- Super-resolution microscopy allows for detailed fluorescent images at nanometer resolution.
- Light-sheet microscopy can provide fluorescent images of thick samples by illuminating the sample with a sheet of light from the side.

## 4.3 Electron Microscopy: High-Resolution Imaging

Electron microscopic imaging of biological samples, such as single proteins, organelles, cells, and tissues, offers a much higher resolution of ultrastructure than can be obtained by light microscopy. The short wavelength of electrons means that the limit of resolution for a transmission electron microscope is theoretically  $0.005\ \text{nm}$  (much less than the diameter of a single atom), or 40,000 times better than that of a light microscope and 2 million times better than that of the unaided human eye. However, the effective resolution of the transmission electron microscope in the study of biological systems is considerably less than this ideal. Under optimal conditions, a resolution of  $0.10\ \text{nm}$  can be obtained with transmission electron microscopes, about 2000 times better than with conventional light microscopes and at least 300 times better than with the current super-resolution microscopes.

The fundamental principles of electron microscopy are similar to those of light microscopy; the major difference is that in electron microscopes, electromagnetic lenses focus a high-velocity electron beam instead of the visible light used by

optical lenses. In the *transmission electron microscope* (TEM), electrons are emitted from a filament and accelerated in an electric field (Figure 4-28, *left*). A condenser lens focuses the electron beam onto the sample; objective and projector lenses focus the electrons that pass through the specimen and project them onto a viewing screen or other detector. Because atoms in air absorb electrons, the entire tube between the electron source and the detector is maintained under an ultrahigh vacuum. Thus living material cannot be imaged by electron microscopy.

In this section, we describe various approaches to viewing biological material by electron microscopy. The most widely used instrument is the transmission electron microscope, but also in common use is the *scanning electron microscope* (SEM), which provides complementary information, as we discuss at the end of this section (Figure 4-28, *right*).

**FIGURE 4-28** In electron microscopy, images are formed from electrons that pass through a specimen or are scattered from a metal-coated specimen. In a transmission electron microscope (TEM, *left*), electrons are extracted from a heated filament, accelerated by an electric field, and focused on the specimen by a magnetic condenser lens. Electrons that pass through the specimen are focused by a series of magnetic objective and projector lenses to form a magnified image of the specimen on a detector, which may be a fluorescent viewing screen, a photographic film, or a charged-couple-device (CCD) camera. In a scanning electron microscope (SEM), electrons are focused by condenser and objective lenses on a metal-coated specimen. Scanning coils move the beam across the specimen, and electrons scattered from the metal are collected by a photomultiplier tube detector. In both types of microscopes, because electrons are easily scattered by air molecules, the entire column is maintained at a very high vacuum.

## Single Molecules or Structures Can Be Imaged Using a Negative Stain or Metal Shadowing

It is common in biology to explore the detailed shapes of single macromolecules, such as proteins or nucleic acids, or of structures, such as viruses and the filaments that make up the cytoskeleton. It is relatively easy to view these objects in the transmission electron microscope, provided they are stained with a heavy metal that scatters the incident electrons. To prepare a sample, it is first absorbed to a 3-mm *electron microscope grid* (Figure 4-29a), which is

**FIGURE 4-29** Transmission electron microscopy of negatively stained samples reveals fine features. (a) Samples for transmission electron microscopy (TEM) are usually mounted on a small copper or gold grid. The grid is usually covered with a very thin film of plastic and carbon to which a sample can adhere. (b) The specimen is then incubated in a heavy metal, such as uranyl acetate, and excess stain is removed. (c) The sample excludes the stain, so when it is observed in the TEM, it is seen in negative outline. The example in (c) is a negative stain of rotaviruses. [Part (c) ISM/Phototake.]

coated with a thin film of plastic and carbon. The sample is then bathed in a solution of a heavy metal, such as uranyl acetate, and excess solution is removed (Figure 4-29b). As a result of this procedure, the uranyl acetate coats the grid, but is excluded from the regions where the sample has adhered. When we view the sample in the TEM, we see where the stain has been excluded, so the sample is said to be *negatively stained*. Because the stain can precisely reveal the topology of the sample, a high-resolution image can be obtained (Figure 4-29c).

Samples can also be prepared by *metal shadowing* (Figure 4-30). In this technique, the sample is absorbed to a small piece of mica, then coated with a thin film of platinum by evaporation of the metal, then dissolved with acid or bleach, leaving the platinum coating (known as a replica). The platinum coating can be generated from a fixed angle or at a low angle as the sample is rotated, in which case it is called *low-angle rotary shadowing*. When the replica is transferred to a grid and examined in the TEM, it provides information about the three-dimensional topology of the sample.

**FIGURE 4-30 Metal shadowing makes surface details on very small objects visible by transmission electron microscopy.** (a) The sample is spread on a mica surface and then dried in a vacuum evaporator (step **1**). The sample grid is coated with a thin film of a heavy metal, such as platinum or gold, evaporated from an electrically heated metal filament (step **2**). To stabilize the replica, the specimen is then coated with a carbon film evaporated from an overhead elec-

## Cells and Tissues Are Cut into Thin Sections for Viewing by Electron Microscopy

Single cells and pieces of tissue are too thick to be viewed directly in the standard transmission electron microscope. To overcome this problem, methods were developed to prepare and cut *thin sections* of cells and tissues. When these sections were examined in the electron microscope, the organization, beauty, and complexity of the cell interior was revealed and led to a revolution in cell biology—for the first time, new organelles and the first glimpses of the cytoskeleton were seen.

To prepare thin sections, it is necessary to chemically fix the sample, dehydrate it, impregnate it with a liquid plastic that hardens (similar to Plexiglas), and then cut sections of about 5 to 100 nm in thickness. For structures to be seen, the sample has to be stained with heavy metals such as uranium and lead salts, which can be done either before embedding in the plastic or after sections are cut. Examples of cells and tissues viewed by thin-section electron microscopy appear here and throughout this book (Figure 4-31). It is important

trode (step **3**). The biological material is then dissolved by acid and bleach (step **4**), and the remaining metal replica is viewed in a TEM. In electron micrographs of such preparations, the carbon-coated areas appear light—the reverse of micrographs of simple metal-stained preparations, in which the areas of heaviest metal staining appear the darkest. (b) A platinum-shadowed replica of poliovirus particles. [Part (b) Science Source]

Rough  
endoplasmic  
reticulum

**FIGURE 4-31** Example of a thin section viewed by transmission electron microscopy. Section through a pancreatic cell showing the extensive rough endoplasmic reticulum involved in the synthesis and secretion of digestive enzymes. [Keith R. Porter Archive, University of Maryland, Baltimore County.]

to realize that the images obtained represent just a thin slice through a cell, so to get a three-dimensional view, it is necessary to cut *serial sections* through the sample and reconstruct the sample from a series of sequential images (Figure 4-32).

### Immunoelectron Microscopy Localizes Proteins at the Ultrastructural Level

Just as immunofluorescence microscopy is used for localizing proteins at the light-microscope level, methods have been developed to use antibodies to localize proteins in thin sections at the electron microscope level. However, the harsh procedures used to prepare traditional thin sections—chemical fixation and embedding in plastic—can denature or modify the antigens so that they are no longer recognized by specific antibodies.

**FIGURE 4-32** Model of the Golgi complex based on three-dimensional reconstruction of electron microscopy images. Transport vesicles (white spheres) that have budded off the rough ER fuse with the *cis* membranes (light blue) of the Golgi complex. By mechanisms described in Chapter 14, proteins move from the *cis* region to the *medial* region and finally to the *trans* region of the Golgi complex. Eventually, vesicles bud off the *trans*-Golgi membranes (orange and red); some move to the cell surface and others move to lysosomes. The Golgi complex, like the rough endoplasmic reticulum, is especially prominent in secretory cells. [B. J. Marsh & K. E. Howell, 2002, *Nature Rev. Mol. Cell Biol.* **3**:789–795.]

Gentler methods, such as light fixation, sectioning of material after freezing at the temperature of liquid nitrogen, and finally incubation with antibody at room temperature, have been developed. To make the antibody visible in the electron microscope, it must be attached to an electron-dense marker. One way to do this is to use electron-dense gold particles coated with protein A, a bacterial protein that binds the Fc segment of all antibody molecules (Figure 4-33). Because the gold particles diffract incident electrons, they appear as dark spots.

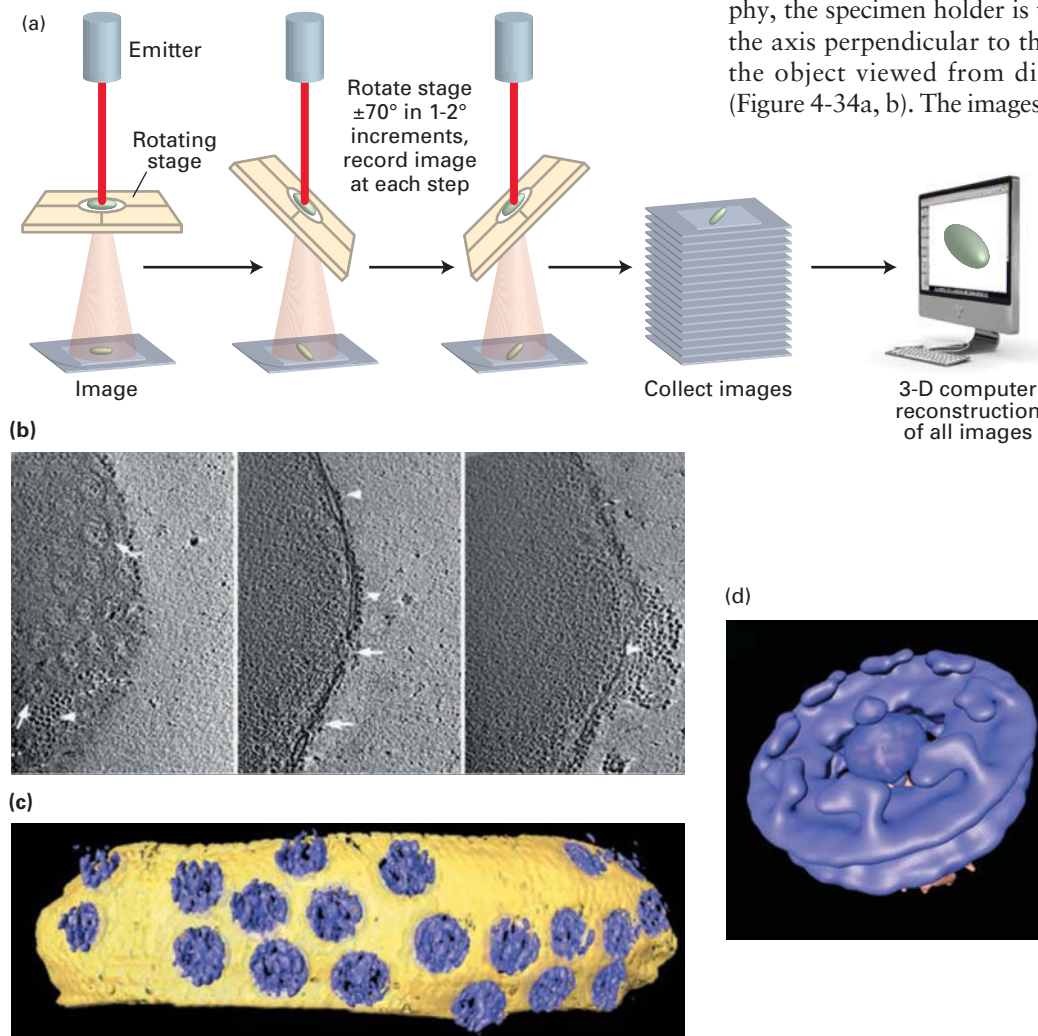

**FIGURE 4-33** Gold particles coated with protein A are used to detect an antibody-bound protein by transmission electron microscopy. (a) First, antibodies are allowed to interact with their specific antigen in a section of fixed tissue. Then the section is treated with electron-dense gold particles coated with protein A from the bacterium *S. aureus*. Binding of the bound protein A to the Fc domains of the antibody molecules makes the location of the target protein visible in the electron microscope. (b) HIV particle budding from an infected HeLa cell. A cryosection of the specimen was prepared and first incubated with an antibody to capsid protein, then with protein A-coated 5-nm gold particles to localize the internal capsid protein. The unoccupied sites in the protein A were inactivated, and the specimen was incubated with antibody to the membrane-bound Env protein, followed by protein A-coated 10-nm gold particles. The distinct localization of the 5-nm gold labeling the capsid protein and the 10-nm gold labeling the Env protein can be seen. Scale bar is 100 nm. [Courtesy of Annegret Pelchen-Matthews and Mark Marsh, MRC-Laboratory for Molecular Cell Biology, University College London, UK.]

## Cryoelectron Microscopy Allows Visualization of Specimens Without Fixation or Staining

Standard transmission electron microscopy cannot be used to study live cells, and the absence of water in samples causes macromolecules to become denatured and nonfunctional. However, hydrated, unfixed, and unstained biological specimens can be viewed directly in a transmission electron microscope if the samples are frozen. In *cryoelectron microscopy*, an aqueous suspension of a sample is applied to a grid in an extremely thin film, frozen in liquid nitrogen, and maintained in this state by means of a special mount. The frozen sample is then placed in the electron microscope. The very low temperature ( $-196^{\circ}\text{C}$ ) keeps water from evaporating,

even in a vacuum. Thus the sample can be observed in detail in its native, hydrated state without fixing or heavy metal staining. By computer-based averaging of hundreds of images, a three-dimensional model can be generated almost to atomic resolution. For example, this method has been used to generate models of ribosomes, the muscle calcium pump discussed in Chapter 11, and the three-dimensional structure of a poliovirus capsid (see Figure 5-43b).

An extension of this technique, *cryoelectron tomography*, allows researchers to determine the three-dimensional architecture of organelles or even whole cells embedded in ice; that is, in a state close to life. A single picture is a two-dimensional representation of a structure that lacks depth information. However, looking at the same structure from different angles gives us a three-dimensional perspective. In cryoelectron tomography, the specimen holder is tilted in small increments around the axis perpendicular to the electron beam; thus images of the object viewed from different directions are obtained (Figure 4-34a, b). The images are then merged computationally

**FIGURE 4-34 Structure of the nuclear pore complex (NPC) imaged by cryoelectron tomography.** (a) In cryoelectron tomography, a semicircular series of two-dimensional projection images is recorded from the three-dimensional specimen that is located at the center; the specimen is tilted while the electron optics and detector remain stationary. The three-dimensional structure is then computed from the collected two-dimensional images. (b) Isolated nuclei from the cellular slime mold *Dictyostelium discoideum* were quick-frozen in liquid nitrogen and maintained in this state as the sample was observed in the electron

microscope. The panel shows three sequential tilted images. Different orientations of NPCs (arrows) are shown in top view (*left and center*) and side view (*right*). Ribosomes connected to the outer nuclear membrane are visible, as is a patch of rough ER (arrowheads). (c) Computer-generated surface-rendered representation of a segment of the nuclear envelope membrane (yellow) studded with NPCs (blue). (d) By averaging the images of multiple nuclear pores, much more detail can be discerned. See S. Nickell et al., 2006, *Nature Rev. Mol. Cell Biol.* **7**:225. [Parts (b), (c), and (d) from M. Beck et al., 2004, *Science* **306**:1387.]

into a three-dimensional reconstruction termed a *tomogram* (Figure 4-34c, d). A disadvantage of cryoelectron tomography is that the samples must be relatively thin, about 200 nm; this is much thinner than the samples (200  $\mu\text{m}$  thick) that can be studied by confocal light microscopy.

### Scanning Electron Microscopy of Metal-Coated Specimens Reveals Surface Features

*Scanning electron microscopy (SEM)* allows investigators to view the surfaces of unsectioned metal-coated specimens. An intense electron beam inside the microscope scans rapidly over the sample. Molecules in the coating are excited and release secondary electrons that are focused onto a scintillation detector; the resulting signal is displayed on a cathode-ray tube much like a conventional television (see Figure 4-28, *right*). The resulting scanning electron micrograph has a three-dimensional appearance because the number of secondary electrons produced by any one point on the sample depends on the angle of the electron beam in relation to the surface (Figure 4-35). The resolving power of scanning electron microscopes, which is limited by the thickness of the metal coating, is only about 10 nm, much less than that of transmission instruments.

#### KEY CONCEPTS OF SECTION 4.3

##### Electron Microscopy: High-Resolution Imaging

- Electron microscopy provides very high-resolution images because of the short wavelength of the high-energy electrons used to image the sample.

- Simple specimens, such as proteins or viruses, can be negatively stained or shadowed with heavy metals for examination in a transmission electron microscope (TEM).
- Thicker sections generally must be fixed, dehydrated, embedded in plastic, sectioned, and then stained with electron-dense heavy metals before viewing by TEM.
- Specific proteins can be localized by TEM by employing specific antibodies associated with a heavy metal marker, such as small gold particles.
- Cryoelectron microscopy allows examination of hydrated, unfixed, and unstained biological specimens in the TEM by maintaining them at very low temperatures.
- Scanning electron microscopy (SEM) of metal-shadowed material reveals the surface features of specimens.

### 4.4 Isolation of Cell Organelles

The examination of cells by light and electron microscopy led to the appreciation that eukaryotic cells contain a common set of organelles, introduced in Chapter 1 (see Figure 1-12a). However, observing organelles and documenting their detailed structure by microscopy does not clearly reveal the roles they play and how they work. For this, it is necessary to isolate organelles in their native state and identify and dissect the function of each component. For this reason, methods to isolate and characterize organelles were developed in parallel with advances in microscopy. Lysosomes, for example, are organelles in which biological molecules are degraded, as described in Chapter 1. Lysosomes had been seen by microscopy, but their function was discovered only after a method was developed to isolate

**FIGURE 4-35** Scanning electron microscopy (SEM) produces a three-dimensional image of the surface of an unsectioned specimen. Seen here is an SEM image of cells of the trachea. In the middle is a goblet cell, which secretes mucus. On either side of the goblet cell are epithelial cells with abundant cilia on their apical surfaces. [Steve Gschmeissner/Science Source.]

them. When a method is developed to purify a type of organelle, it is possible to begin to catalogue all of its components and probe the function of each one. In another example, electron microscopy revealed that some ribosomes are associated with the endoplasmic reticulum, suggesting that the ER is a site of protein synthesis. We now know that proteins to be secreted from the cell are made by these ribosomes, and that the nascent secretory protein is translocated across the membrane into the lumen of the endoplasmic reticulum. As we describe in Chapter 13, understanding the mechanism by which this occurs depended on the isolation of the endoplasmic reticulum and the development of *in vitro* assays for the synthesis and translocation of secretory proteins. Thus, before one can begin to fully understand organelles, biochemical assays need to be established to probe the functions of each component, with the eventual goal of reconstituting functional organelles from purified components.

Most organelles are enclosed in a lipid bilayer and perform a specific function. Each type of organelle has a recognizable structure and contains a specific set of proteins to perform its function. Cell biologists use this fact to identify specific organelles. For example, as discussed in Chapter 12, most of the ATP in a cell is made by ATP synthase, which converts ADP to ATP in mitochondria, so ATP synthase is a good marker for mitochondria. As we will discuss below, the availability of specific markers for organelles has helped in the development of organelle purification.

In this section, we discuss methods that are used to open up cells for the purification of organelles. We end with recent advances in proteomics aimed at defining the complete protein inventories of organelles.

## Disruption of Cells Releases Their Organelles and Other Contents

The initial step in purifying subcellular structures is to release the cell's contents by rupturing the plasma membrane and the cell wall, if present. To do this, the cells are suspended in a solution of appropriate pH and salt content, usually isotonic sucrose (0.25 M) or a combination of salts similar in composition to those in the cell's interior. Many cells can then be broken by stirring the cell suspension in a high-speed blender or by exposing it to ultrahigh-frequency sound (*sonication*). Alternatively, plasma membranes can be sheared by special pressurized tissue homogenizers in which cells are forced through a very narrow space between a plunger and the wall of the vessel; the pressure of being forced between the vessel wall and the plunger ruptures the cell.

Recall that water flows into cells when they are placed in a hypotonic solution; that is, one with a lower concentration of ions and small molecules than is found inside the cell. This osmotic flow can be used to cause cells to swell, weakening the plasma membrane and facilitating its rupture. Generally the cell solution is best kept at 0 °C to preserve enzymes and other constituents after their release from the stabilizing forces of the cell.

Disrupting the cell produces a mix of suspended cellular components, the *homogenate*, from which the desired organelles can be retrieved. Because rat liver contains an abundance of a single cell type, this tissue has been used in many classic studies of cell organelles. However, the same isolation principles apply to virtually all cells and tissues, and modifications of these cell-fractionation techniques can be used to separate and purify any desired components.

## Centrifugation Can Separate Many Types of Organelles

In Chapter 3, we considered the principles of centrifugation and the uses of centrifugation techniques for separating proteins and nucleic acids. Similar approaches are used for separating and purifying various organelles, which differ in both size and density and thus undergo sedimentation at different rates.

Most cell-fractionation procedures begin with *differential centrifugation* of a filtered cell homogenate at increasingly higher speeds (Figure 4-36). After centrifugation at each speed for an appropriate time, the liquid that remains at the top of the vessel, called the *supernatant*, is poured off and centrifuged at higher speed. The pelleted fractions obtained by differential centrifugation generally contain a mixture of organelles, although nuclei and viral particles can sometimes be purified completely by this procedure.

An impure organelle fraction obtained by differential centrifugation can be further purified by *equilibrium density-gradient centrifugation*, which separates cellular components according to their density. After the fraction is resuspended, it is layered on top of a solution that contains a gradient of a dense non-ionic substance (e.g., sucrose or glycerol). The tube is centrifuged at a high speed (about 40,000 rpm) for several hours, allowing each particle to migrate to an equilibrium position where the density of the surrounding liquid is equal to the density of the particle (Figure 4-37). The different layers of the gradient are then recovered by pumping out the contents of the centrifuge tube through a narrow piece of tubing and collecting the fractions (see Classic Experiment 4-1).

Because each organelle has unique morphological features, the purity of organelle preparations can be assessed by examination in an electron microscope. Alternatively, organelle-specific marker molecules can be quantified. For example, the protein cytochrome *c* is present only in mitochondria, so the presence of this protein in a fraction of lysosomes would indicate its contamination by mitochondria. Similarly, catalase is present only in peroxisomes; acid phosphatase, only in lysosomes; and ribosomes, only in the rough endoplasmic reticulum or the cytosol.

## Organelle-Specific Antibodies Are Useful in Preparing Highly Purified Organelles

Cell fractions remaining after differential and equilibrium density-gradient centrifugation usually contain more than

**FIGURE 4-36 Differential centrifugation is a common first step in fractionating a cell homogenate.** The homogenate that results from disrupting cells is usually filtered to remove unbroken cells and then centrifuged at a fairly low speed to selectively pellet the nuclei—the largest organelle. The undeposited material (the supernatant) is next centrifuged at a higher speed to sediment the mitochondria, chloroplasts, lysosomes, and peroxisomes. Subsequent centrifugation in an ultracentrifuge at 100,000g for 60 minutes results in deposition of the plasma membrane, fragments of the endoplasmic reticulum, and large polyribosomes. The recovery of ribosomal subunits, small polyribosomes, and particles such as complexes of enzymes requires additional centrifugation at still higher speeds. Only the cytosol—the soluble aqueous part of the cytoplasm—remains in the supernatant after centrifugation at 300,000g for 2 hours.

**FIGURE 4-37 A mixed-organelle fraction can be further separated by equilibrium density-gradient centrifugation.** In this example, using rat liver, material in the pellet from centrifugation at 15,000g (see Figure 4-36) is resuspended and layered on a gradient of increasingly dense sucrose solutions in a centrifuge tube. During centrifugation for several hours, each organelle migrates to its appropriate equilibrium density and remains there. To obtain a good separation of lysosomes from mitochondria, the liver is perfused with a solution containing a small amount of detergent before the tissue is disrupted. During this perfusion period, detergent is taken into the cells by endocytosis and transferred to the lysosomes, making them less dense than they would normally be and permitting a “clean” separation of lysosomes from mitochondria.

one type of organelle. Monoclonal antibodies to various organelle-specific membrane proteins are a powerful tool for further purifying such fractions. One example is the purification of vesicles whose outer surface is covered with the protein **clathrin**; these coated vesicles are derived from coated pits at the plasma membrane during receptor-mediated endocytosis, a topic we will discuss in detail in Chapter 14. An antibody to clathrin, bound to a dead bacterial cell that expressed protein A on its surface, can selectively bind these vesicles in a crude preparation of membranes, and the whole antibody complex can then be isolated by low-speed centrifugation (Figure 4-38). A related technique uses tiny metallic beads coated with specific antibodies. Organelles that bind to the antibodies, and are thus linked to the metallic beads, are recovered from the preparation by adhesion to a small magnet on the side of the test tube.

All cells contain a dozen or more different types of small membrane-limited vesicles of about the same size (50–100 nm in diameter) and density, which makes them difficult to separate from one another by centrifugation techniques. Immunological techniques are particularly useful for purifying specific classes of such vesicles. Fat and muscle cells, for instance, contain a particular glucose transporter (GLUT4) that is localized to the membrane of one of these vesicle types. When insulin is added to the cells, these vesicles fuse with the plasma membrane and increase the number of glucose transporters able to take up glucose from the blood. As we will see in Chapter 15, this process is critical to maintaining the appropriate concentration of sugar in the blood. The GLUT4-containing vesicles

**FIGURE 4-38 Coated vesicles can be purified by binding to an antibody specific for a vesicle surface protein and linkage to bacterial cells.** In this example, a suspension of membranes from rat liver is incubated with an antibody specific for clathrin, a protein that coats the outer surface of certain cytosolic vesicles. To this mixture is added a suspension of killed *Staphylococcus aureus* bacteria, whose surface membrane contains protein A, which binds to the constant (Fc)

region of antibodies. (a) Interaction of protein A with antibodies bound to clathrin-coated vesicles links the vesicles to the bacterial cells. The vesicle-bacteria complexes can then be recovered by low-speed centrifugation. (b) A thin-section electron micrograph reveals clathrin-coated vesicles bound to an *S. aureus* cell. See E. Merisko et al., 1982, *J. Cell Biol.* **93**:846. [Micrograph courtesy of George Palade.]

can be purified by using an antibody that binds to a segment of the GLUT4 protein that faces the cytosol. Likewise, the various transport vesicles discussed in Chapter 14 are characterized by unique surface proteins that permit their separation with the aid of specific antibodies.

A variation of this technique is employed when no antibody specific for the organelle under study is available. A gene encoding an organelle-specific membrane protein is modified by the addition of a segment encoding an epitope tag; the tag is placed on a segment of the protein that faces the cytosol. Following stable expression of the recombinant protein in the cell under study, an anti-epitope monoclonal antibody (described above) can be used to purify the organelle.

## Proteomics Reveals the Protein Composition of Organelles

We introduced this section by emphasizing how important it is to isolate organelles to identify their components. For many years, the technology was not sufficiently sophisticated to generate a complete inventory of the proteins in each organelle, but recent advances in genomics and mass

spectrometry have now made it possible. This approach combines organelle isolation with the proteomics techniques discussed in Chapter 3.

Identifying all the proteins in an organelle requires three steps. First, one has to be able to isolate the organelle to a high degree of purity. Second, one has to have a way to identify all the sequences of the proteins in the organelle. This identification is generally done by digesting all the proteins with a protease such as trypsin, which cleaves all polypeptides at lysine and arginine residues, and then determining the mass and sequence of all the resulting peptides by mass spectrometry. Third, one has to have a genomic sequence to identify the proteins from which all the peptides came. In this way, the proteomes of many organelles have been determined. As one example, a recent proteomic study on mitochondria purified from mouse brain, heart, kidney, and liver revealed 591 mitochondrial proteins, including 163 proteins not previously known to be associated with this organelle. Several proteins were found in mitochondria only from specific cell types. Determining the functions associated with these newly identified mitochondrial proteins is a major objective of current research on this organelle.

## KEY CONCEPTS OF SECTION 4.4

### Isolation of Cell Organelles

- Microscopy has revealed a common set of organelles that are present in eukaryotic cells.
- Disruption of cells by vigorous homogenization, sonication, or other techniques releases their organelles. Swelling of cells in a hypotonic solution weakens the plasma membrane, making it easier to rupture.
- Sequential differential centrifugation of a cell homogenate yields fractions of partly purified organelles that differ in mass and density.
- Equilibrium density-gradient centrifugation, which separates cellular components according to their densities, can further purify cell fractions obtained by differential centrifugation.
- Immunological techniques using antibodies against organelle-specific membrane proteins are particularly useful in purifying organelles and vesicles of similar sizes and densities.
- Proteomic analysis can identify all the protein components in a preparation of a purified organelle.

### Review the Concepts

1. Both light and electron microscopy are commonly used to visualize cells, cell structures, and the location of specific molecules. Explain why a scientist may choose one or the other microscopy technique for use in research.
2. The magnification possible with any type of microscope is an important property, but its resolution, the ability to distinguish between two very closely apposed objects, is even more critical. Describe why the resolving power of a microscope is more important for seeing finer details than its magnification. What is the formula used to describe the resolution of a microscope lens, and what are the limitations placed on the values in the formula?
3. Why are chemical stains required for visualizing cells and tissues with the basic light microscope? What advantage do fluorescent dyes and fluorescence microscopy provide in comparison to the chemical dyes used to stain specimens for light microscopy? What advantages do confocal and deconvolution microscopy provide in comparison to conventional fluorescence microscopy?
4. In certain electron microscopy methods, the specimen is not directly imaged. How do these methods provide information about cellular structure, and what types of structures do they visualize? What limitation applies to most forms of electron microscopy?
5. What is the difference between a cell strain, a cell line, and a clone?
6. Explain why the process of cell fusion is necessary to produce monoclonal antibodies used for research.
7. Much of what we know about cell function depends on experiments using specific cells and specific parts (e.g., organelles) of cells. What techniques do scientists commonly use to isolate cells and organelles from complex mixtures, and how do these techniques work?
8. Hoechst 33258 is a chemical dye that binds specifically to DNA in live cells, and when excited by UV light, it fluoresces

in the visible spectrum. Name and describe one specific method, employing Hoechst 33258, an investigator would use to isolate fibroblasts in the G<sub>2</sub> phase of the cell cycle from those fibroblasts in interphase.

**Colored transmission electron micrograph of one ribosomal RNA transcription unit from a *Xenopus* oocyte.** Transcription proceeds from left to right, with nascent ribosomal ribonucleoprotein complexes (rRNPs) growing in length as each successive RNA polymerase I molecule moves along the DNA template at the center. In this preparation, each rRNP is oriented either above or below the central strand of DNA being transcribed, so that the overall shape is similar to a feather. In the nucleolus of a living cell, the nascent rRNPs extend in all directions, like a bottlebrush. [Professor Oscar L. Miller/Science Photo Library.]

**The extraordinary versatility** of proteins as the components of cellular structures, cellular catalysts, and molecular switches and machines was described in Chapter 3. In this chapter, we consider the process by which proteins are made as well as other cellular processes that are critical for the survival of an organism and its descendants. Our focus will be on the vital molecules known as **nucleic acids**, and how they ultimately are responsible for governing all cellular function. As we saw in Chapter 2, nucleic acids are linear polymers of four types of nucleotides (see Figures 2-13, 2-16, and 2-17). These macromolecules (1) contain in the precise sequence of their nucleotides the information for determining the amino acid sequence, and hence the structure and function, of all the proteins of a cell; (2) are critical functional components of the cellular macromolecular factories

# Fundamental Molecular Genetic Mechanisms

that select amino acids and align them in the correct order as a polypeptide chain is being synthesized; (3) catalyze a number of fundamental chemical reactions in cells, including formation of peptide bonds between amino acids during protein synthesis; and (4) regulate the expression of genes.

**Deoxyribonucleic acid (DNA)** is an informational molecule that contains in the sequence of its nucleotides the information required to build all the proteins and RNAs of an organism, and hence the cells and tissues of that organism. Chemically, it is ideally suited to perform this function. It is extraordinarily stable under most terrestrial conditions, as exemplified by our ability to recover DNA sequence from bones and tissues that are tens of thousands of years old. Because of this, and because of the repair mechanisms that operate in living cells, the long polymers that make up a

### 5.7 Viruses: Parasites of the Cellular Genetic System

DNA molecule can be up to  $10^9$  nucleotides long. Virtually all the information required for the development of a fertilized human egg into an adult made of trillions of cells with specialized functions can be stored in the sequence of the four types of nucleotides that make up the roughly  $3 \times 10^9$  base pairs in the human genome. Because of the principles of base pairing discussed in the following sections, this information is readily copied with an error rate of only about 1 in  $2.5 \times 10^8$  nucleotides per generation. The exact replication of this information in any species ensures its genetic continuity from generation to generation and is critical to the normal development of individuals. DNA fulfills these functions so well that it is the vessel for genetic information in all known forms of life (excluding RNA viruses, which are limited to extremely short genomes because of the relative instability of RNA compared with DNA, as we will see). The discovery that virtually all forms of life use DNA to encode their genetic information and use a nearly identical genetic code implies that all forms of life descended from a common ancestor whose genetic information was stored in nucleic acid sequence. This information is accessed and replicated by specific base pairing between nucleotides. The information stored in DNA is arranged in hereditary units, known as genes, that control identifiable traits of an organism. In the process of *transcription*, the information stored in DNA is copied into **ribonucleic acid (RNA)**, which has three distinct roles in protein synthesis, in addition to its more recently discovered functions in the regulation of chromatin structure, transcription, and protein synthesis, which we will discuss in Chapters 8, 9, and 10.

Portions of the DNA nucleotide sequence are copied into **messenger RNA (mRNA)** molecules that direct the synthesis of a specific protein. The nucleotide sequence of an mRNA molecule contains information that specifies the correct order of amino acids during the synthesis of a protein. The remarkably accurate, stepwise assembly of amino acids into proteins occurs by *translation* of mRNA. In this process, the nucleotide sequence of an mRNA molecule is “read” by a second type of RNA called **transfer RNA (tRNA)** with the aid of a third type of RNA, **ribosomal RNA (rRNA)**, and associated proteins. As the correct amino acids are brought into sequence by tRNAs, they are linked by peptide bonds to make proteins. RNA synthesis is called **transcription** because the four-base sequence “language” of DNA is precisely copied, or *transcribed*, into the nucleotide sequence of an RNA molecule. Protein synthesis is referred to as **translation** because the four-base sequence “language” of DNA and RNA is *translated* into the twenty-amino acid sequence “language” of proteins.

Discovery of the structure of DNA in 1953 and the subsequent elucidation of how DNA directs synthesis of RNA, which then directs assembly of proteins—the so-called *central dogma*—were monumental achievements marking the early days of molecular biology. However, the simplified representation of the central dogma as DNA → RNA → protein does not reflect the role of proteins in the synthesis

of nucleic acids. Moreover, as discussed here for bacteria and in later chapters for eukaryotes, proteins are largely responsible for *regulating gene expression*, the entire process whereby the information encoded in DNA is decoded into proteins in the correct cells at the correct times in development. As a consequence, hemoglobin is expressed only in cells in the bone marrow (erythroid progenitors) destined to develop into circulating red blood cells (erythrocytes), and developing neurons make the proper synapses (connections) with  $10^{11}$  other developing neurons in the human brain. The fundamental molecular genetic processes of DNA replication, transcription, and translation must be carried out with extraordinary fidelity, speed, and accurate regulation for the normal development of organisms as complex as bacteria, archaea, and eukaryotes (see Figure 1-1). This is achieved by chemical processes that operate with extraordinary accuracy coupled with multiple layers of checkpoint or surveillance mechanisms that test whether critical steps in these processes have occurred correctly before the next step is initiated. The highly regulated expression of genes necessary for the development of a multicellular organism requires integration of information from signals sent by distant cells in the developing organism, as well as from neighboring cells, and an intrinsic developmental program determined by earlier steps in embryogenesis taken by each cell’s progenitors. All of this regulation is dependent on control sequences in the DNA that function with proteins called *transcription factors* to coordinate the expression of every gene. The RNA sequences we discuss in Chapters 8, 9, and 10 also serve to regulate chromatin structure, transcription, RNA processing, and translation. Nucleic acids function as the “brains and central nervous system” of the cell, while proteins carry out most of the functions they specify.

In this chapter, we first review the structures and properties of DNA and RNA and explore how the different characteristics of these two types of nucleic acids make them suited for their respective functions in the cell. In the next several sections, we discuss the basic processes summarized in Figure 5-1: transcription of DNA into RNA precursors, processing of these precursors to make functional RNA molecules, translation of mRNAs into proteins, and the replication of DNA. Proteins regulate cell structure and most of the biochemical reactions in cells, so we first consider how the amino acid sequences of proteins, which determine their three-dimensional structures and hence their functions, are encoded in DNA and translated. After outlining the functions of mRNA, tRNA, and rRNA in protein synthesis, we present a detailed description of the components and biochemical steps in translation. Understanding these processes gives us a deep appreciation of the need to copy the nucleotide sequence of DNA precisely. Consequently, we next consider the molecular problems involved in DNA replication and the complex cellular machinery that ensures accurate copying of the genetic material. Along the way, we compare these processes in prokaryotes and eukaryotes. The next section describes how damage to DNA is repaired and how

**FIGURE 5-1 Overview of four basic molecular genetic processes.**

In this chapter, we cover the three processes that lead to production of proteins **1–3** and the process for replicating DNA **4**. Because viruses utilize host-cell machinery, they have been important models for studying these processes. During transcription of a protein-coding gene by RNA polymerase **1**, the four-base DNA code specifying the amino acid sequence of a protein is copied, or *transcribed*, into a precursor messenger RNA (pre-mRNA) by the polymerization of ribonucleoside triphosphate monomers (rNTPs). Removal of noncoding sequences and other modifications to the pre-mRNA **2**, collectively known as *RNA processing*, produce a functional mRNA, which is transported to the cytoplasm.

During *translation* **3**, the four-base code of the mRNA is decoded into the 20-amino acid language of proteins. Ribosomes, the macromolecular machines that translate the mRNA code, are composed of two subunits assembled in the nucleolus from ribosomal RNAs (rRNAs) and multiple proteins (*left*). After transport to the cytoplasm, ribosomal subunits associate with an mRNA and carry out protein synthesis with the help of transfer RNAs (tRNAs) and translation factor proteins. During DNA replication **4**, which occurs only in cells preparing to divide, deoxyribonucleoside triphosphate monomers (dNTPs) are polymerized to yield two identical copies of each chromosomal DNA molecule. Each daughter cell receives one of the identical copies.

regions of different DNA molecules are exchanged in the process of recombination to generate new combinations of traits in the individual organisms of a species. The final section of the chapter presents basic information about viruses, parasites that exploit the cellular machinery for DNA replication, transcription, and protein synthesis. In addition to being significant pathogens, viruses are important model organisms for studying these cellular mechanisms of macromolecular synthesis and other cellular processes. Viruses have relatively simple structures compared with cells, and their small genomes made them tractable for historic early studies of these fundamental cellular processes. Viruses continue to teach important lessons in molecular cell biology today and have been adapted as experimental tools for introducing genes into cells, tools that are currently being tested for their effectiveness in human gene therapy.

## 5.1 Structure of Nucleic Acids

DNA and RNA are chemically very similar. The primary structures of both are linear **polymers** composed of **monomers** called **nucleotides**. DNA and messenger RNA function primarily as informational molecules, carrying information in the exact sequence of their nucleotides. Cellular RNAs range in length from about 22 to many thousands of nucleotides. Cellular DNA molecules can be as long as several hundred million nucleotides. These large DNA units in association with proteins can be stained with dyes and visualized in the light microscope as *chromosomes*, so named because of their stainability. Though chemically similar, DNA and RNA exhibit some very important differences. For example, RNA can also function as a catalytic molecule. As we will see, the different and unique properties

**FIGURE 5-2 Chemical directionality of a nucleic acid strand.** Shown here are alternative representations of a single strand of DNA containing only three bases: cytosine (C), adenine (A), and guanine (G). (a) The chemical structure shows a hydroxyl group at the 3' end and a phosphate group at the 5' end. Note also that two phosphoester bonds link adjacent nucleotides; this two-bond linkage is commonly referred to as a *phosphodiester bond*. (b) In the "stick" diagram (*top*), the sugars are indicated as vertical lines and the phosphodiester bonds as slanting lines; the bases are denoted by their single-letter abbreviations. In the simplest representation (*bottom*), only the bases are indicated. By convention, a polynucleotide sequence is always written in the 5'→3' direction (left to right) unless otherwise indicated.

of DNA and RNA make them each suited for their specific functions in the cell.

## A Nucleic Acid Strand Is a Linear Polymer with End-to-End Directionality

In all organisms, DNA and RNA are each made up of only four different nucleotides. Recall from Chapter 2 that all nucleotides consist of an organic base linked to a five-carbon sugar that has a phosphate group attached to the 5' carbon. In RNA, the sugar is ribose; in DNA, deoxyribose (see Figure 2-16). The nucleotides used in synthesis of DNA and RNA contain five different bases. The bases *adenine* (A) and *guanine* (G) are **purines**, which contain a pair of fused rings; the bases *cytosine* (C), *thymine* (T), and *uracil* (U) are **pyrimidines**, which contain a single ring (see Figure 2-17). Three of these bases—A, G, and C—are found in both DNA and RNA; however, T is found only in DNA and U only

in RNA. (Note that the single-letter abbreviations for these bases are also commonly used to denote the entire nucleotides in nucleic acid polymers.)

A single nucleic acid strand has a *backbone* composed of repeating pentose-phosphate units from which the purine and pyrimidine bases extend as side groups. Like a polypeptide, a nucleic acid strand has an end-to-end chemical orientation: the 5' *end* has a hydroxyl or phosphate group on the 5' carbon of its terminal sugar; the 3' *end* usually has a hydroxyl group on the 3' carbon of its terminal sugar (Figure 5-2). This directionality, plus the fact that synthesis proceeds 5' to 3', has given rise to the convention that polynucleotide sequences are written and read in the 5'→3' direction (from left to right); for example, the sequence AUG is assumed to be (5')AUG(3'). As we will see, the 5'→3' directionality of a nucleic acid strand is an important property of the molecule. The chemical linkage between adjacent nucleotides, commonly called a **phosphodiester bond**, actually consists of two phosphoester bonds, one on the 5' side of the phosphate and another on the 3' side.

The linear sequence of nucleotides linked by phosphodiester bonds constitutes the *primary structure* of a nucleic acid molecule. Like polypeptides, polynucleotides can twist and fold into three-dimensional conformations stabilized by non-covalent bonds. Although the primary structures of DNA and RNA are generally similar, their three-dimensional conformations are quite different. These structural differences are critical to the different functions of the two types of nucleic acids.

## Native DNA Is a Double Helix of Complementary Antiparallel Strands

The modern era of molecular biology began in 1953 when James D. Watson and Francis H. C. Crick proposed that DNA has a double-helical structure. Their proposal was based on analysis of x-ray diffraction patterns of DNA fibers generated by Rosalind Franklin and Maurice Wilkins, which showed that the structure was helical, and analyses of the base composition of DNA from multiple organisms by Erwin Chargaff and colleagues. Chargaff's studies revealed that while the base composition of DNA (percentages of A, T, G, and C) varies greatly between distantly related organisms, the percentage of A always equals the percentage of T, and the percentage of G always equals the percentage of C, in all organisms. Based on these discoveries and the structures of the four nucleotides, Watson and Crick performed careful molecular model building, proposing a **double helix**, with A always hydrogen-bonded to T and G always hydrogen-bonded to C at the axis of the double helix, as the structure of DNA. The Watson and Crick model proved correct and paved the way for our modern understanding of how DNA functions as the genetic material. Today our most accurate models for DNA structure come from high-resolution x-ray diffraction studies of crystals of DNA, made possible by the chemical synthesis of large amounts of short DNA molecules of uniform length and sequence that are amenable to crystallization (Figure 5-3a).

**FIGURE 5-3 The DNA double helix.** (a) Space-filling model of B DNA, the most common form of DNA in cells. The bases (light shades) project inward from the sugar-phosphate backbones (dark red and blue) of each strand, but their edges are accessible through major and minor grooves. Arrows indicate the 5'→3' direction of each strand. Hydrogen bonds between the bases are in the center of the structure. The major and minor grooves are lined by potential hydrogen bond donors and acceptors (highlighted in yellow). (b) Chemical structure of DNA double helix. This extended schematic shows the two sugar-phosphate backbones and hydrogen bonding between the Watson-Crick base pairs, A·T and G·C. See R. E. Dickerson, 1983, *Sci. Am.* **249**:94. [Part (a) data from R. Wing et al., 1980, *Nature* **287**:755, PDB ID 1bna.]

DNA consists of two associated polynucleotide strands that wind together to form a double helix. The two sugar-phosphate backbones are on the outside of the double helix, and the bases project into the interior. The adjoining bases in each strand stack on top of one another in parallel planes (see Figure 5-3a). The orientation of the two strands is *antiparallel*; that is, their 5'→3' directions are opposite. The strands are held in precise register by formation of **base pairs** between the two strands: A is paired with T through two hydrogen bonds; G is paired with C through three hydrogen bonds (Figure 5-3b). This base-pair complementarity is a consequence of the size, shape, and chemical composition of the bases. The presence of thousands of such hydrogen bonds in a DNA molecule contributes greatly to the stability of the double helix. Hydrophobic and van der Waals interactions between the stacked adjacent base pairs further stabilize the double-helical structure.

In natural DNA, A always hydrogen-bonds with T and G with C, forming A·T and G·C base pairs as shown in Figure 5-3b. These associations, always between a larger purine and a smaller pyrimidine, are often called *Watson-Crick base pairs*. Two polynucleotide strands, or regions thereof, in which all the nucleotides form such base pairs are said to be **complementary**. However, in theory and in synthetic DNAs, other base pairs can form. For example, guanine (a purine) could theoretically form hydrogen bonds with thymine (a pyrimidine), causing only a minor distortion in the helix. The space available in the helix would also allow pairing between the two pyrimidines cytosine and

thymine. Although the nonstandard G·T and C·T base pairs are not normally found in DNA, G·U base pairs are quite common in double-helical regions that form within otherwise single-stranded RNA. Nonstandard base pairs do not occur naturally in double-stranded (*duplex*) DNA because the DNA copying enzyme, described later in this chapter, does not permit them.

Most DNA in cells takes the form of a *right-handed* helix. The x-ray diffraction pattern of DNA indicates that the stacked bases are regularly spaced 0.34 nm apart along the helix axis. The helix makes a complete turn every 3.4 to 3.6 nm, depending on the sequence; thus there are about 10–10.5 base pairs per turn. This helical form, referred to as the *B form* of DNA, is the normal form present in most DNA stretches in cells. On the outside of the helix, the spaces between the intertwined strands form two helical grooves of different widths, described as the *major groove* and the *minor groove* (see Figure 5-3a). As a consequence, the atoms on the edges of each base within these grooves are accessible from outside the helix, forming two types of binding surfaces. DNA-binding proteins can “read” the sequence of bases in duplex DNA by contacting atoms in either the major or the minor grooves.

Under laboratory conditions in which most of the water is removed from DNA, the crystallographic structure of DNA changes to the *A form*, which is wider and shorter than B-form DNA, with a wider and deeper major groove and a narrower and shallower minor groove (Figure 5-4). RNA-DNA and RNA-RNA helices also exist in this form in cells and in vitro.

**FIGURE 5-4 Comparison of A-Form and B-Form DNA.** The sugar-phosphate backbones of the two polynucleotide strands, which are on the outside in both structures, are shown in red and blue; the bases (lighter shades) are oriented inward. (a) The B form of DNA has about 10.5 base pairs per helical turn. Adjacent stacked base pairs are 0.34 nm apart. (b) The more compact A form of DNA has 11 base pairs per turn, with a much deeper major groove and a much shallower minor groove than B-form DNA. [Part (a) data from R. Wing et al., 1980, *Nature* **287**:755, PDB ID 1bna. Part (b) data from B. N. Conner et al., 1984, *J. Mol. Biol.* **174**:663, PDB ID 1ana.]

Important modifications in the structure of standard B-form DNA come about as a result of protein binding to specific DNA sequences. Although the multitude of hydrogen and hydrophobic bonds between the bases provides stability to DNA, the double helix is flexible about its long axis. Unlike the  $\alpha$  helix in proteins (see Figure 3-4), it has no hydrogen bonds parallel to the axis of the helix. This property allows DNA to bend when complexed with a DNA-binding protein, such as the transcription factor TBP (Figure 5-5).

**FIGURE 5-5 Interaction with a protein can bend DNA.** The conserved C-terminal domain of the TATA box-binding protein (TBP) binds to the minor groove of specific DNA sequences rich in A and T, untwisting and sharply bending the double helix. Transcription of most eukaryotic genes requires participation of TBP. [Data from D. B. Nikolov and S. K. Burley, 1997, *Proc. Natl. Acad. Sci. USA* **94**:15, PDB ID 1cdw.]

Bending of DNA is also critical to the dense packing of DNA in chromatin, the protein-DNA complex in which nuclear DNA occurs in eukaryotic cells (see Chapter 8).

Why did DNA, rather than RNA, evolve to be the carrier of genetic information in cells? The hydrogen at the 2' position in the deoxyribose of DNA makes it a far more stable molecule than RNA, which instead has a hydroxyl group at the 2' position of ribose (see Figure 2-16). The 2'-hydroxyl groups in RNA participate in the slow,  $\text{OH}^-$ -catalyzed hydrolysis of phosphodiester bonds at neutral pH (Figure 5-6). The absence of 2'-hydroxyl groups in DNA prevents this process. Therefore, the presence of deoxyribose in DNA makes it a more stable molecule—a characteristic that is critical to its function in the long-term storage of genetic information.

## DNA Can Undergo Reversible Strand Separation

During replication and transcription of DNA, the strands of the double helix must separate to allow the internal edges of the bases to pair with the bases of the nucleotides being polymerized into new complementary polynucleotide chains. In later sections, we describe the cellular mechanisms that separate and subsequently reassociate DNA strands during replication and transcription. Here we discuss the fundamental factors that influence the separation and reassociation of DNA strands. These properties of DNA were elucidated by *in vitro* experiments.

The unwinding and separation of DNA strands, referred to as **denaturation**, or **melting**, can be induced experimentally by increasing the temperature of a solution of DNA. As the thermal energy increases, the resulting increase in molecular motion eventually breaks the hydrogen bonds and other forces that stabilize the double helix. The strands then separate, driven apart by the electrostatic repulsion of the negatively charged deoxyribose-phosphate backbones of the two strands. Near the denaturation temperature, a small increase in temperature causes a rapid, nearly simultaneous loss of the multiple weak interactions holding the strands together along the entire length of the DNA molecules. Because the stacked base pairs in duplex DNA absorb less ultraviolet (UV) light than the unstacked bases in single-stranded DNA, this change leads to an abrupt increase in the absorption of UV light. This phenomenon, known as *hyperchromicity* (Figure 5-7a), is useful for monitoring DNA denaturation.

The *melting temperature* ( $T_m$ ) at which DNA strands separate depends on several factors. Molecules that contain a greater proportion of G·C pairs require higher temperatures to denature because the three hydrogen bonds in G·C pairs make these base pairs more stable than A·T pairs, which have only two hydrogen bonds. Indeed, the percentage of G·C base pairs in a DNA sample can be estimated from its  $T_m$  (Figure 5-7b). The ion concentration of the solution also influences the  $T_m$  because the negatively charged phosphate groups in the two strands are shielded by positively charged ions. When the ion concentration is low, this shielding is decreased, thus increasing the repulsive forces between the strands and reducing the  $T_m$ . Agents that

**FIGURE 5-6 Base-catalyzed hydrolysis of RNA.** The 2'-hydroxyl group in RNA can act as a nucleophile, attacking the phosphodiester bond. The 2',3' cyclic monophosphate derivative is further hydro-

lyzed to a mixture of 2' and 3' monophosphates. This mechanism of phosphodiester bond hydrolysis cannot occur in DNA, which lacks 2'-hydroxyl groups.

destabilize hydrogen bonds, such as formamide or urea, also lower the  $T_m$ . Finally, extremes of pH denature DNA at low temperatures. At low (acid) pH, the bases become protonated and thus positively charged, repelling each other. At high (alkaline) pH, the bases lose protons and become negatively charged, again repelling each other because of their similar charges. In cells, pH and temperature are, for the most part, maintained at a constant level. These features of

DNA denaturation are most useful for manipulating DNA in a laboratory setting.

The single-stranded DNA molecules that result from denaturation form random coils without an organized structure. Lowering the temperature, increasing the ion concentration, or neutralizing the pH causes two complementary strands to reassociate into a perfect double helix. The extent of such *renaturation* is dependent on time, the DNA

**EXPERIMENTAL FIGURE 5-7 G-C content of DNA affects melting temperature.** The temperature at which DNA denatures increases with the proportion of G-C pairs. (a) Melting of double-stranded DNA can be monitored by its absorption of UV light at 260 nm. As regions of double-stranded DNA unpair, the absorption of light by those regions increases almost twofold. Light absorption

by single-stranded DNA changes much less as the temperature is increased. (b) The temperature at which half the bases in a double-stranded DNA sample have denatured is denoted  $T_m$  (for "temperature of melting"). The  $T_m$  is a function of the G-C content of the DNA; the greater the G+C percentage, the higher the  $T_m$ .

concentration, and the ion concentration. Two DNA strands that are not related in sequence will remain as random coils and will not renature, but they will not inhibit complementary DNA partner strands from finding each other and renaturing. Denaturation and renaturation of DNA are the basis of nucleic acid **hybridization**, a powerful technique used to study the relatedness of two DNA samples and to detect and isolate specific DNA molecules in a mixture containing numerous different DNA sequences (see Chapter 6).

### Torsional Stress in DNA Is Relieved by Enzymes

Many bacterial genomic DNAs and many viral DNAs are circular molecules. Circular DNA molecules also occur in mitochondria, which are present in almost all eukaryotic cells, and in chloroplasts, which are present in plants and some unicellular eukaryotes. Although eukaryotic nuclear DNA is linear, long loops of DNA are fixed in place within chromosomes (see Chapter 8). Each of the two strands in a circular DNA molecule or in a fixed loop of a eukaryotic chromosome forms a closed structure without free ends and is therefore subject to torsional stress.

Most bacterial DNA in chromosomes and DNA isolated from viruses containing circular double-stranded DNA is underwound, meaning that it has fewer helical turns than B-form linear DNA of the same length. As a result, the DNA molecule twists back on itself like a twisted rubber band, forming *supercoils* (Figure 5-8a). Localized unwinding or overwinding of a DNA molecule, which occurs during DNA replication and transcription, induces torsional stress into the remaining portion of the molecule because the ends of the strands are not free to rotate. All cells, however, contain *topoisomerase I*, which can relieve the torsional stress that

develops in cellular and viral DNA molecules during replication and transcription. This enzyme binds to DNA at random sites and breaks a phosphodiester bond in one strand. Such a one-strand break in DNA is called a *nick*. The broken end then winds around the uncut strand, leading to loss of supercoils (Figure 5-8b). Finally, the same enzyme joins (ligates) the two ends of the broken strand. Another type of enzyme, *topoisomerase II*, makes breaks in both strands of a double-stranded DNA and then religates them. As a result, topoisomerase II can both relieve torsional stress and link together two circular DNA molecules as in the links of a chain.

### Different Types of RNA Exhibit Various Conformations Related to Their Functions

The primary structure of RNA is generally similar to that of DNA, with two exceptions: the sugar component of RNA, ribose, has a hydroxyl group at the 2' position (see Figure 2-16b), and thymine in DNA is replaced by uracil in RNA. The presence of thymine rather than uracil in DNA is important to the long-term stability of DNA because of its function in DNA repair (see Section 5.6). As noted earlier, the hydroxyl group on the 2' carbon of ribose makes RNA more chemically labile than DNA. As a result of this lability, RNA is cleaved into mononucleotides by an alkaline solution (see Figure 5-6), whereas DNA is not. The 2'-hydroxyl group of RNA also provides a chemically reactive group that takes part in RNA-mediated catalysis. Like DNA, RNA is a long polynucleotide that can be double-stranded or single-stranded, linear or circular. It can also participate in a hybrid helix composed of one RNA strand and one DNA strand. As mentioned above, RNA-RNA and RNA-DNA double helices have a compact conformation like the A form of DNA (see Figure 5-4b).

(a) Supercoiled

(b) Relaxed circle

#### EXPERIMENTAL FIGURE 5-8 Topoisomerase I relieves torsional stress on DNA.

(a) Electron micrograph of SV40 viral DNA. When the circular DNA of the SV40 virus is isolated and separated from its associated protein, the DNA duplex is underwound and assumes the supercoiled configuration. (b) If a supercoiled DNA is nicked (i.e., one strand cleaved), the strands can rewind, leading to loss of a supercoil. Topoisomerase I catalyzes this reaction and also reseals the broken ends. All the supercoils in isolated SV40 DNA can be removed by the sequential action of this enzyme, producing the relaxed-circle conformation. For clarity, the shapes of the molecules at the bottom have been simplified. [Photos courtesy of Laurien Polder, from A. Kornberg (1980) *DNA Replication*, p. 29, W.H. Freeman, New York.]

(a) Secondary structure

The diagram illustrates two types of secondary structure motifs in nucleic acids. On the left, a 'Hairpin' motif is shown as a single red line that folds back on itself to form a stem, represented by a blue ladder-like structure. On the right, a 'Stem-loop' motif is shown as a red line that forms a stem (blue ladder-like structure) and then loops back to form a large loop. Labels 'Hairpin' and 'Stem-loop' are placed below their respective structures. The text 'Double-helical stem region' is placed to the right of the stem in the stem-loop structure.

Unlike DNA, which exists primarily as a very long double helix, most cellular RNAs are single-stranded, and they exhibit a variety of conformations (Figure 5-9). Differences in the sizes and conformations of the various types of RNA permit them to carry out specific functions in a cell. The simplest secondary structures in single-stranded RNAs are formed by pairing of complementary bases. “Hairpins” are formed by pairing of bases within about five to ten nucleotides of each other, and “stem-loops” by pairing of bases that are separated by eleven to several hundred nucleotides. These simple folds can cooperate to form more complicated tertiary structures, one of which is termed a “pseudoknot.”

As discussed in detail later, tRNA molecules adopt a well-defined three-dimensional architecture in solution that is crucial to protein synthesis. Larger rRNA molecules also have locally well-defined three-dimensional structures with

In this chapter, we focus on the functions of mRNA, tRNA, and rRNA in gene expression. In later chapters, we will encounter other RNAs, often associated with proteins, that participate in other cell functions.

## Structure of Nucleic Acids

- 5.1 Structure of Nucleic Acids 175

(see Figure 5-3). Base pairing between the strands and hydrophobic interactions between adjacent base pairs stacked perpendicular to the helix axis stabilize this native structure.

- The bases in nucleic acids can interact via hydrogen bonds. The standard Watson-Crick base pairs are G•C, A•T (in DNA), and G•C, A•U (in RNA). Base pairing stabilizes the native three-dimensional structures of DNA and RNA.
- Binding of protein to DNA can deform its helical structure, causing local bending or unwinding of the DNA molecule.
- Heat causes the DNA strands to separate (denature). The melting temperature ( $T_m$ ) of DNA increases with the percentage of G•C base pairs. Under suitable conditions, separated complementary nucleic acid strands will renature.
- Circular DNA molecules can be twisted on themselves, forming supercoils (see Figure 5-8). Enzymes called topoisomerases can relieve torsional stress and remove supercoils from circular DNA molecules. Long linear DNA can also experience torsional stress because long loops are fixed in place within chromosomes.
- Cellular RNAs are single-stranded polynucleotides, some of which form well-defined secondary and tertiary structures (see Figure 5-9). Some RNAs, called ribozymes, have catalytic activity.

## 5.2 Transcription of Protein-Coding Genes and Formation of Functional mRNA

The simplest definition of a *gene* is “a unit of DNA that contains the information to specify synthesis of a single polypeptide chain or functional RNA (such as a tRNA).” The DNA molecules of small viruses contain only a few genes, whereas the single DNA molecule in each of the chromosomes of higher animals and plants may contain several thousand genes. The vast majority of genes carry information used to build protein molecules, and it is the RNA copies of such *protein-coding genes* that constitute the mRNA molecules of cells.

During synthesis of RNA, the four-base language of DNA containing A, G, C, and T is simply copied, or *transcribed*, into the four-base language of RNA, which is identical except that U replaces T. In contrast, during protein synthesis, the four-base language of DNA and RNA is *translated* into the 20-amino acid language of proteins. In this section, we focus on the formation of functional mRNAs from protein-coding genes (see Figure 5-1, step 1). A similar process yields precursors of rRNAs and tRNAs, encoded by rRNA and tRNA genes; these precursors are then further modified to yield functional rRNAs and tRNAs (see Chapters 9 and 10). Similarly, thousands of *micro-RNAs* (*miRNAs*), which regulate the translation and stability of specific target mRNAs,

are transcribed into precursors by RNA polymerases and processed into functional miRNAs (see Chapter 10). Other non-protein-coding (or simply *noncoding*) RNAs help to regulate the transcription of specific protein-coding genes. Regulation of transcription allows distinct sets of genes to be expressed in the multiple different types of cells that make up a multicellular organism. It also allows different amounts of mRNA to be transcribed from different genes, resulting in differences in the amounts of the encoded proteins in a cell. Regulation of transcription is addressed in Chapter 9.

### A Template DNA Strand Is Transcribed into a Complementary RNA Chain by RNA Polymerase

During transcription of DNA, one DNA strand acts as a *template*, determining the order in which ribonucleoside triphosphate (rNTP) monomers are linked together to form a complementary RNA chain. Bases in the template DNA strand base-pair with complementary incoming rNTPs, which are then joined in a polymerization reaction catalyzed by **RNA polymerase**. The polymerization reaction involves a nucleophilic attack by the 3' oxygen in the growing RNA chain on the  $\alpha$  phosphate of the next nucleotide precursor to be added, which results in the formation of a phosphodiester bond and the release of pyrophosphate ( $PP_i$ ). As a consequence of this mechanism, RNA molecules are always synthesized in the 5'→3' direction (Figure 5-10a).

The energetics of the polymerization reaction strongly favor the addition of ribonucleotides to the growing RNA chain because the high-energy bond between the  $\alpha$  and  $\beta$  phosphates of rNTP monomers is replaced by the lower-energy phosphodiester bond between nucleotides. The equilibrium for the reaction is driven further toward chain elongation by pyrophosphatase, an enzyme that catalyzes cleavage of the released  $PP_i$  into two molecules of inorganic phosphate. Like the two strands in DNA, the template DNA strand and the growing RNA strand that is base-paired to it have opposite 5'→3' directionality.

By convention, the site on the DNA template at which RNA polymerase begins transcription is numbered +1 (Figure 5-10b). *Downstream* denotes the direction in which a template DNA strand is transcribed; *upstream* denotes the opposite direction. Nucleotide positions in the DNA sequence downstream from a start site are indicated by a positive (+) sign; those upstream, by a negative (−) sign. Because RNA is synthesized 5'→3', RNA polymerase moves down the template DNA strand in a 3'→5' direction. The newly synthesized RNA is complementary to the template DNA strand; therefore, it is identical to the nontemplate DNA strand, with uracil in place of thymine.

**Stages in Transcription** To carry out transcription, RNA polymerase performs several distinct functions, as depicted in Figure 5-11. During transcription *initiation*, RNA polymerase, with the help of initiation factors (discussed later), recognizes and binds to a specific sequence of double-stranded DNA called a **promoter** (step 1). After binding,

RNA polymerase and the initiation factors separate the DNA strands to make the bases in the template strand available for base pairing with the bases of the rNTPs that it will polymerize (step 2). Approximately 12–14 base pairs of DNA around the transcription start site on the template strand are separated, which allows the template strand to enter the active site of the enzyme. The *active site* is where catalysis of phosphodiester bond formation between rNTPs that are complementary to the template strand takes place. The 12–14-base-pair region of melted DNA in the polymerase is known as the *transcription bubble*. Transcription initiation is considered complete when the first two ribonucleotides of an RNA chain are linked by a phosphodiester bond (step 3).

After several ribonucleotides have been polymerized, RNA polymerase dissociates from the promoter DNA and initiation factors (called  $\sigma$ -factors in bacteria, and general transcription factors in archaea and eukaryotes). During the

**FIGURE 5-10 RNA is synthesized 5'→3'.** (a) Polymerization of ribonucleotides by RNA polymerase during transcription. The ribonucleotide to be added at the 3' end of a growing RNA strand is specified by base pairing between the next base in the template DNA strand and the complementary incoming ribonucleoside triphosphate (rNTP). A phosphodiester bond is formed when RNA polymerase catalyzes a reaction between the 3' oxygen of the growing strand and the  $\alpha$  phosphate of a correctly base-paired rNTP. RNA strands are always synthesized in the 5'→3' direction and are opposite in polarity to their template DNA strands. (b) Conventions for describing RNA transcription. *Top:* The DNA nucleotide where RNA polymerase begins transcription is designated +1. The direction the polymerase travels on the DNA is “downstream,” and downstream bases are marked with positive numbers. The opposite direction is “upstream,” and upstream bases are marked with negative numbers. Some important gene features lie upstream of the transcription start site, including the promoter sequence that localizes RNA polymerase to the gene. *Bottom:* The DNA strand that is being transcribed is the template strand; its complement is the nontemplate strand. The RNA being synthesized is complementary to the template strand and is therefore identical with the nontemplate strand sequence, except with uracil in place of thymine.

**FIGURE 5-11 Three stages in transcription.**

During initiation of transcription, RNA polymerase forms a transcription bubble and begins polymerization of ribonucleotides (rNTPs) at the start site, which is located within the promoter region. Once a DNA region has been transcribed, the separated strands reassociate into a double helix. The nascent RNA is displaced from its template strand except at its 3' end. The 5' end of the RNA strand exits the RNA polymerase through a channel in the enzyme. Termination occurs when the polymerase encounters a specific termination sequence (stop site). See the text for details. For simplicity, the diagram depicts transcription of four turns of the DNA helix encoding some 40 nucleotides of RNA. Most RNAs are considerably longer, requiring transcription of a longer region of DNA.

*strand elongation* stage, RNA polymerase moves along the template DNA, opening the double-stranded DNA in front of its direction of movement and guiding the strands back together so that they reassociate at the upstream end of the transcription bubble (step **4**). One ribonucleotide at a time is added by the polymerase to the 3' end of the growing (*nascent*) RNA chain. During strand elongation, the enzyme maintains a melted region of approximately 14–20 base pairs in the transcription bubble. Approximately eight nucleotides at the 3' end of the growing RNA strand remain base-paired to the template DNA strand in the transcription bubble. The *elongation complex*, comprising RNA polymerase, template DNA, and the nascent RNA strand, is extraordinarily stable. For example, RNA polymerase transcribes the longest known mammalian gene, containing about 2 million base pairs, without dissociating from the DNA template or releasing the nascent RNA. RNA synthesis occurs at a rate of about 1000–2000 nucleotides per minute at 37 °C, so the

elongation complex must remain intact for more than 24 hours to ensure continuous synthesis of pre-mRNA from this very long gene.

During transcription *termination*, the final stage in RNA synthesis, the completed RNA molecule is released from the RNA polymerase and the polymerase dissociates from the template DNA (step **5**). Once it is released, an RNA polymerase is free to transcribe the same gene again or another gene.

**Structure of RNA Polymerases** The RNA polymerases of bacteria, archaea, and eukaryotic cells are fundamentally similar in structure and function. Bacterial RNA polymerases are composed of two related large subunits ( $\beta'$  and  $\beta$ ), two copies of a smaller subunit ( $\alpha$ ), and one copy of a fifth subunit ( $\omega$ ) that is not essential for transcription or cell viability, but that stabilizes the enzyme and assists in the assembly of its subunits. Archaeal and eukaryotic RNA

**FIGURE 5-12 Bacterial RNA polymerase.** This structure corresponds to the polymerase molecule in the elongation stage (step 4) of Figure 5-11. In this diagram, transcription is proceeding in the rightward direction. Arrows indicate where downstream DNA enters the polymerase and upstream DNA exits at an angle from the downstream DNA. The template strand is light violet, the nontemplate strand, dark violet; the nascent RNA, red. The RNA polymerase  $\beta'$  subunit is gold; the  $\beta$  subunit, light yellow; and the  $\alpha$  subunits visible from this angle, brown. Nucleotides complementary to the template DNA are added to the 3' end of the nascent RNA strand on the right side of the transcription bubble. The newly synthesized nascent RNA exits the polymerase at the upstream side through a channel formed by the  $\beta$  subunit. The  $\omega$  subunit is also visible from this angle. [Data courtesy of Seth Darst; see N. Korzheva et al., 2000, *Science* **289**:619–625, and N. Opalka et al., 2003, *Cell* **114**:335–345.]

polymerases have several additional small subunits associated with this core complex, which we describe in Chapter 9. Schematic diagrams of the transcription process generally show RNA polymerase bound to an unbent DNA molecule, as in Figure 5-11. However, x-ray crystallography and other studies of an elongating bacterial RNA polymerase indicate that the DNA bends at the transcription bubble (Figure 5-12).

## Organization of Genes Differs in Prokaryotic and Eukaryotic DNA

Having outlined the process of transcription, we now briefly consider the large-scale arrangement of information in DNA and how this arrangement dictates the requirements for RNA synthesis so that information transfer goes smoothly. In recent years, sequencing of entire genomes from multiple

organisms has revealed not only large variations in the number of protein-coding genes, but also differences in their organization in bacteria and in eukaryotes.

The most common arrangement of protein-coding genes in bacteria has a powerful and appealing logic: genes encoding proteins that function together—for example, the enzymes required to synthesize the amino acid tryptophan—are most often found in a contiguous array in the DNA. Such an arrangement of genes in a functional group is called an **operon** because it operates as a unit from a single promoter. Transcription of an operon produces a continuous strand of mRNA that carries the message for a related series of proteins (Figure 5-13a). Each section of the mRNA represents the unit (or gene) that encodes one of the proteins in the series. This arrangement results in the *coordinate expression* of all the genes in the operon. Every time an RNA polymerase molecule initiates transcription at the promoter of the operon, all the genes of the operon are transcribed and translated. In prokaryotic DNA the genes are closely packed with very few noncoding gaps, and the DNA is transcribed directly into mRNA. Because DNA is not sequestered in a nucleus in prokaryotes, ribosomes have immediate access to the translation start sites in the mRNA as they emerge from the surface of the RNA polymerase. Consequently, translation of the mRNA begins even while the 3' end of the mRNA is still being synthesized at the active site of the RNA polymerase.

This economical clustering of genes devoted to a single metabolic function is rarely found in eukaryotes, even simple ones such as yeasts, which can be metabolically similar to bacteria. Rather, eukaryotic genes encoding proteins that function together are most often physically separated in the DNA; indeed, such genes are usually located on different chromosomes. Each gene is transcribed from its own promoter, producing one mRNA, which is generally translated to yield a single polypeptide (Figure 5-13b).

Early research on the structure of eukaryotic genes involved studies of viruses that infect animals. When researchers analyzed the regions of a viral DNA molecule that encode viral mRNAs, they were surprised to observe that the sequence of a single viral mRNA was encoded in several regions of the viral DNA separated by DNA sequences that are not present in the mRNA. Later, the development of gene cloning and DNA sequencing (see Chapter 6) allowed researchers to compare the genomic DNA sequences of multicellular organisms with the sequences of their mRNAs. This research revealed that most cellular mRNAs are also encoded in several separate regions of genomic DNA, called *exons*, separated by sequences of DNA called *introns*. Further studies showed that a gene is first transcribed into a long primary transcript that includes both exon sequences and the intron sequences that separate them. Subsequently, the introns are removed and the exons are spliced together (see Chapter 10). Although introns are common in multicellular eukaryotes, they are extremely rare in bacteria and archaea and uncommon in many unicellular eukaryotes, such as baker's yeast.

(a) Prokaryotes

**FIGURE 5-13 Gene organization in prokaryotes and in eukaryotes.** (a) The tryptophan (*trp*) operon is a continuous segment of the *E. coli* chromosome containing five genes (blue) that encode the enzymes necessary for the stepwise synthesis of tryptophan. The entire operon is transcribed from one promoter into one long continuous *trp* mRNA (red). Translation of this mRNA begins at five different start sites, yielding five proteins (green). The order of the genes in the bacterial

(b) Eukaryotes

genome parallels the sequential function of the encoded proteins in the tryptophan synthesis pathway. (b) The five genes encoding the enzymes required for tryptophan synthesis in baker's yeast (*Saccharomyces cerevisiae*) are carried on four different chromosomes. Each gene is transcribed from its own promoter to yield a primary transcript that is processed into a functional mRNA encoding a single protein. The lengths of the various chromosomes are given in kilobases ( $10^3$  bases).

## Eukaryotic Precursor mRNAs Are Processed to Form Functional mRNAs

In bacterial cells, which have no nuclei, translation of an mRNA into protein can begin at the 5' end of the mRNA even while the 3' end is still being synthesized by RNA polymerase. In other words, transcription and translation occur concurrently in bacteria. In eukaryotic cells, however, the site of RNA synthesis—the nucleus—is separated from the site of translation—the cytoplasm. Furthermore, the primary transcripts of protein-coding genes are precursor mRNAs (pre-mRNAs) that must undergo several modifications, collectively termed *RNA processing*, to yield a functional mRNA (see Figure 5-1, step 2). This mRNA then must be exported to the cytoplasm before it can be translated into protein. Thus transcription and translation cannot occur concurrently in eukaryotic cells.

All eukaryotic pre-mRNAs are initially modified at the two ends, and these modifications are retained in mRNAs. As the 5' end of a nascent RNA chain emerges from the surface of RNA polymerase, it is immediately acted on

by several enzymes that together synthesize the 5' cap, a 7-methylguanylate that is connected to the terminal nucleotide of the RNA by an unusual 5',5' triphosphate linkage (Figure 5-14). The cap protects an mRNA from enzymatic degradation and assists in its export to the cytoplasm. The cap is also bound by a protein factor required to begin translation in the cytoplasm.

Processing at the 3' end of a pre-mRNA involves cleavage by an endonuclease to yield a free 3'-hydroxyl group, to which a string of adenylic acid residues is added one at a time by an enzyme called *poly(A) polymerase*. The resulting *poly(A) tail* contains 100–250 bases, being shorter in yeasts and invertebrates than in vertebrates. Poly(A) polymerase is part of a complex of proteins that can locate and cleave a transcript at a specific site and then add the correct number of A residues, in a process that does not require a template. As discussed further in Section 5.4 and in Chapter 10, the poly(A) tail has important functions both in translation of mRNA and in stabilizing pre-mRNAs in the nucleus and fully processed mRNAs in the nucleus and cytoplasm.

**FIGURE 5-14 Structure of the 5' methylated cap.** The distinguishing chemical features of the 5' methylated cap on eukaryotic mRNA are (1) the 5'→5' linkage of 7-methylguanylate to the initial nucleotide of the mRNA molecule and (2) the methyl group on the 2' hydroxyl of the ribose of the first nucleotide (base 1). Both of these features occur in all animal cells and in cells of higher plants; yeasts lack the methyl group on nucleotide 1. The ribose of the second nucleotide (base 2) is also methylated in vertebrates. See A. J. Shatkin, 1976, *Cell* **9**:645.

Another step in the processing of many different eukaryotic mRNA molecules is **RNA splicing**: the internal cleavage of a transcript to excise the introns and stitch together the coding exons. Figure 5-15 summarizes the basic steps in eukaryotic mRNA processing using the  $\beta$ -globin gene as an example. We examine the cellular machinery for carrying out processing of mRNA, as well as tRNA and rRNA, in Chapter 10.

The functional eukaryotic mRNAs produced by RNA processing retain noncoding regions, referred to as *untranslated regions (UTRs)*, at each end. In mammalian mRNAs, the 5' UTR may be a hundred or more nucleotides long, and the 3' UTR may be several kilobases in length. Bacterial mRNAs also usually have 5' and 3' UTRs, but these regions are much shorter than those in eukaryotic mRNAs, generally containing fewer than 10 nucleotides. As discussed in Chapter 10, the 5' UTR and 3' UTR sequences participate in

**FIGURE 5-15 Overview of RNA processing.** RNA processing produces functional mRNA in eukaryotes. The  $\beta$ -globin gene contains three protein-coding exons (constituting the coding region) and two intervening noncoding introns. The introns interrupt the protein-coding sequence between the codons for amino acids 31 and 32 and 105 and 106. Transcription of eukaryotic protein-coding genes starts before the sequence that encodes the first amino acid and extends beyond the sequence that encodes the last amino acid, resulting in noncoding regions at the ends of the primary transcript. These untranslated regions (UTRs) are retained during processing. The 5' cap ( $m^7$ Gppp) is added during formation of the primary RNA transcript, which extends beyond the poly(A) site. After cleavage at the poly(A) site and addition of multiple A residues to the 3' end, splicing removes the introns and joins the exons. The small numbers refer to positions in the 147-amino acid sequence of  $\beta$ -globin.

regulation of mRNA translation and stability, and 3' UTRs also function in the localization of many mRNAs to specific regions of the cytoplasm.

### Alternative RNA Splicing Increases the Number of Proteins Expressed from a Single Eukaryotic Gene

In contrast to bacterial and archaeal genes, the vast majority of genes in multicellular eukaryotes contain multiple introns. As noted in Chapter 3, many proteins from higher eukaryotes have a multidomain tertiary structure (see Figure 3-11). Individual repeated protein domains are often encoded by one exon or by a small number of exons that are repeated in genomic DNA and encode identical or nearly identical amino acid sequences. Such repeated exons are thought to have evolved from multiple duplications of a length of DNA lying between two sites in

**FIGURE 5-16 Alternative splicing.** The ~75-kb fibronectin gene (top) contains multiple exons; splicing of the fibronectin transcript varies by cell type. The EIIIB and EIIIA exons (green) encode binding domains for specific proteins on the surface of fibroblasts. The fibronectin mRNA

produced in fibroblasts includes the EIIIA and EIIIB exons, whereas these exons are spliced out of fibronectin mRNA in hepatocytes. In this diagram, introns (black lines in the top diagram of the fibronectin gene) are not drawn to scale; most of them are much longer than any of the exons.

introns on either side of an exon, resulting in insertion of a string of repeated exons separated by introns. The presence of multiple introns in many eukaryotic genes permits expression of multiple, related proteins from a single gene by means of **alternative splicing**. In higher eukaryotes, alternative splicing is an important mechanism for production of different forms of a protein, called **isoforms**, by different types of cells.

Fibronectin, a multidomain protein found in mammals, provides a good example of alternative splicing (Figure 5-16). Fibronectin is a long, adhesive protein secreted into the extracellular space that can bind other proteins together. What and where it binds depends on which domains are spliced together. The fibronectin gene contains numerous exons, grouped into several regions corresponding to specific domains of the protein. Fibroblasts produce fibronectin mRNAs that contain exons EIIIA and EIIIB; these exons encode a protein domain that binds tightly to proteins in the fibroblast plasma membrane. Consequently, this fibronectin isoform adheres fibroblasts to the extracellular matrix. Alternative splicing of the fibronectin primary transcript in hepatocytes, the major type of cell in the liver, yields mRNAs that lack the EIIIA and EIIIB exons. As a result, the fibronectin secreted by hepatocytes into the blood does not adhere tightly to fibroblasts or to most other cell types, which allows it to circulate. During formation of blood clots, however, other fibrin-binding domains of hepatocyte fibronectin bind to fibrin, one of the principal constituents of blood clots. Yet another domain of the bound fibronectin then interacts with integrins on the membranes of passing platelets, thereby expanding the clot by addition of platelets.

More than 20 different isoforms of fibronectin have been identified, each encoded by a different, alternatively spliced mRNA composed of a unique combination of fibronectin gene exons. Sequencing of large numbers of mRNAs isolated from various tissues and comparison of their sequences with genomic DNA has revealed that nearly 90 percent of all human genes are expressed as alternatively spliced mRNAs. Clearly alternative RNA splicing greatly expands the number of proteins encoded by the genomes of higher, multicellular organisms.

## KEY CONCEPTS OF SECTION 5.2

### Transcription of Protein-Coding Genes and Formation of Functional mRNA

- Transcription of DNA is carried out by RNA polymerase, which adds one ribonucleotide at a time to the 3' end of a growing RNA chain (see Figure 5-11). The sequence of the template DNA strand determines the order in which ribonucleotides are polymerized to form an RNA chain.
- During transcription initiation, RNA polymerase binds to a specific site in DNA (the promoter), locally melts the double-stranded DNA to reveal the unpaired template strand, and polymerizes the first two nucleotides complementary to the template strand. The melted region of 12–14 base pairs is known as the transcription bubble.
- During strand elongation, RNA polymerase moves down the DNA, melting the DNA ahead of the polymerase so that the template strand can enter the active site of the enzyme, and allowing the complementary strands of the region just transcribed to reanneal behind it. The transcription bubble moves with the polymerase as the enzyme adds ribonucleotides complementary to the template strand to the 3' end of the growing RNA chain.
- When RNA polymerase reaches a termination sequence in the DNA, the enzyme stops transcription, leading to release of the completed RNA and dissociation of the enzyme from the template DNA.
- In prokaryotic DNA, several protein-coding genes are commonly clustered into a functional region, called an operon, that is transcribed from a single promoter into one mRNA encoding multiple proteins with related functions (see Figure 5-13a). Translation of a bacterial mRNA can begin before synthesis of the mRNA is complete.
- In eukaryotic DNA, each protein-coding gene is transcribed from its own promoter. The initial primary transcript very often contains noncoding regions (introns) interspersed with coding regions (exons).

- Eukaryotic primary transcripts must undergo RNA processing to yield functional RNAs. During processing, the ends of nearly all primary transcripts from protein-coding genes are modified by addition of a 5' cap and 3' poly(A) tail. Transcripts from genes containing introns undergo splicing, the removal of the introns and joining of the exons (see Figure 5-15).

- The individual domains of multidomain proteins found in higher eukaryotes are often encoded by individual exons or a small number of exons. Distinct isoforms of such proteins are often expressed in specific cell types as the result of alternative splicing of exons.

### 5.3 The Decoding of mRNA by tRNAs

Although DNA stores the information for protein synthesis and mRNA conveys the instructions encoded in DNA, most biological activities are carried out by proteins. As we saw in Chapter 3, the linear order of amino acids in each protein determines its three-dimensional structure and activity. For this reason, assembly of amino acids in their correct order, as encoded in DNA, is critical to production of functional proteins and hence the proper functioning of cells and organisms.

Translation is the whole process by which the nucleotide sequence of an mRNA is used as a template to join the amino acids of a polypeptide chain in the correct order (see Figure 5-1, step **3**). In eukaryotic cells, protein synthesis occurs in the cytoplasm, where three types of RNA molecules come together to perform different but cooperative functions (Figure 5-17):

1. **Messenger RNA (mRNA)** carries the genetic information transcribed from DNA in a linear form. The mRNA is read in sets of three-nucleotide sequences, called **codons**, each of which specifies a particular amino acid.
2. **Transfer RNA (tRNA)** is the key to deciphering the codons in mRNA. Each type of amino acid has its own subset of tRNAs, which are covalently bound to that amino acid and carry it to the growing end of a polypeptide chain when the next codon in the mRNA calls for it. The correct tRNA with its attached amino acid is selected at each step because each specific tRNA molecule contains a three-nucleotide sequence, an **anticodon**, that can base-pair with its complementary codon in the mRNA.
3. **Ribosomal RNA (rRNA)** associates with a set of proteins to form **ribosomes**. These complex structures, which physically move along an mRNA molecule, catalyze the assembly of amino acids into polypeptide chains. They also bind tRNAs and various accessory proteins necessary for protein synthesis. Ribosomes are composed of a large and a small subunit, each of which contains its own rRNA molecule or molecules.

**FIGURE 5-17 Three roles of RNA in protein synthesis.** Messenger RNA (mRNA) is translated into protein by the joint action of transfer RNA (tRNA) and the ribosome, which is composed of numerous proteins and three (bacterial) or four (eukaryotic) ribosomal RNA (rRNA) molecules (not shown). Note the base pairing between tRNA anticodons and complementary codons in the mRNA. Formation of a peptide bond between the amino-group N on the incoming aa-tRNA and the carboxy-terminal C on the growing protein chain (green) is catalyzed by one of the rRNAs. aa = amino acid; R = side group. Note that these are simplified diagrams of tRNAs and the ribosomal subunits. Their actual structures are shown in Figure 5-20b and Figure 5-22.

These three types of RNA participate in the synthesis of proteins in all organisms. In this section, we focus on the decoding of mRNA by tRNAs and how the structure of each of these RNAs relates to its specific task. How they work together with ribosomes and protein factors to synthesize proteins is detailed in the following section. Because translation is essential for protein synthesis, the two processes are commonly referred to interchangeably. However, the polypeptide chains resulting from translation must undergo post-translational folding and often other changes (e.g., chemical modifications, association with other chains) that are required for the production of mature, functional proteins (see Chapter 3).

#### Messenger RNA Carries Information from DNA in a Three-Letter Genetic Code

As noted above, the **genetic code** used by cells is a *triplet* code, in which every three-nucleotide sequence, or codon, is “read” from a specified starting point in the mRNA. Of the 64 possible codons in the genetic code (one of four

**TABLE 5-1 The Genetic Code (Codons to Amino Acids)\***

\*AUG is the most common initiation codon; GUG usually codes for valine and CUG for leucine, but rarely, these codons can also code for methionine to initiate a protein chain.

nucleotides at each of the three positions of a codon yields  $4 \times 4 \times 4 = 64$  possible codons), 61 specify individual amino acids, and three are stop codons. Table 5-1 shows that most amino acids are encoded by more than one codon. Only two—methionine and tryptophan—have a single codon; at the other extreme, leucine, serine, and arginine are each specified by six different codons. The different codons for a given amino acid are said to be *synonymous*. The code itself is termed *degenerate*, meaning that a particular amino acid can be specified by several codons.

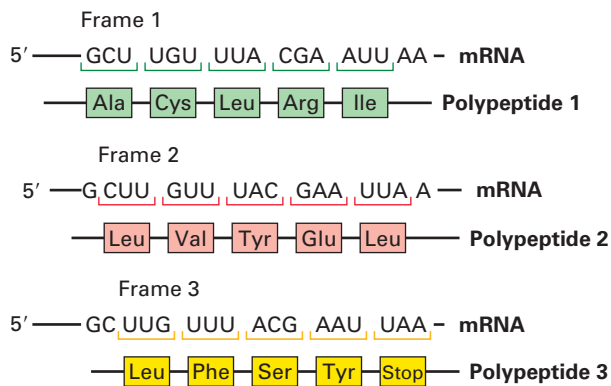

Synthesis of all polypeptide chains in prokaryotic and eukaryotic cells begins with the amino acid methionine. In bacteria, a specialized form of methionine with a formyl group linked to its amino group is used. In most mRNAs, the *start (initiation) codon* specifying this amino-terminal methionine is AUG. In a few bacterial mRNAs, GUG is used as the initiation codon, and CUG is occasionally used as an initiation codon for methionine in eukaryotes. The three codons UAA, UGA, and UAG do not specify amino acids, but rather constitute *stop (termination) codons* that mark the carboxyl terminus of polypeptide chains in almost all cells. The sequence of codons that runs from a specific start codon to a stop codon is called a **reading frame**. This precise linear

array of ribonucleotides in groups of three in mRNA specifies the precise linear sequence of amino acids in a polypeptide chain and also signals where synthesis of the chain starts and stops.

Because the genetic code is a non-overlapping triplet code without divisions between codons, a particular mRNA theoretically could be translated in three different reading frames. Indeed, some mRNAs have been shown to contain overlapping information that can be translated in different reading frames, yielding different polypeptides (Figure 5-18). The vast majority of mRNAs, however, can be read in only one frame because stop codons encountered in the other two possible reading frames terminate translation before a functional protein is produced. Very rarely, another unusual coding arrangement occurs because of *frame shifting*. In this case, the protein-synthesizing machinery may read four nucleotides as one amino acid and then continue reading triplets, or it may back up one base and read all succeeding triplets in the new reading frame until termination of the chain occurs. Only a few dozen such instances are known.

The meaning of each codon is the same in most known organisms—strong evidence that life on Earth evolved only

**FIGURE 5-18 Multiple reading frames in an mRNA sequence.** If translation of the mRNA sequence shown begins at three different upstream start sites (not shown), then three overlapping reading frames are possible. In this example, the codons are shifted one base to the right in the middle frame and two bases to the right in the third frame, which ends in a stop codon. As a result, the same mRNA nucleotide sequence can specify different amino acids. Although regions of sequence that are translated in more than one of the three possible reading frames are rare, there are examples in both prokaryotes and eukaryotes, and especially in their viruses, in which the same sequence is used in two alternative mRNAs expressed from the same region of DNA, and the sequence is read in one reading frame in one mRNA and in an alternative reading frame in the other mRNA. There are even a few instances in which the same short sequence is read in all three possible reading frames.

once. In fact, the genetic code shown in Table 5-1 is known as the *universal code*. However, the genetic code has been found to differ for a few codons in many mitochondria, in ciliated protozoans, and in *Acetabularia*, a single-celled plant. As shown in Table 5-2, most of these differences involve the reading of normal stop codons as amino acids, not an exchange of one amino acid for another. These exceptions to the universal code probably were later evolutionary developments; that is, at no single time was the code immutably fixed, although massive changes were not tolerated once a general code began to function early in evolution.

## The Folded Structure of tRNA Promotes Its Decoding Functions

Translation, or decoding, of the four-nucleotide language of DNA and mRNA into the twenty-amino acid language of proteins requires both tRNAs and enzymes called *aminoacyl-tRNA synthetases*. To participate in protein synthesis, a tRNA molecule must become chemically linked to a particular amino acid via a high-energy bond, forming an **aminoacyl-tRNA** (Figure 5-19). The anticodon in the tRNA then base-pairs with a codon in mRNA so that the activated amino acid can be added to the growing polypeptide chain (see Figure 5-17).

Some 30–40 different tRNAs have been identified in bacterial cells and as many as 50–100 in animal and plant cells. Thus the number of tRNAs in most cells is more than the number of amino acids used in protein synthesis (20) and also differs from the number of amino acid codons in the genetic code (61). Consequently, many amino acids have more than one tRNA to which they can attach (explaining how there can be more tRNAs than amino acids); in addition, many tRNAs can pair with more than one codon (explaining how there can be more codons than tRNAs).

The function of tRNA molecules, which are 70–80 nucleotides long, depends on their precise three-dimensional structures. In solution, all tRNA molecules fold into a similar stem-loop arrangement that resembles a cloverleaf when drawn in two dimensions (Figure 5-20a). The four stems are short double helices stabilized by Watson-Crick base pairing; three of the four stems have loops containing seven or eight bases at their ends, while the remaining, unlooped stem contains the free 3' and 5' ends of the chain. The three nucleotides composing the anticodon are located at the center of the middle loop, in an accessible position that facilitates codon-anticodon base pairing. In all tRNAs, the 3' end of the unlooped *acceptor stem*, to which a specific amino acid is attached, has the sequence CCA, which in most cases is added after synthesis and processing of the tRNA are complete. Several bases in most tRNAs are also modified after transcription, creating nonstandard nucleotides such as inosine, dihydrouridine, and pseudouridine. As we will see shortly, some of these modified bases are known to play an important role in protein

**TABLE 5-2 Known Deviations from the Universal Genetic Code**

Codon	Universal code	Unusual code*	Occurrence
UGA	Stop	Trp	<i>Mycoplasma</i> , <i>Spiroplasma</i> , mitochondria of many species
CUG	Leu	Thr	Mitochondria in yeasts
UAA, UAG	Stop	Gln	<i>Acetabularia</i> , <i>Tetrahymena</i> , <i>Paramecium</i> , etc.
UGA	Stop	Cys	<i>Euplotes</i>

\*Found in nuclear genes of the listed organisms and in mitochondrial genes as indicated.

**FIGURE 5-19 Translating nucleic acid sequence into amino acid sequence.** (a) The process for translating nucleic acid sequences in mRNA into amino acid sequences in proteins involves two steps. Step **1**: An aminoacyl-tRNA synthetase first couples a specific amino acid, via a high-energy ester bond (yellow), to either the 2' or 3' hydroxyl of the terminal adenosine in the corresponding tRNA. Step **2**: A three-base sequence in the tRNA (the anticodon) then base-pairs with a codon in the mRNA specifying the attached amino acid. If an error occurs in either step, the wrong amino acid may be incorporated into a polypeptide chain. Phe = phenylalanine. (Note that this is a simplified diagram of tRNA<sup>Phe</sup>; its actual structure is shown in Figure 5-20b.) (b) Molecular model of the human mitochondrial aminoacyl-tRNA synthetase for Phe in complex with tRNA<sup>Phe</sup>. [Data from Klipcan L., et al., 2012. *J. Mol. Biol.* **415**:527, PDB ID 3tup.]

synthesis. Viewed in three dimensions, the folded tRNA molecule has an L shape, with the anticodon loop and acceptor stem forming the ends of the two arms (Figure 5-20b).

### Nonstandard Base Pairing Often Occurs Between Codons and Anticodons

If perfect Watson-Crick base pairing between codons and anticodons were required, cells would have to contain at least 61 different types of tRNAs, one for each codon that specifies an amino acid. As noted above, however, many cells contain fewer than 61 tRNAs. The explanation for the smaller number lies in the capability of a single tRNA anticodon to recognize more than one, but not necessarily every, codon corresponding to a given amino acid. This broader recognition can occur because of nonstandard pairing between bases in the so-called *wobble* position: that is, the third (3') base in an mRNA codon and the corresponding first (5') base in its tRNA anticodon.

The first and second bases of a codon almost always form standard Watson-Crick base pairs with the third and second bases, respectively, of the corresponding anticodon, but four nonstandard interactions can occur between bases

in the wobble position. Particularly important is the G•U base pair, which fits into the short, 3-bp RNA-RNA double-stranded region formed between the codon and the anticodon almost as well as the standard G•C pair. Thus a tRNA anticodon with G in the first (wobble) position can base-pair with the two corresponding codons that have either pyrimidine (C or U) in the third position (Figure 5-21). For example, the phenylalanine codons UUU and UUC (5'→3') are both recognized by the tRNA that has GAA (5'→3') as its anticodon. In fact, any two codons of the type NN<sub>Pyr</sub> (N = any base; Pyr = pyrimidine) encode a single amino acid and are decoded by a single tRNA with G in the first (wobble) position of the anticodon.

Although adenine is rarely found in the anticodon wobble position, many tRNAs in plants and animals contain inosine (I), a deaminated product of adenine, at this position. Inosine can form nonstandard base pairs with A, C, and U. A tRNA with inosine in the wobble position thus can recognize the corresponding mRNA codons with A, C, or U in the third (wobble) position (see Figure 5-21). For this reason, inosine-containing tRNAs are heavily employed in translation of the synonymous codons that specify a single amino acid. For example, four of the six codons for leucine (CUA,

**FIGURE 5-20 Structure of tRNAs.** (a) Although the exact nucleotide sequence varies among tRNAs, they all fold into four base-paired stems and three loops. The CCA sequence at the 3' end is also found in all tRNAs. Attachment of an amino acid to the 3' A yields an aminoacyl-tRNA. Some of the A, C, G, and U residues are modified post-transcriptionally in most tRNAs (see key). Dihydrouridine (D) is nearly always present in the D loop; likewise, ribothymidine (T) and pseudouridine

(Ψ) are almost always present in the TΨCG loop. Yeast alanine tRNA, represented here, also contains other modified bases. The triplet at the tip of the anticodon loop base-pairs with the corresponding codon in mRNA. See R. W. Holly et al., 1965, *Science* **147**:1462. (b) Three-dimensional model of the generalized backbone of all tRNAs. Note the L shape of the molecule. [Part (b) data from J. G. Arnez and D. Moras, 1997, *Trends Biochem. Sci.* **22**:211, PDB ID 1vtq.]

**FIGURE 5-21 Nonstandard base pairing at the wobble position.**

The base in the third (or wobble) position of an mRNA codon often forms a nonstandard base pair with the base in the first (or wobble) position of a tRNA anticodon. Wobble pairing allows a tRNA to recognize more than one mRNA codon (*top*); conversely, it allows a codon to be recognized by more than one kind of tRNA (*bottom*), although each of those tRNAs will bear the same amino acid. Note that a tRNA with I (inosine) in the wobble position can “read” (become paired with) three different codons, and a tRNA with G or U in the wobble position can read two codons. Although A is theoretically possible in the wobble position of the anticodon, it is almost never found in nature. (Note that this is a simplified diagram of a tRNA. The actual structure of a tRNA is shown in Figure 5-20b.)

CUC, CUU, and UUA) are all recognized by the same tRNA with the anticodon 3'-GAI-5'; the inosine in the wobble position forms nonstandard base pairs with the third base in each of these four codons. In the case of the UUA codon, a nonstandard G·U pair also forms between position 3 of the anticodon and position 1 of the codon.

## Amino Acids Become Activated When Covalently Linked to tRNAs

Recognition of the codon or codons specifying a given amino acid by a particular tRNA is actually the second step in decoding the genetic message. The first step, attachment of the appropriate amino acid to a tRNA, is catalyzed by a specific aminoacyl-tRNA synthetase. Each of the 20 different synthetases recognizes *one* amino acid and *all* its compatible, or *cognate*, tRNAs. These coupling enzymes link an amino acid to the free 2' or 3' hydroxyl of the adenosine at the 3' terminus of the tRNA molecule by an ATP-requiring reaction. In this reaction, the amino acid is linked to the tRNA by a high-energy bond and is thus said to be *activated*. The energy of this bond subsequently drives the formation of the peptide bonds linking adjacent amino acids in a growing polypeptide chain. The equilibrium of the aminoacylation reaction is driven further toward activation of the amino acid by hydrolysis of the high-energy phosphoanhydride bond in the released pyrophosphate (see Figure 5-19).

Aminoacyl-tRNA synthetases recognize their cognate tRNAs primarily by interacting with the anticodon loop and acceptor stem, although interactions with other regions of a tRNA also contribute to recognition in some cases. Furthermore, specific bases in incorrect tRNAs that are structurally similar to a cognate tRNA will inhibit charging of the incorrect tRNA. Thus recognition of the correct tRNA depends on both positive interactions and the absence of negative interactions. Still, because some amino acids are so similar structurally, aminoacyl-tRNA synthetases sometimes make mistakes. These mistakes are corrected, however, by the enzymes themselves, which have a *proofreading* activity that checks the fit in their amino acid-binding pocket. If the wrong amino acid becomes attached to a tRNA, the bound synthetase catalyzes removal of the amino acid from the tRNA. This crucial function helps guarantee that a tRNA delivers the correct amino acid to the protein-synthesizing machinery. The overall error rate for translation in *E. coli* is very low, approximately 1 per 50,000 codons, evidence of both the fidelity of tRNA recognition and the importance of proofreading by aminoacyl-tRNA synthetases.

### KEY CONCEPTS OF SECTION 5.3

#### The Decoding of mRNA by tRNAs

- Genetic information from DNA is carried by mRNA in the form of a non-overlapping, degenerate triplet code.

- Each amino acid is encoded by one or more three-nucleotide sequences (codons) in mRNA. Each codon specifies one amino acid, but most amino acids are encoded by multiple codons (see Table 5-1).
- The AUG codon for methionine is the most common start codon, specifying the amino acid at the amino-terminus of a protein chain. Three codons (UAA, UAG, UGA) function as stop codons and specify no amino acids.
- A reading frame, the uninterrupted sequence of codons in mRNA from a specific start codon to a stop codon, is translated into the linear sequence of amino acids in a polypeptide chain.
- Decoding of the nucleotide sequence in mRNA into the amino acid sequence of proteins depends on tRNAs and aminoacyl-tRNA synthetases.
- All tRNAs have a similar three-dimensional structure that includes an acceptor stem for attachment of a specific amino acid and a stem-loop with a three-base anticodon sequence at its end (see Figure 5-20). The anticodon can base-pair with its corresponding codon in mRNA.
- Because of nonstandard interactions, a tRNA may base-pair with more than one mRNA codon; conversely, a particular codon may base-pair with multiple tRNAs. In each case, however, only the proper amino acid is inserted into a growing polypeptide chain.
- Each of the 20 aminoacyl-tRNA synthetases recognizes a single amino acid and covalently links it to a cognate tRNA, forming an aminoacyl-tRNA (see Figure 5-19). This reaction activates the amino acid so that it can participate in peptide bond formation.

## 5.4 Stepwise Synthesis of Proteins on Ribosomes

The previous sections have introduced two of the major participants in protein synthesis: mRNA and aminoacyl-tRNA. Here we first describe the third key player in protein synthesis—the rRNA-containing ribosome—before taking a detailed look at how all three components are brought together to carry out the biochemical events leading to the formation of polypeptide chains by ribosomes. Like transcription, the complex process of translation can be divided into three stages—initiation, elongation, and termination—which we consider in order. We focus our description on translation in eukaryotic cells, but the mechanism of translation is fundamentally the same in all cells.

### Ribosomes Are Protein-Synthesizing Machines

If the many components that participate in translating mRNA had to interact in free solution, the likelihood of their

coming together would be so low that the rate of amino acid polymerization would be very slow. The efficiency of translation is greatly increased by the binding of mRNA and the individual aminoacyl-tRNAs within a ribosome. The ribosome, the most abundant RNA-protein complex in the cell, directs elongation of polypeptides at a rate of 3 to 5 amino acids added per second. Small proteins of 100–200 amino acids are therefore made in a minute or less. On the other hand, it takes 2–3 hours to make the largest known protein, titin, which is found in muscle and contains about 30,000 amino acid residues. The cellular machine that accomplishes this task must be precise and persistent.

With the aid of the electron microscope, ribosomes were first discovered as small, discrete, RNA-rich particles in cell types that secrete large amounts of protein. However, their role in protein synthesis was not recognized until reasonably pure ribosome preparations were obtained. In vitro radiolabeling experiments with such preparations showed that radioactive amino acids were incorporated into growing polypeptide chains associated with ribosomes before appearing in finished chains.

Although there are differences between the ribosomes of bacteria, archaea, and eukaryotes, the great structural and functional similarities between ribosomes from all species reflect the common evolutionary origin of the most basic constituents of living cells. A ribosome is composed of three (in bacteria and archaea) or four (in eukaryotes) different rRNA molecules and as many as 80 proteins, organized into a large subunit and a small subunit (Figure 5-22 and Table 5-3). The ribosomal subunits and the rRNA molecules are commonly designated in svedberg units (S), a measure of

**FIGURE 5-22 Structure of the bacterial ribosome.** Model of the *T. thermophilus* ribosome viewed along the interface between the large (50S) and small (30S) subunits. The 16S rRNA and proteins in the small subunit are dark gray. RNA is depicted as a tube model and protein surfaces are shown; the 23S rRNA and proteins in the large subunit are light gray; and the 5S rRNA is an intermediate shade of gray. The surface of the ribosome is made partially transparent to display the positions of tRNAs in the A, P, and E sites. Note that the ribosomal proteins are located primarily on the surface of the ribosome. [Data from A. Korostelev et al., 2006, *Cell* **126**:1065-1077, PDB ID 4v4i.]

Khatter et al., 2015, *Nature* **520**:640; PDB ID 4ug0.]

the sedimentation rate of macromolecules centrifuged under standard conditions—essentially, a logarithmic measure of size. The small ribosomal subunit contains a single rRNA molecule, referred to as *small rRNA*. The large subunit contains a molecule of *large rRNA* and one molecule of 5S rRNA, plus an additional molecule of 5.8S rRNA in vertebrates. The lengths of the rRNA molecules, the numbers of proteins in each subunit, and consequently, the sizes of the subunits differ between bacterial and eukaryotic cells (see Table 5-3). The assembled ribosome is 70S in bacteria and 80S in vertebrates.

The sequences of the small and large rRNAs from several thousand organisms are now known. Although the primary nucleotide sequences of these rRNAs vary considerably, the same parts of each type of rRNA theoretically can form base-paired hairpins, stem-loops, and loop-loop interactions (see Figure 5-9), which would generate a similar three-dimensional core structure in the rRNAs and proteins of all organisms. The three-dimensional structures of bacterial and yeast ribosomes (see Figure 5-23) and of the large subunit of an archaeal ribosome have been determined by x-ray crystallography. The structures of human (see Figure 5-23) and plant ribosomes have also been determined by cryoelectron microscopy. The structure of the rRNAs in the common core, where mRNAs and tRNAs are bound and where peptide bond formation is catalyzed, is similar in all three domains of life. However, archaeal rRNAs and proteins are more similar to those of eukaryotic ribosomes than to those of bacterial ribosomes, reflecting their later divergence from a common ancestor (see Figure 1-1). For the most part, the multiple ribosomal proteins are much smaller than the rRNAs and associate with the surface of the ribosomes. Although the number of protein molecules in ribosomes greatly exceeds the number of RNA molecules,

RNA constitutes about 60 percent of the mass of a bacterial ribosome, and about 50 percent of the mass of a human ribosome. Eukaryotic ribosomes are generally similar to bacterial ribosomes, but are larger because of eukaryote-specific insertions of RNA segments into regions of the common core rRNAs as well as the presence of a larger number of proteins (see Figure 5-23 and Table 5-3). Basic aspects of protein synthesis are thought to be similar among all three domains, although initiation of translation in eukaryotes, discussed later, is more complex and subject to additional mechanisms of regulation.

 The high-resolution structures of ribosomes are providing new insights into the mechanism by which many antibiotics inhibit bacterial protein synthesis without affecting the function of mammalian ribosomes. These insights are providing important clues for the design and synthesis of new antibiotics. Such research is desperately needed as the occurrence of bacteria resistant to currently available antibiotics becomes increasingly more common, especially in hospitals, where antibiotic-resistant bacteria are under positive selection. ■

### Methionyl-tRNA<sup>Met</sup> Recognizes the AUG Start Codon

As noted earlier, the AUG codon for methionine functions as the start codon in the vast majority of mRNAs. A critical aspect of translation initiation is to begin protein synthesis at the start codon, thereby establishing the correct reading frame for the entire mRNA. Both bacteria and eukaryotes contain two different methionine tRNAs: tRNA<sup>Met</sup> can initiate protein synthesis, and tRNA<sup>Met</sup> can incorporate methionine only into a growing protein chain. The same

aminoacyl-tRNA synthetase (MetRS) charges both tRNAs with methionine. But *only* Met-tRNA<sub>i</sub><sup>Met</sup> (i.e., activated methionine attached to tRNA<sub>i</sub><sup>Met</sup>) can bind at the appropriate site on the small ribosomal subunit, the *P site*, to begin synthesis of a polypeptide chain. The regular Met-tRNA<sup>Met</sup>, and all other charged tRNAs, bind only to the *A site*, as described later. tRNAs enter the exit or *E site* after transferring their covalently bound amino acids to the growing polypeptide chain.

## Eukaryotic Translation Initiation Usually Occurs at the First AUG Downstream from the 5' End of an mRNA

During the first stage of translation, the small and large ribosomal subunits assemble around an mRNA that has a Met-tRNA<sub>i</sub><sup>Met</sup> correctly positioned at the start codon in the ribosomal P site. In eukaryotes, the assembly of this complex is mediated by a special set of proteins known as **eukaryotic translation initiation factors (eIFs)**. As each individual component joins the complex, it is guided by interactions with specific eIFs. Several of the initiation factors bind GTP, and the hydrolysis of GTP to GDP functions as a proofreading switch that allows subsequent steps to proceed only if the preceding step has occurred correctly. Before GTP hydrolysis, the complex is unstable, allowing dissociation of the components and a second attempt at complex formation until the correct complex assembles, resulting in GTP hydrolysis and stabilization of the appropriate complex.

Considerable progress has been made in the past few years in understanding translation initiation in vertebrates. The current model for initiation of translation in vertebrates is depicted in Figure 5-24. Large and small ribosomal subunits released from a previous round of translation are kept apart by the binding of eIFs 1, 1A, and 3 to the small 40S subunit (Figure 5-24, *top*). The first step of translation initiation is formation of a *43S preinitiation complex*. This preinitiation complex is formed when the 40S subunit with eIFs 1, 1A, and 3 associates with eIF5 and a ternary (three-part) complex consisting of the Met-tRNA<sub>i</sub><sup>Met</sup> and eIF2 bound to GTP (Figure 5-24, steps **1** and **2**). The initiation factor eIF2 alternates between association with GTP and GDP; it can bind Met-tRNA<sub>i</sub><sup>Met</sup> only when it is associated with GTP. Cells can inhibit protein synthesis by phosphorylating a serine residue on the eIF2 bound to GDP; the phosphorylated complex is unable to exchange the bound GDP for GTP and cannot bind Met-tRNA<sub>i</sub><sup>Met</sup> so protein synthesis cannot occur.

The mRNA to be translated is bound by the multisubunit eIF4 complex, which interacts with both the 5' cap and the cytoplasmic poly(A)-binding protein (PABPC) bound in multiple copies to the mRNA poly(A) tail. Both interactions are required for translation of most mRNAs. This binding results in the formation of a circular complex (Figure 5-24, step **3**). The eIF4 cap-binding complex consists of several subunits with different functions. The eIF4E subunit binds

the 5' cap on mRNAs (see Figure 5-14). The large eIF4G subunit binds cooperatively to several PABPC proteins bound to the mRNA poly(A) tail, and also forms a scaffold to which the other eIF4 subunits bind. The mRNA-eIF4 complex then associates with the preinitiation complex through an interaction between eIF4G and eIF3 (step **4**).

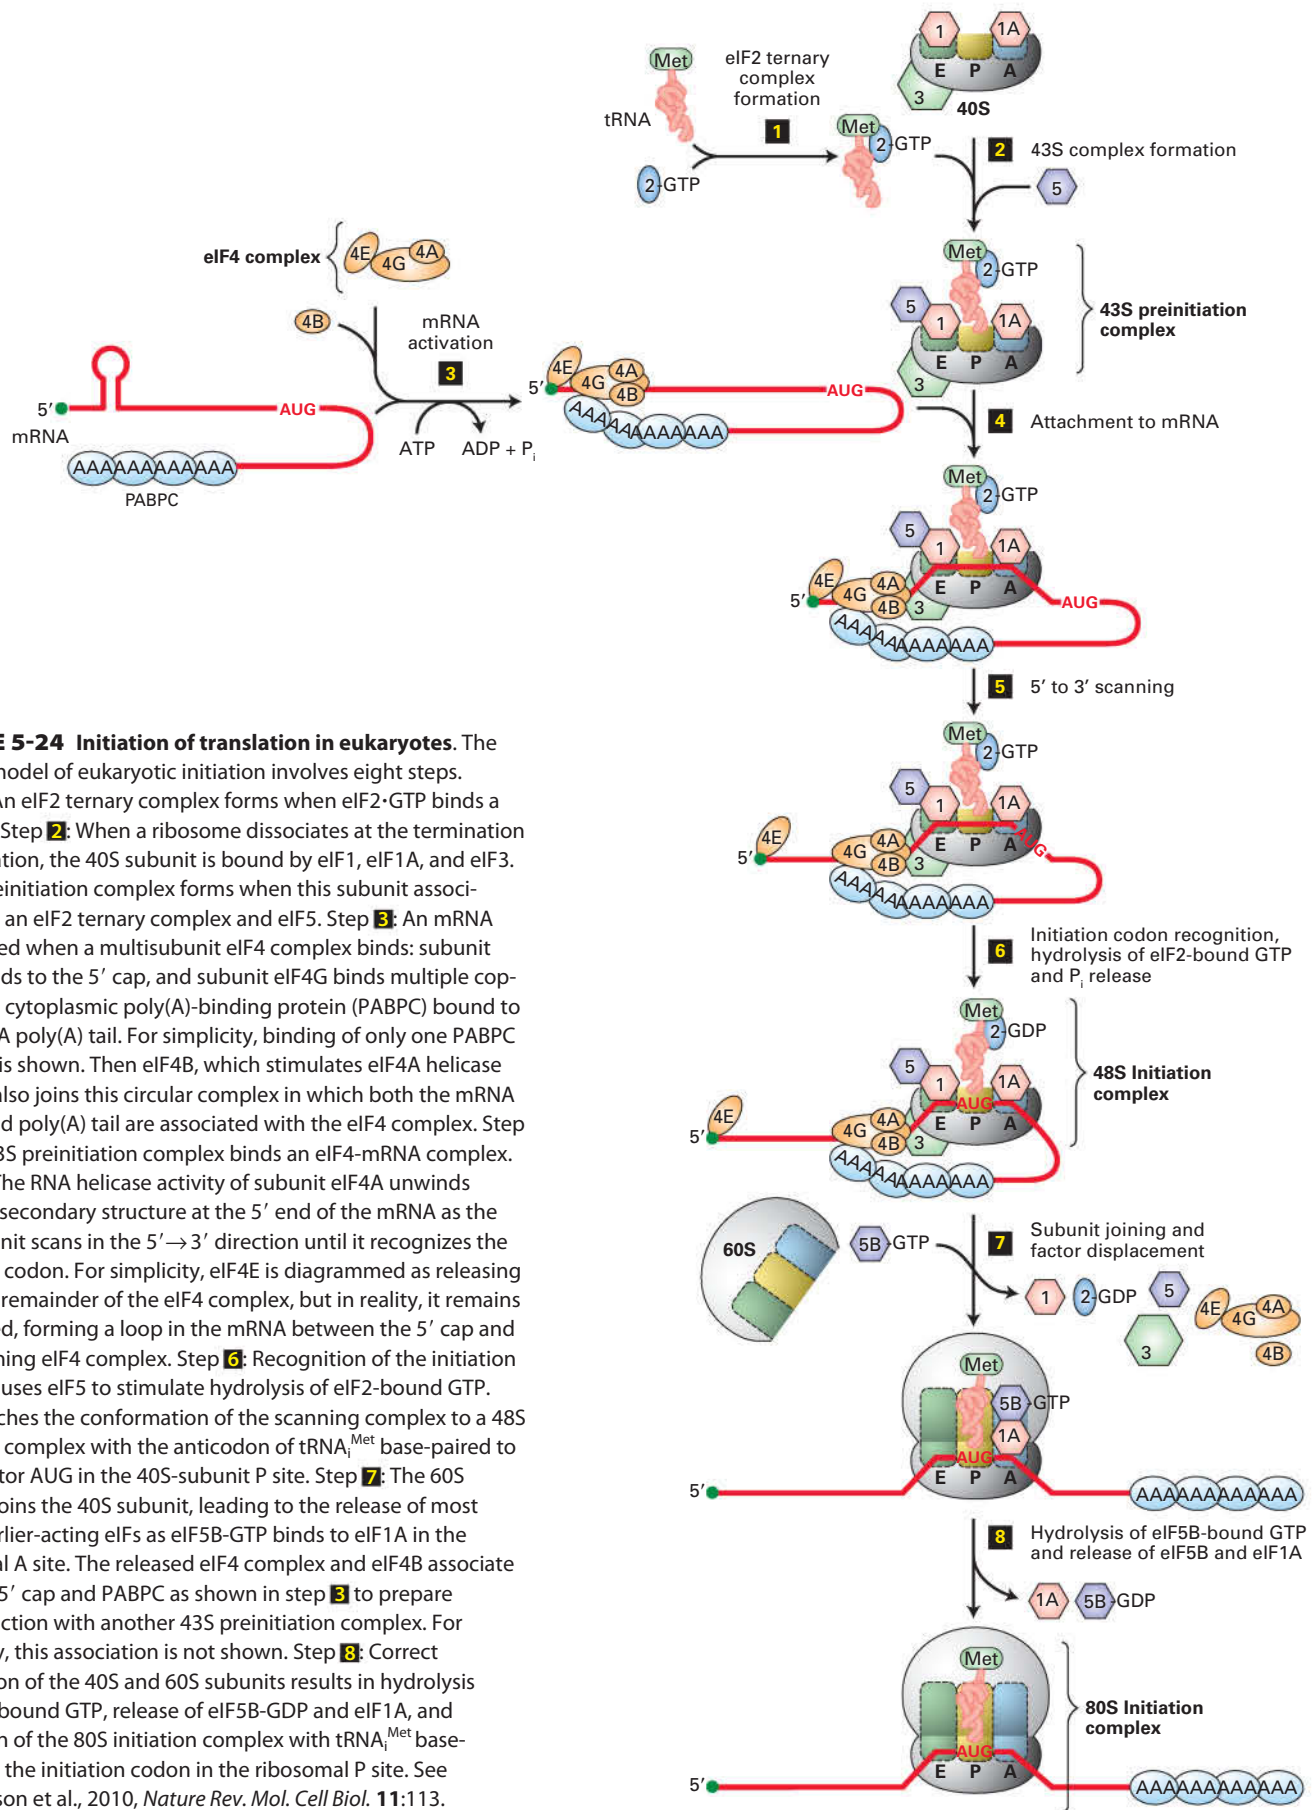

The initiation complex then slides along, or *scans*, the associated mRNA as the **helicase** activity of eIF4A, stimulated by eIF4B, uses energy from ATP hydrolysis to unwind the RNA secondary structure (step **5**). Scanning stops when the tRNA<sub>i</sub><sup>Met</sup> anticodon recognizes the start codon, which is the first AUG downstream from the 5' end in most eukaryotic mRNAs. Recognition of the start codon leads to hydrolysis of the GTP associated with eIF2, an irreversible step that prevents further scanning, resulting in formation of the *48S initiation complex* (step **6**). This commitment to the correct initiation codon is facilitated by eIF5, an eIF2 GTPase-activating protein (GAP, see Figure 3-34). Selection of the initiating AUG is facilitated by specific surrounding nucleotides called the *Kozak sequence*, for Marilyn Kozak, who defined it: (5')**ACCAUGG**(3'). The A preceding the AUG (in bold) and the G immediately following it are the most important nucleotides affecting translation initiation efficiency.

Association of the large (60S) subunit with the small subunit, which is mediated by eIF5B bound to GTP, results in displacement of many of the initiation factors (step **7**). Correct association between the ribosomal subunits results in hydrolysis of the eIF5B-bound GTP to GDP and the release of eIF5B-GDP and eIF1A (step **8**), completing the formation of an *80S initiation complex*. Coupling of the ribosome subunit-joining reaction to GTP hydrolysis by eIF5B allows the initiation process to continue only when the subunit interaction has occurred correctly. It also makes this an irreversible step, so that the ribosomal subunits do not dissociate until the entire mRNA is translated and protein synthesis is terminated.

The eukaryotic protein-synthesizing machinery begins translation of most cellular mRNAs within about 100 nucleotides of the 5'-capped end as just described. However, some cellular mRNAs contain an internal ribosome entry site (IRES) located far downstream from the 5' end. It is thought that cellular IRESs form RNA structures that interact with a complex of eIF4A and eIF4G, which then associates with eIF3 bound to a 40S subunit with eIF1 and eIF1A. This assembly then binds an eIF2 ternary complex to assemble an initiation complex directly on a neighboring AUG codon. In addition, translation of some positive-stranded viral RNAs, which lack a 5' cap, is initiated at viral IRES sequences. These RNAs fall into different classes depending on how many of the standard eIFs are required for initiation. In the case of cricket paralysis virus, the ~200-nt-long IRES folds into a complex structure that interacts directly with the 40S ribosomal subunit and leads to initiation without any of the eIFs or even the initiator Met-tRNA<sub>i</sub><sup>Met</sup>!

In bacteria, binding of the small ribosomal subunit to an initiation site occurs by a different mechanism that

**FIGURE 5-24 Initiation of translation in eukaryotes.** The current model of eukaryotic initiation involves eight steps. **Step 1:** An eIF2 ternary complex forms when eIF2-GTP binds a tRNA<sup>Met</sup>. **Step 2:** When a ribosome dissociates at the termination of translation, the 40S subunit is bound by eIF1, eIF1A, and eIF3. A 43S preinitiation complex forms when this subunit associates with an eIF2 ternary complex and eIF5. **Step 3:** An mRNA is activated when a multisubunit eIF4 complex binds: subunit eIF4E binds to the 5' cap, and subunit eIF4G binds multiple copies of the cytoplasmic poly(A)-binding protein (PABPC) bound to the mRNA poly(A) tail. For simplicity, binding of only one PABPC to eIF4G is shown. Then eIF4B, which stimulates eIF4A helicase activity, also joins this circular complex in which both the mRNA 5' cap and poly(A) tail are associated with the eIF4 complex. **Step 4:** The 43S preinitiation complex binds an eIF4-mRNA complex. **Step 5:** The RNA helicase activity of subunit eIF4A unwinds any RNA secondary structure at the 5' end of the mRNA as the 40S subunit scans in the 5' → 3' direction until it recognizes the initiation codon. For simplicity, eIF4E is diagrammed as releasing from the remainder of the eIF4 complex, but in reality, it remains associated, forming a loop in the mRNA between the 5' cap and the scanning eIF4 complex. **Step 6:** Recognition of the initiation codon causes eIF5 to stimulate hydrolysis of eIF2-bound GTP. This switches the conformation of the scanning complex to a 48S initiation complex with the anticodon of tRNA<sup>Met</sup> base-paired to the initiator AUG in the 40S-subunit P site. **Step 7:** The 60S subunit joins the 40S subunit, leading to the release of most of the earlier-acting eIFs as eIF5B-GTP binds to eIF1A in the ribosomal A site. The released eIF4 complex and eIF4B associate with the 5' cap and PABPC as shown in step 3 to prepare for interaction with another 43S preinitiation complex. For simplicity, this association is not shown. **Step 8:** Correct association of the 40S and 60S subunits results in hydrolysis of eIF5B-bound GTP, release of eIF5B-GDP and eIF1A, and formation of the 80S initiation complex with tRNA<sup>Met</sup> base-paired to the initiation codon in the ribosomal P site. See R. J. Jackson et al., 2010, *Nature Rev. Mol. Cell Biol.* 11:113.

allows initiation at internal sites in the polycistronic mRNAs transcribed from operons. In bacterial mRNAs, a ~6-bp sequence complementary to the 3' end of the small rRNA precedes the AUG start codon by 4–7 nucleotides. Base pairing between this sequence in the mRNA, called the Shine-Dalgarno sequence after its discoverers, and the small rRNA places the small ribosomal subunit in the proper position for initiation. Initiation factors comparable to eIF1A, eIF2, eIF3, and f-Met-tRNA<sub>i</sub><sup>Met</sup> then associate with the small subunit, followed by association of the large subunit to form the complete bacterial ribosome.

### During Chain Elongation Each Incoming Aminoacyl-tRNA Moves Through Three Ribosomal Sites

The correctly positioned ribosome–Met-tRNA<sub>i</sub><sup>Met</sup> complex is now ready to begin the task of stepwise addition of amino acids by in-frame translation of the mRNA. As is the case with initiation, a set of specialized proteins, termed translation **elongation factors** (EFs), is required to carry out this process of chain elongation. The key steps in elongation are the entry of each succeeding aminoacyl-tRNA with an anticodon complementary to the next codon, the formation of a peptide bond, and the movement, or *translocation*, of the ribosome one codon at a time along the mRNA.

At the completion of translation initiation, as noted already, Met-tRNA<sub>i</sub><sup>Met</sup> is bound to the P site on the assembled 80S ribosome (Figure 5-25, *top*). This region of the ribosome is called the *P* site because the tRNA chemically linked to the growing polypeptide chain is located here. The second aminoacyl-tRNA is brought into the ribosome as a ternary complex in association with EF1α•GTP and becomes bound to the *A* site, so named because it is where aminoacyl-tRNAs bind (step **1**). EF1α•GTP bound to various aminoacyl-tRNAs diffuse into the *A* site, but the next step in translation proceeds only when the tRNA anticodon base-pairs with the second codon in the coding region. When that occurs properly, the GTP in the associated EF1α•GTP is hydrolyzed. The hydrolysis of GTP promotes a conformational change

in EF1α that leads to release of the resulting EF1α•GDP complex and tight binding of the aminoacyl-tRNA in the *A* site (step **2**). This conformational change also positions the aminoacylated 3' end of the tRNA in the *A* site close to the 3' end of the Met-tRNA<sub>i</sub><sup>Met</sup> in the *P* site. GTP hydrolysis, and hence tight binding, does not occur if the anticodon of the incoming aminoacyl-tRNA cannot base-pair with the

**FIGURE 5-25 Chain elongation in eukaryotes.** Once the 80S ribosome with Met-tRNA<sub>i</sub><sup>Met</sup> in the ribosome P site is assembled (*top*), a ternary complex bearing the second amino acid (aa<sub>2</sub>) coded by the mRNA binds to the A site (step **1**). Following a conformational change in the ribosome induced by hydrolysis of GTP in EF1α•GTP (step **2**), the large rRNA catalyzes peptide bond formation between Met<sub>i</sub> and aa<sub>2</sub> (step **3**). Hydrolysis of GTP in EF2•GTP causes another conformational change in the ribosome that results in its translocation one codon along the mRNA and shifts the unacylated tRNA<sub>i</sub><sup>Met</sup> to the E site and the tRNA with the bound peptide to the P site (step **4**). The cycle can begin again with binding of a ternary complex bearing aa<sub>3</sub> to the now open A site. In the second and subsequent elongation cycles, the tRNA at the E site is ejected during step **2** as a result of the conformational change induced by hydrolysis of GTP in EF1α•GTP.

codon at the A site. In this case, the ternary complex diffuses away, leaving an empty A site that can associate with other aminoacyl-tRNA- $\text{EF1}\alpha\cdot\text{GTP}$  complexes until a correctly base-paired tRNA is bound. Thus GTP hydrolysis by  $\text{EF1}\alpha$  is another proofreading step that allows protein synthesis to proceed only when the correct aminoacyl-tRNA is bound to the A site. This phenomenon contributes to the fidelity of protein synthesis.

With the initiating  $\text{Met-tRNA}_i^{\text{Met}}$  at the P site and the second aminoacyl-tRNA tightly bound at the A site, the  $\alpha$ -amino group of the second amino acid reacts with the “activated” (ester-linked) methionine on the initiator tRNA, forming a peptide bond (Figure 5-25, step 3; see Figure 5-17). This *peptidyltransferase reaction* is catalyzed by the large rRNA, which precisely orients the interacting atoms, permitting the reaction to proceed. The 2'-hydroxyl of the terminal A of the peptidyl-tRNA in the P site also participates in catalysis. The catalytic ability of the large rRNA in bacteria has been demonstrated by carefully removing the vast majority of the protein from large ribosomal subunits. The nearly pure bacterial 23S rRNA can catalyze a peptidyltransferase reaction between analogs of aminoacyl-tRNA and peptidyl-tRNA. Further support for the catalytic role of large rRNA in protein synthesis came from high-resolution crystallographic studies showing that no proteins lie near the site of peptide bond synthesis in the crystal structure of the bacterial large subunit.

Following peptide bond synthesis, the ribosome translocates a distance equal to one codon along the mRNA. This translocation step is monitored by hydrolysis of the GTP in eukaryotic  $\text{EF2}\cdot\text{GTP}$ . Once translocation has occurred correctly, the bound GTP is hydrolyzed, another irreversible process that prevents the ribosome from moving along the RNA in the wrong direction or from translocating an incorrect number of nucleotides. As a result of conformational changes in the ribosome that accompany proper translocation and the resulting GTP hydrolysis by  $\text{EF2}$ ,  $\text{tRNA}_i^{\text{Met}}$ , now without its activated methionine, is moved to the E (exit) site on the ribosome; concurrently, the second tRNA, now covalently bound to a dipeptide (a peptidyl-tRNA), is moved to the P site (Figure 5-25, step 4). Translocation thus returns the ribosome conformation to a state in which the A site is open and able to accept another aminoacyl-tRNA complexed with  $\text{EF1}\alpha\cdot\text{GTP}$ , beginning another cycle of chain elongation.

Repetition of the elongation cycle depicted in Figure 5-25 adds amino acids one at a time to the carboxyl terminus of the growing polypeptide as directed by the mRNA sequence until a stop codon is encountered. In subsequent cycles, the conformational change that occurs in step 2 ejects the unacylated tRNA from the E site. As the nascent polypeptide chain becomes longer, it threads through a channel in the large ribosomal subunit, exiting at a position opposite the side that interacts with the small subunit (Figures 5-22, 5-26).

In the absence of the ribosome, the three-base-pair RNA-RNA hybrid between the tRNA anticodons and the mRNA codons in the A and P sites would not be stable; RNA-RNA duplexes between separate RNA molecules must be considerably

**FIGURE 5-26 Termination of translation in eukaryotes.** When a ribosome bearing a nascent protein chain reaches a stop codon (UAA, UGA, UAG), release factor  $\text{eRF1}$  enters the A site together with  $\text{eRF3}\cdot\text{GTP}$ . Hydrolysis of the bound GTP is accompanied by cleavage of the peptide chain from the tRNA in the P site and ejection of the tRNA in the E site, forming a post-termination complex. The ribosomal subunits are separated by the action of the ABC E1 ATPase together with  $\text{eIF1}$ ,  $\text{eIF1A}$ , and  $\text{eIF3}$ . The 40S subunit is released bound to these eIFs, ready to initiate another cycle of translation (see Figure 5-24).

longer to be stable under physiological conditions. However, multiple interactions between the large and small rRNAs and the general domains of tRNAs (e.g., the D and T $\psi$ CG loops,

see Figure 5-20) stabilize the tRNAs in the A and P sites, while other RNA-RNA interactions sense correct codon-anticodon base pairing, ensuring that the genetic code is read properly. Then, interactions between rRNAs and the general domains of all tRNAs result in the movement of the tRNAs between the A, P, and E sites as the ribosome translocates along the mRNA one three-nucleotide codon at a time.

### Translation Is Terminated by Release Factors When a Stop Codon Is Reached

The final stages of translation, like initiation and elongation, require highly specific molecular signals that decide the fate of the mRNA-ribosome-peptidyl-tRNA complex. Two types of specific protein **release factors (RFs)** have been discovered. Eukaryotic eRF1, whose shape is similar to that of tRNAs, acts by binding to the ribosomal A site and recognizing stop codons directly. Like some of the initiation and elongation factors discussed previously, the second eukaryotic release factor, eRF3, is a GTP-binding protein. The eRF3-GTP complex acts in concert with eRF1 to promote cleavage of the peptidyl-tRNA bond, thus releasing the completed protein chain and terminating translation (Figure 5-26). Bacteria have two release factors (RF1 and RF2) that are functionally analogous to eRF1 and a GTP-binding factor (RF3) that is analogous to eRF3. Once again, the eRF3 GTPase monitors the correct recognition of a stop codon by eRF1. The peptidyl-tRNA bond of the tRNA in the P site is not cleaved until one of the three stop codons is correctly recognized by eRF1, another example of a proof-reading step in protein synthesis.

Release of the completed protein leaves a free tRNA in the P site and the mRNA still associated with the 80S ribosome, to which eRF1 and eRF3-GDP are still bound in the A site. In eukaryotes, ribosome recycling occurs when this post-termination complex is bound by a protein called ABCE1, which uses energy from ATP hydrolysis to separate the subunits and release the mRNA and tRNA in the P site. Initiation factors eIF1, eIF1A, and eIF3, which are also required for separation of the subunits, load onto the 40S subunit, making it ready for another round of initiation (see Figure 5-24, *top*). In reality, a free mRNA is never released as diagrammed in Figure 5-26 for simplicity. Rather, the mRNA has other ribosomes associated with it in various stages of elongation, PABPC bound to the poly(A) tail, and the eIF4 complex associated with the 5' cap, ready to associate with another 43S preinitiation complex (see Figure 5-24).

In addition to these functions in protein synthesis, ribosomes also associate transiently with protein chaperones that assist in folding the polypeptide chain as it emerges from the ribosome surface (see Figure 3-17). As we will see in Chapter 13, ribosomes that synthesize proteins destined to be inserted into the endoplasmic reticulum (ER), transported into the ER lumen and later secreted from the cell, or introduced into other organelles such as lysosomes, also associate with a ribonucleoprotein complex called SRP (signal recognition particle) that arrests protein synthesis until

the nascent polypeptide encounters specialized channels for insertion into the ER. SRP also assists with the insertion and threading of these proteins through these ER channels when protein synthesis is permitted to resume.

### Polysomes and Rapid Ribosome Recycling Increase the Efficiency of Translation

Translation of a single eukaryotic mRNA molecule to yield a typical-sized protein takes 1 to 2 minutes. Two phenomena significantly increase the overall rate at which cells can synthesize a protein: the simultaneous translation of a single mRNA molecule by multiple ribosomes, and rapid recycling of ribosomal subunits after they disengage from a stop codon. Simultaneous translation of an mRNA by multiple ribosomes is readily observable in electron micrographs and by sedimentation analysis, revealing mRNA molecules attached to multiple ribosomes bearing nascent growing polypeptide chains. These structures, referred to as **polyribosomes** or *polysomes*, were seen to be circular in electron micrographs of some tissues. Subsequent studies with purified initiation factors explained the circular shape of polyribosomes and suggested the mechanism by which ribosomes recycle efficiently.

These studies revealed that multiple copies of the cytoplasmic poly(A)-binding protein (PABPC) interact with both an mRNA poly(A) tail and the eIF4G subunit of eIF4. Since the eIF4E subunit of eIF4 binds to the cap structure on the 5' end of an mRNA, the two ends of an mRNA molecule are bridged by the intervening proteins, forming a “circular” mRNA (Figure 5-27a). Because the two ends of a polysome are relatively close together, ribosomal subunits that disengage from a stop codon are positioned near the 5' end, facilitating reinitiation by the interaction of the 40S subunit and its associated initiation factors with eIF4 bound to the 5' cap. The circular pathway depicted in Figure 5-27b is thought to enhance ribosome recycling and thus increase the efficiency of protein synthesis.

### GTPase-Superfamily Proteins Function in Several Quality-Control Steps of Translation

We can now see that one or more GTP-binding proteins participate in each stage of translation. These proteins belong to the **GTPase superfamily** of switch proteins that cycle between a GTP-bound active form and a GDP-bound inactive form (see Figure 3-34). Hydrolysis of the bound GTP causes a conformational change in the GTPase itself and in other associated proteins that are critical to various complex molecular processes. In translation initiation, for instance, hydrolysis of eIF2-GTP to eIF2-GDP prevents further scanning of the mRNA once the start site is encountered and allows binding of the large ribosomal subunit to the small subunit (see Figure 5-24, step 6). Similarly, hydrolysis of eIF5B-GTP monitors successful association of the large and small ribosomal subunits (Figure 5-24 step 8). Recall that if the correct complex does not form, eIF5B-GTP does not hydrolyze the GTP and the complex is unstable, free to diffuse apart

**EXPERIMENTAL FIGURE 5-27 Circular structure of mRNA increases translation efficiency.** Eukaryotic mRNA forms a circular structure owing to interactions of three proteins. (a) In the presence of purified yeast poly(A)-binding protein [PABP; there is only one PABP in *S. cerevisiae*, rather than a nuclear (PABPN) and cytoplasmic (PABPC) protein as in higher eukaryotes], eIF4E, and eIF4G, eukaryotic mRNAs form circular structures, visible in this force-field electron micrograph. In these structures, protein-protein and protein-mRNA interactions form a bridge between the 5' and 3' ends of the mRNA. (b) Model of protein synthesis on circular polysomes and recycling of ribosomal subunits. Multiple individual ribosomes can simultaneously translate a eukaryotic mRNA, shown here in a circular form stabilized by interactions between proteins bound at the 3' and 5' ends. When a ribosome completes translation and dissociates from the 3' end, the separated subunits can rapidly find the nearby 5' cap (m<sup>7</sup>G) and PABPC-bound poly(A) tail and initiate another round of synthesis. [Part (a) courtesy of Alan Sachs and Sandra Wells.]

and try again. When the precise alignment of the subunits required for elongation occurs, eIF5B hydrolyzes the GTP to GDP, locking the correct complex in place. Energy released from the high energy  $\beta$ - $\gamma$  bond in GTP drives the reaction in one direction. In another example, hydrolysis of EF1 $\alpha$ ·GTP to EF1 $\alpha$ ·GDP during chain elongation occurs only when the A site is occupied by a charged tRNA with an anticodon that base-pairs with the codon in that site. GTP hydrolysis causes a conformational change in EF1 $\alpha$  that results in the release of its bound tRNA, allowing the aminoacylated 3' end of the charged tRNA to move into the position required for peptide bond formation (see Figure 5-25, step 2). Hydrolysis of EF2·GTP to EF2·GDP leads to correct translocation of the ribosome along the mRNA (see Figure 5-25, step 4), and hydrolysis of eRF3·GTP to eRF3·GDP ensures correct termination of translation (see Figure 5-26).

### Nonsense Mutations Cause Premature Termination of Protein Synthesis

One kind of mutation that can inactivate a gene in any organism is a base-pair change that converts a codon normally encoding an amino acid into a stop codon, such as a change from UAC (encoding tyrosine) to UAG (stop). When such a mutation occurs early in the reading frame, the resulting truncated protein is usually nonfunctional. Such mutations are called *nonsense* mutations because when the genetic code equating each triplet codon sequence with a single amino acid was being deciphered by researchers, the three stop codons were found not to encode any amino acid—they did not “make sense.”

In genetic studies with the bacterium *E. coli*, it was discovered that the effect of a nonsense mutation can be suppressed by a second mutation in a tRNA gene. This occurs when the sequence in a tRNA gene that encodes the anticodon is changed to a triplet that is complementary to the original mutant stop codon. For example, if a mutation in tRNA<sup>Tyr</sup> changes its anticodon from GUA to CUA, which can base-pair with the UAG stop codon, then the mutant tRNA<sup>Tyr</sup> can still be recognized by the tyrosine aminoacyl-tRNA synthetase and coupled to tyrosine. Cells that have both the original nonsense mutation and the second mutation in the anticodon of the tRNA<sup>Tyr</sup> gene consequently can insert a tyrosine at the position of the mutant stop codon, allowing protein synthesis to continue past the original nonsense mutation. This mechanism is not highly efficient, so translation of normal mRNAs with a UAG stop codon terminates at the normal position in most instances. If enough of the protein encoded by the original gene with the nonsense mutation is produced to provide its essential functions, the effect of the first mutation is said to be *suppressed* by the second mutation in the anticodon of the tRNA gene.

This mechanism of *nonsense suppression* is a powerful tool in genetic studies of bacteria. For example, it allows us to isolate mutant bacterial viruses that cannot grow in normal cells but can grow in cells expressing a nonsense-suppressing tRNA because the mutant virus has a nonsense mutation in an essential gene. Such mutant viruses grown on nonsense-suppressing cells can then be used in experiments to analyze

the function of the mutant gene by infecting normal cells that do not suppress the mutation and analyzing what step in the viral life cycle is defective in the absence of the mutant protein.

## KEY CONCEPTS OF SECTION 5.4

### Stepwise Synthesis of Proteins on Ribosomes

- Bacterial, archaeal, and eukaryotic ribosomes—the large ribonucleoprotein complexes on which translation occurs—consist of a small and a large subunit (see Table 5-3). Each subunit contains numerous different proteins and one major rRNA molecule (small or large). The large subunit also contains one accessory 5S rRNA in bacteria and archaea and two accessory rRNAs in eukaryotes (5S and 5.8S).
- Analogous rRNAs from many different species fold into quite similar three-dimensional structures containing numerous stem-loops and binding sites for proteins, mRNA, and tRNAs. Much smaller ribosomal proteins are associated with the periphery of the rRNAs.
- Of the two methionine tRNAs found in all cells, only one ( $\text{tRNA}_i^{\text{Met}}$ ) functions in initiation of translation.
- Each stage of translation—initiation, chain elongation, and termination—requires specific protein factors, including GTP-binding proteins that hydrolyze their bound GTP to GDP when a step has been completed successfully.
- During initiation, the ribosomal subunits assemble near the translation start site in an mRNA molecule on which a tRNA carrying the amino-terminal methionine ( $\text{Met-tRNA}_i^{\text{Met}}$ ) has base-paired with the start codon (see Figure 5-24).
- Chain elongation entails a repetitive four-step cycle: loose binding of an incoming aminoacyl-tRNA to the A site on the ribosome; tight binding of the correct aminoacyl-tRNA to the A site accompanied by release of the previously used tRNA from the E site; transfer of the growing polypeptide chain to the incoming amino acid catalyzed by large rRNA; and translocation of the ribosome to the next codon, thereby moving the peptidyl-tRNA in the A site to the P site and the now unacylated tRNA in the P site to the E site (see Figure 5-25).
- In each cycle of chain elongation, the ribosome undergoes two conformational changes monitored by GTP-binding proteins. The first of these proteins ( $\text{EF1}\alpha$ ) permits tight binding of the incoming aminoacyl-tRNA to the A site and ejection of a tRNA from the E site, and the second ( $\text{EF2}$ ) monitors translocation.
- Termination of translation is carried out by two types of termination factors: those that recognize stop codons and those that promote hydrolysis of peptidyl-tRNA (see Figure 5-26). Once again, correct recognition of a stop codon is monitored by a GTPase ( $\text{eRF3}$ ).

- The efficiency of protein synthesis is increased by the simultaneous translation of a single mRNA by multiple ribosomes, forming a polyribosome or polysome. In eukaryotic cells, protein-mediated interactions bring the two ends of a polyribosome close together, thereby promoting the rapid recycling of ribosomal subunits, which further increases the efficiency of protein synthesis (see Figure 5-27b).

## 5.5 DNA Replication

Now that we have seen how the genetic information encoded in the nucleotide sequence of DNA is translated into the proteins and RNAs that perform most cell functions, we can appreciate the necessity for precisely copying DNA sequences during DNA replication, in preparation for cell division (see Figure 5-1, step 4). The regular pairing of bases in the double-helical DNA structure suggested to Watson and Crick that new DNA strands are synthesized by using the existing (*parent*) strands as templates in the formation of new, *daughter* strands that are complementary to the parent strands.

This base-pairing template model theoretically could proceed by either a conservative or a semiconservative mechanism. If a *conservative* mechanism were used, the two daughter strands would form a new double-stranded DNA molecule and the parent duplex would remain intact. If a *semiconservative* mechanism were used, the parent strands would be permanently separated and each would form a duplex molecule with the newly synthesized daughter strand base-paired to it. Definitive evidence that duplex DNA is replicated by a semiconservative mechanism came from a now classic experiment conducted by M. Meselson and W. F. Stahl, outlined in Figure 5-28.

Copying of a DNA template strand into a complementary strand is thus a common feature of DNA replication, transcription of DNA into RNA, and as we will see later in this chapter, DNA repair and recombination. In all cases, the information in the template, in the form of the specific sequence of nucleotides, is preserved. In some viruses, single-stranded RNA molecules function as templates for the synthesis of complementary RNA or DNA strands. However, the vast preponderance of RNA and DNA in cells is synthesized from preexisting duplex DNA.

### DNA Polymerases Require a Primer to Initiate Replication

DNA is synthesized from deoxyribonucleoside 5'-triphosphate precursors (dNTPs) in a manner analogous to RNA synthesis. Also like RNA synthesis, DNA synthesis always proceeds in the 5'→3' direction because chain growth results from formation of a phosphoester bond between the 3'

**EXPERIMENTAL FIGURE 5-28 The Meselson-Stahl experiment.** This experiment showed that DNA replicates by a semiconservative mechanism. *E. coli* cells were initially grown in a medium containing ammonium salts prepared with “heavy” nitrogen ( $^{15}\text{N}$ ) until all the cellular DNA was labeled. After the cells were transferred to a medium containing the normal “light” isotope ( $^{14}\text{N}$ ), samples were removed periodically from the cultures, and the DNA in each sample was analyzed by equilibrium density-gradient centrifugation, a procedure that separates macromolecules on the basis of their density. This technique can separate heavy-heavy (H-H), light-light (L-L), and heavy-light (H-L) duplexes into distinct bands. (a) Expected composition of daughter duplex molecules synthesized from  $^{15}\text{N}$ -labeled DNA after cells are shifted to  $^{14}\text{N}$ -containing medium if DNA replication occurs by a conservative or by a semiconservative mechanism. Parent heavy (H) strands are in red; light (L) strands synthesized after shift to  $^{14}\text{N}$ -containing medium are in blue. Note that the conservative mechanism would never generate H-L DNA, and that the semiconservative mechanism would never generate H-H DNA but would generate H-L DNA during the first and subsequent doublings. With additional replication cycles, the  $^{15}\text{N}$ -labeled (H) strands from the original DNA would be diluted, so that the vast bulk of the DNA would consist of L-L duplexes with either mecha-

nism. (b) Actual banding patterns of DNA subjected to equilibrium density-gradient centrifugation before and after  $^{15}\text{N}$ -labeled cells were shifted to  $^{14}\text{N}$ -containing medium. DNA bands were visualized under UV light and photographed. The traces on the left are a measure of the density of the photographic signal, and hence the DNA concentration, along the length of the centrifuged cells from left to right. The number of generations (far left) following the shift to  $^{14}\text{N}$ -containing medium was determined by counting the concentration of cells in the culture. This value corresponds to the number of DNA replication cycles that had occurred at the time each sample was taken. After one generation of growth, all the extracted DNA had the density of H-L DNA. After 1.9 generations, approximately half the DNA had the density of H-L DNA; the other half had the density of L-L DNA. With additional generations, a larger and larger fraction of the extracted DNA consisted of L-L duplexes; H-H duplexes never appeared. These results match the predicted pattern for the semiconservative replication mechanism depicted in (a). The bottom two centrifuge cells contained mixtures of H-H DNA and DNA isolated at 1.9 and 4.1 generations in order to clearly show the positions of H-H, H-L, and L-L DNA in the density gradient. See M. Meselson and F. W. Stahl, 1958, *Proc. Nat'l Acad. Sci. USA* **44**:671. [Part (b) photo courtesy of M. Meselson and F. W. Stahl, 1958.]

oxygen of a growing strand and the  $\alpha$  phosphate of a dNTP (see Figure 5-10a). As discussed earlier, an RNA polymerase can find an appropriate transcription start site on duplex DNA and initiate the synthesis of an RNA complementary to the template DNA strand (see Figure 5-11). In contrast, **DNA polymerases** cannot initiate chain synthesis *de novo*; instead, they require a short, preexisting RNA or DNA strand, called a **primer**, to begin chain growth. With a primer base-paired to the template strand, a DNA polymerase adds

deoxyribonucleotides to the free hydroxyl group at the 3' end of the primer as directed by the sequence of the template strand:

When RNA is the primer, the daughter strand that is formed is RNA at the 5' end and DNA at the 3' end.

## Duplex DNA Is Unwound, and Daughter Strands Are Formed at the DNA Replication Fork

In order for duplex DNA to function as a template during replication, the two intertwined strands must be unwound, or melted, to make their bases available for pairing with the bases of the dNTPs that are polymerized into the newly synthesized daughter strands. This unwinding of the parent DNA strands is performed by enzymes called **helicases**. Unwinding begins at segments in a DNA molecule called *replication origins*, or simply *origins*. The nucleotide sequences of origins from different organisms vary greatly, although they usually contain AT-rich sequences. Once helicases have unwound the parent DNA at an origin, a specialized RNA polymerase called **primase** forms a short (~12-nucleotide) RNA primer complementary to the unwound template strands. The primer, still base-paired to its complementary DNA strand, is then elongated by *DNA polymerase α* for another 25 nucleotides or so, forming a primer made of RNA at the 5' end and DNA at the 3' end. This primer is further extended by DNA polymerase δ, thereby forming a new daughter strand.

The DNA region at which all these proteins come together to carry out the synthesis of daughter strands is called the **replication fork**. As replication proceeds, the replication fork and the associated proteins move away from the origin. As noted earlier, local unwinding of duplex DNA produces torsional stress, which is relieved by topoisomerase I. In order for DNA polymerases to move along and copy a duplex DNA, helicase must sequentially unwind the duplex and topoisomerase must remove the supercoils that form.

A major complication in the operation of a DNA replication fork arises from two properties of DNA: the two strands of the parent DNA duplex are antiparallel, and DNA polymerases (like RNA polymerases) can add nucleotides to the growing daughter strands only in the 5'→3' direction. Synthesis of one daughter strand, called the **leading strand**, can proceed continuously from a single RNA primer in the 5'→3' direction, *the same direction as movement of the replication fork* (Figure 5-29). The problem comes in synthesis of the other daughter strand, called the **lagging strand**.

Because growth of the lagging strand must occur in the 5'→3' direction, copying of its template strand must somehow proceed in the *opposite* direction from the movement of the replication fork. A cell accomplishes this feat by synthesizing a new primer every 100 to 200 nucleotides on that template strand as more of the strand is exposed by unwinding. Each of these primers, base-paired to the template strand, is elongated in the 5'→3' direction, forming discontinuous segments named **Okazaki fragments** after their discoverer, Reiji Okazaki (see Figure 5-29). The RNA primer of each Okazaki fragment is removed and replaced by DNA chain growth from the neighboring Okazaki fragment; finally, an enzyme called *DNA ligase* joins the adjacent fragments.

**FIGURE 5-29 Leading-strand and lagging-strand DNA synthesis.**

Nucleotides are added by a DNA polymerase to each growing daughter strand in the 5'→3' direction (indicated by arrowheads). The leading strand is synthesized continuously from a single RNA primer (red) at its 5' end. The lagging strand is synthesized discontinuously from multiple RNA primers that are formed periodically as each new region of the parent duplex is unwound. Elongation of these primers initially produces Okazaki fragments. As each growing fragment approaches the previous primer, that primer is removed and the fragments are ligated. Repetition of this process eventually results in synthesis of the entire lagging strand.

## Several Proteins Participate in DNA Replication

Detailed understanding of the eukaryotic proteins that participate in DNA replication initially came largely from studies with small viral DNAs, particularly SV40 DNA, the circular genome of a virus that infects monkeys. Virus-infected cells replicate large numbers of the simple viral genome in a short period of time, which makes them an ideal model system for studying basic aspects of DNA replication. Because simple viruses such as SV40 depend largely on the DNA replication machinery of their host cells (in this case monkey cells), they offer a unique opportunity to study the replication of multiple identical small DNA molecules by cellular proteins. Figure 5-30 depicts the multiple proteins that coordinate the copying of SV40 DNA at a replication fork. The assembled proteins at a replication fork further illustrate the concept of molecular machines introduced in Chapter 3. These multicomponent complexes permit the cell to carry out an ordered sequence of events that accomplishes essential cell functions.

The molecular machine that replicates SV40 DNA contains only one viral protein; all other proteins involved in SV40 DNA replication are provided by the host cell. This viral protein, *large T-antigen*, forms a hexameric *replicative helicase*, a protein that uses energy from ATP hydrolysis to unwind the parent strands at a replication fork. Primers for the leading and lagging daughter strands are synthesized by a complex of *primase*, which synthesizes a short RNA primer (~12 nucleotides), and DNA polymerase α (Pol α),

**FIGURE 5-30 Model of an SV40 DNA replication fork.** (a) A hexamer of large T-antigen, a viral protein, functions as a helicase to unwind the parent DNA strands. The leading strand is extended by DNA polymerase  $\epsilon$  (Pol  $\epsilon$ ) up to the replication fork. Pol  $\epsilon$  is bound to a ring of PCNA that surrounds the daughter double-stranded DNA so that the Pol  $\epsilon$ -PCNA complex remains stably associated with the replication fork. The single-stranded region of the lagging strand template generated by T-antigen helicase is bound by multiple copies of the heterotrimeric protein RPA. Primers for lagging-strand synthesis (red, RNA; light green, DNA) are synthesized by a complex of primase and DNA polymerase  $\alpha$  (Pol  $\alpha$ ). The 3' end of each primer synthesized by Pol  $\alpha$ -primase is then bound by a PCNA-Pol  $\delta$  complex, which extends the primer and synthesizes most of each Okazaki fragment. (b) The helicase domain of SV40 T-antigen forms a hexameric replicative helicase. Subunits are shown in alternating light and dark orange. (c) Model

of DNA polymerase  $\epsilon$  extending the 3'-end of the leading strand. (d) The three subunits of PCNA, shown in different shades of yellow, form a circular structure with a central hole through which daughter double-stranded DNA passes. (e) RFC, the pentameric "clamp-loader" (monomers shown in different shades of green) is shown bound to a circular trimer PCNA before the PCNA "clamp" is opened. (f) The large subunit of RPA contains two domains that bind single-stranded DNA. Note that the single DNA strand is extended, with the bases oriented in an optimal conformation for replication by Pol  $\delta$ . See M. O'Donnell, L. Langston, and B. Stillman, 2013, *Cold Spring Harbor Perspect. Biol.* 5:a010108. [Part (b) data from D. Li et al., 2003, *Nature* 423:512, PDB ID 1n25. Part (c) data from M. Hogg et al., 2014, *Nat. Struct. Mol. Kuriyan, 2004, *Nature* 429:724, PDB ID 1sxj. Part (f) data from A. Bochkarev et al., 1997, *Nature* 385:176, PDB ID 1jmc.]

which extends the RNA primer with deoxyribonucleotides for another 25 nucleotides or so, forming a mixed RNA-DNA primer.

The primer is extended into daughter-strand DNA by DNA polymerase  $\delta$  (Pol  $\delta$ ), which is less likely to make errors during copying of the template strand than is Pol  $\alpha$  because of its proofreading mechanism (see Section 5.6). During the replication of cellular DNA, Pol  $\delta$  synthesizes lagging-strand DNA, while DNA polymerase  $\epsilon$  (Pol  $\epsilon$ ) synthesizes most of the length of the leading strand. Pol  $\delta$  and Pol  $\epsilon$

each form a complex with PCNA (proliferating cell nuclear antigen), which displaces the primase-Pol  $\alpha$  complex following primer synthesis. As illustrated in Figure 5-30d, PCNA is a homotrimeric protein that has a central hole through which the daughter duplex DNA passes, thereby preventing the PCNA-Pol  $\delta$  and PCNA-Pol  $\epsilon$  complexes from dissociating from the template. As such, PCNA is known as a *sliding clamp* that enables Pol  $\delta$  and Pol  $\epsilon$  to remain stably associated with a single template strand for thousands of nucleotides. A pentameric protein called RFC (replication factor C)

functions to open the PCNA ring so that it can encircle the short region of double-stranded DNA synthesized by Pol  $\alpha$ . Consequently, RFC is called a *clamp loader*.

After parent DNA is separated into single-stranded templates at the replication fork, the leading strand is extended by Pol  $\epsilon$ , which can extend the growing strand up to the replication fork. The single-stranded template for lagging-strand synthesis is bound by multiple copies of RPA (replication protein A), a heterotrimeric protein (Figure 5-30c). Binding of RPA maintains the template in a uniform conformation that is optimal for copying by Pol  $\delta$ . Bound RPA proteins are dislodged from the parent strand by Pol  $\delta$  as it synthesizes the complementary strand base-paired with the parent strand.

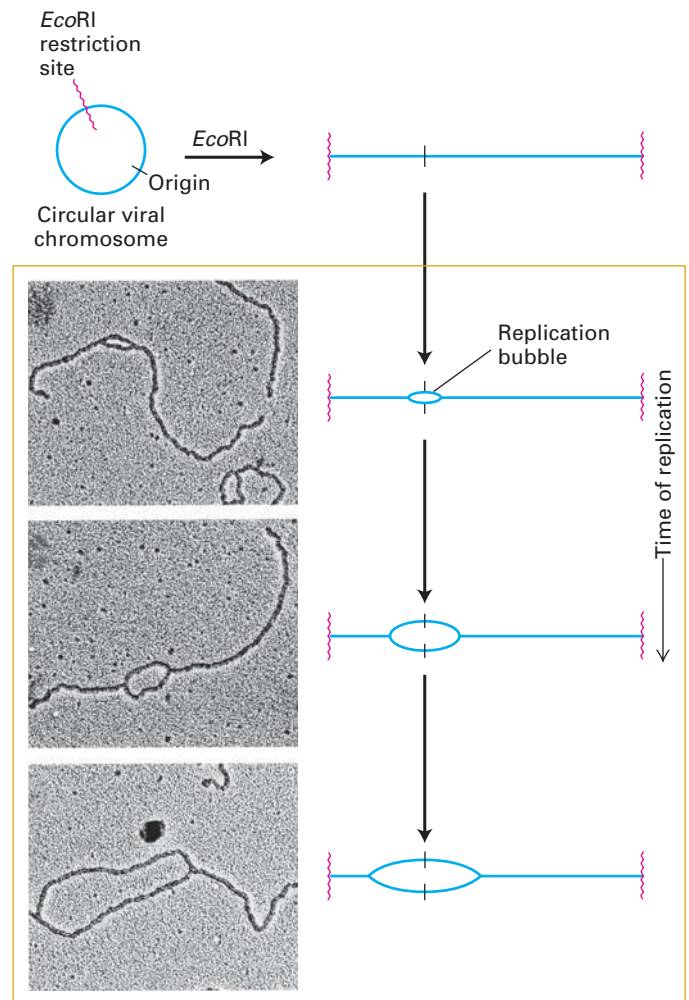

Several other eukaryotic proteins that function in DNA replication are not depicted in Figure 5-30. For example, topoisomerase I associates with the parent DNA ahead of the replicative helicase (i.e., to the left of large T-antigen in Figure 5-30) to remove torsional stress introduced by the unwinding of the parent strands (see Figure 5-8a). Ribonuclease H and FEN I remove the ribonucleotides at the 5' ends of Okazaki fragments; these ribonucleotides are replaced by deoxyribonucleotides added by Pol  $\delta$  as it extends the upstream Okazaki fragment. Successive Okazaki fragments are coupled by DNA ligase through standard 5'→3' phosphoester bonds. Other specialized DNA polymerases are involved in the repair of mismatches and lesions in DNA (see Section 5.6).

## DNA Replication Occurs Bidirectionally from Each Origin

As indicated in Figures 5-29 and 5-30, both parent DNA strands that are exposed by local unwinding at a replication fork are copied into daughter strands. In theory, DNA replication from a single origin could involve one replication fork that moves in one direction. Alternatively, two replication forks might assemble at a single origin and then move in opposite directions, leading to *bidirectional growth* of both daughter strands. Several types of experiments, including the one shown in Figure 5-31, provided early evidence in support of bidirectional strand growth.

The general consensus is that all bacterial, archaeal, and eukaryotic cells employ a bidirectional mechanism of DNA replication. In the case of SV40 DNA, replication is initiated by the binding of two large T-antigen hexameric helicases to the single SV40 origin and the assembly of other proteins to form two replication forks. These forks then move away from the SV40 origin in opposite directions, and leading- and lagging-strand synthesis occurs at both forks. As shown in Figure 5-32, the left replication fork extends DNA synthesis in the leftward direction; similarly, the right replication fork extends DNA synthesis in the rightward direction.

Unlike SV40 DNA, eukaryotic chromosomal DNA molecules contain multiple replication origins separated by tens to hundreds of kilobases. A six-subunit protein called ORC, for origin recognition complex, binds to each origin and associates with other proteins required to load cellular

**EXPERIMENTAL FIGURE 5-31 Bidirectional replication in SV40 DNA.** Electron microscopy of replicating SV40 DNA indicates bidirectional growth of DNA strands from an origin. Replicating viral DNA from SV40-infected cells was cut by the restriction enzyme *EcoRI*, which recognizes one site in the circular viral DNA. This was done to provide a landmark in the SV40 genome: the *EcoRI* recognition sequence could now be easily recognized as the ends of the linear DNA molecules visualized by electron microscopy. Electron micrographs of *EcoRI*-cut, replicating SV40 DNA molecules showed a collection of cut molecules with increasingly longer replication “bubbles,” whose centers were a constant distance from each end of the cut molecules. This finding is consistent with chain growth in two directions from a common origin located at the center of a bubble, as illustrated in the corresponding diagrams. See G. C. Fareed et al., 1972, *J. Virol.* **10**:484. [Micrographs republished with permission of American Society for Microbiology-Journals, from *Journal of Virology*, Fareed et al., 10, 3, 1972; permission conveyed through Copyright Clearance Center, Inc.]

hexameric helicases composed of six homologous MCM proteins. Two MCM helicases, oriented in opposite directions, separate the parent strands at an origin, and RPA proteins bind to the resulting single-stranded DNA. Synthesis of primers and subsequent steps in the replication of cellular DNA are thought to be analogous to those in SV40 DNA replication (see Figures 5-31 and 5-32).

Replication of cellular DNA and other events leading to the proliferation of cells must be tightly regulated so that

the appropriate numbers of cells constituting each tissue will be produced during embryonic development and throughout the life of an organism. Control of the initiation step is the primary mechanism for regulating cellular DNA replication. Activation of MCM helicase, which is required to initiate cellular DNA replication, is regulated by a specific protein kinase (*DDK*), which in turn is regulated by S-phase *cyclin-dependent kinases*. Other cyclin-dependent kinases regulate additional aspects of cell proliferation, including the complex process of mitosis by which a eukaryotic cell divides

**FIGURE 5-32 Bidirectional mechanism of DNA replication.**

The left replication fork here is comparable to the replication fork diagrammed in Figure 5-30 (although that figure also shows proteins other than large T-antigen, which are not shown here). **Top:** Two large T-antigen hexameric helicases first bind at the replication origin in opposite orientations. **Step 1:** Using energy provided by ATP hydrolysis, the helicases move in opposite directions, unwinding the parent DNA and generating single-stranded templates, which are bound by RPA proteins. **Step 2:** Primase–Pol  $\alpha$  complexes synthesize short primers (red) base-paired to each of the separated parent strands. **Step 3:** PCNA–Rfc–Pol  $\epsilon$  complexes replace the primase–Pol  $\alpha$  complexes and extend the short primers, generating the leading strands (dark green) at each replication fork. **Step 4:** The helicases further unwind the parent strands, and RPA proteins bind to the newly exposed single-stranded regions. **Step 5:** PCNA–Rfc–Pol  $\epsilon$  complexes extend the leading strands farther. **Step 6:** Primase–Pol  $\alpha$  complexes synthesize primers for lagging-strand synthesis at each replication fork. **Step 7:** PCNA–Rfc–Pol  $\delta$  complexes displace the primase–Pol  $\alpha$  complexes and extend the lagging-strand Okazaki fragments (light green), which are eventually ligated to the 5' ends of the leading strands. The position where ligation occurs is represented by a circle. Replication continues by further unwinding of the parent strands and synthesis of leading and lagging strands as in Steps 4–7. Although depicted as individual steps for clarity, unwinding and synthesis of leading and lagging strands occur concurrently.

into two daughter cells. Mitosis and another specialized type of cell division called meiosis, which generates haploid sperm and egg cells, are discussed in Chapter 6. We discuss the various regulatory mechanisms that determine the rate of cell division in Chapter 19.

## KEY CONCEPTS OF SECTION 5.5

### DNA Replication

- Each strand in a parent duplex DNA acts as a template for synthesis of a daughter strand and remains base-paired to the new strand, forming a daughter duplex (semiconservative replication). New strands are formed in the 5'→3' direction.
- Replication begins at a sequence called an *origin*. Each eukaryotic chromosomal DNA molecule contains multiple replication origins.
- DNA polymerases, unlike RNA polymerases, cannot unwind the strands of duplex DNA and cannot initiate synthesis of new strands complementary to the template strands.
- At a replication fork, one daughter strand (the leading strand) is elongated continuously. The other daughter strand (the lagging strand) is formed as a series of discontinuous Okazaki fragments from primers synthesized every 100 to 200 nucleotides (Figure 5-29).
- The ribonucleotides at the 5' end of each Okazaki fragment are removed and replaced by elongation of the 3' end

of the next Okazaki fragment. Finally, adjacent Okazaki fragments are joined by DNA ligase.

- Helicases use energy from ATP hydrolysis to separate the parent (template) DNA strands, which are initially bound by multiple copies of a single-stranded DNA-binding protein, RPA. Primase synthesizes a short RNA primer, which remains base-paired to the template DNA. This primer is initially extended at the 3' end by DNA polymerase  $\alpha$  (Pol  $\alpha$ ), resulting in a short (5')-RNA-(3')DNA daughter strand.
- Most of the DNA in eukaryotic cells is synthesized by Pol  $\delta$  and Pol  $\epsilon$ , which take over from Pol  $\alpha$  and continue elongation of the daughter strands in the 5'→3' direction. Pol  $\delta$  synthesizes most of the length of the lagging strand, while Pol  $\epsilon$  synthesizes the leading strand. Pol  $\delta$  and Pol  $\epsilon$  remain stably associated with the template by binding to PCNA, a trimeric protein that encircles the daughter duplex DNA, functioning as a sliding clamp (see Figure 5-30).
- DNA replication generally occurs by a bidirectional mechanism in which two replication forks form at an origin and move in opposite directions, and both template strands are copied at each fork (see Figure 5-32).
- MCM helicases initiate eukaryotic DNA replication in vivo at multiple origins spaced along chromosomal DNA. Synthesis of eukaryotic DNA is regulated by controls on the binding and activity of these helicases.

## 5.6 DNA Repair and Recombination

Damage to DNA is unavoidable and arises in many ways. DNA damage can be caused by spontaneous cleavage of chemical bonds in DNA, by environmental agents such as ultraviolet and ionizing radiation, and by reaction with genotoxic chemicals that are by-products of normal cellular metabolism or occur in the environment. A change in the normal DNA sequence, called a **mutation**, can occur during replication when a DNA polymerase inserts the wrong nucleotide as it reads a damaged template. Mutations also occur at a low frequency as the result of copying errors introduced by DNA polymerases when they replicate an undamaged template. If such mutations were left uncorrected, cells might accumulate so many mutations that they could no longer function properly. In addition, the DNA in germ cells might incur too many mutations for viable offspring to be formed. Thus the prevention of DNA sequence errors in all types of cells is important for their survival, and several cellular mechanisms for repairing damaged DNA and correcting sequence errors have evolved. One of these mechanisms for repairing breaks in double-stranded DNA is also used by eukaryotic cells to generate new combinations of maternal and paternal genes on each chromosome through the exchange of segments of the chromosomes during the production of germ cells (e.g., sperm and eggs), a process known as *genetic recombination*.

Significantly, defects in DNA repair mechanisms and cancer are closely related. When repair mechanisms are compromised, mutations accumulate in the cell's DNA. If these mutations affect genes that are normally involved in the careful regulation of cell division, cells can begin to divide uncontrollably, leading to tumor formation and cancer. Chapter 24 outlines in detail how cancer arises from defects in DNA repair mechanisms. We will encounter a few examples in this section as well as we first consider the ways in which DNA integrity can be compromised, then discuss the repair mechanisms that cells have evolved to ensure the fidelity of this very important molecule.

### DNA Polymerases Introduce Copying Errors and Also Correct Them

The first line of defense in preventing mutations is DNA polymerase itself. Occasionally, when replicative DNA polymerases (Pol  $\delta$  and Pol  $\epsilon$ ) progress along the template DNA, an incorrect nucleotide is added to the growing 3' end of the daughter strand. *E. coli* DNA polymerases, for instance, introduce about 1 incorrect nucleotide per  $10^4$  (ten thousand) polymerized nucleotides. Yet the measured mutation rate in bacterial cells is much lower: about 1 mistake in  $10^9$  (one billion) nucleotides incorporated into a growing strand. This remarkable accuracy is largely due to *proofreading* by *E. coli* DNA polymerases. Eukaryotic Pol  $\delta$  and Pol  $\epsilon$  employ a similar mechanism.

Proofreading depends on the 3'→5' *exonuclease activity* of some DNA polymerases. When an incorrect base is incorporated during DNA synthesis, base pairing between the 3' nucleotide of the nascent strand and the template strand does not occur. As a result, the polymerase pauses, then transfers the 3' end of the growing chain to its exonuclease site, where the incorrect mispaired base is removed (Figure 5-33). Then the 3' end is transferred back to the polymerase site, where this region is copied correctly. All three *E. coli* DNA polymerases have proofreading activity, as do the two eukaryotic DNA polymerases,  $\delta$  and  $\epsilon$ , used for replication of most chromosomal DNA in animal cells. It seems likely that proofreading is indispensable for all cells to avoid excessive mutations.

### Chemical and Radiation Damage to DNA Can Lead to Mutations

DNA is continually subjected to a barrage of damaging chemical reactions; estimates of the number of DNA damage events in a single human cell range from  $10^4$  to  $10^6$  per day! Even if DNA were not exposed to damaging chemicals, certain aspects of DNA structure are inherently unstable. For example, the bond connecting a purine base to deoxyribose is prone to hydrolysis at a low rate under physiological conditions, leaving a sugar without an attached base. Thus coding information is lost, and this loss can lead to a mutation during DNA replication. Normal cellular reactions, including the movement of electrons along the electron-transport

**FIGURE 5-33 Proofreading by DNA polymerase.** All DNA polymerases have a similar three-dimensional structure, which resembles a half-opened right hand. The “fingers” bind the single-stranded segment of the template strand, and the polymerase catalytic activity (Pol) lies in the junction between the fingers and palm. As long as the correct nucleotides are added to the 3′ end of the growing strand, it remains in the polymerase site. Incorporation of an incorrect base at

the 3′ end causes melting of the newly formed end of the duplex. As a result, the polymerase pauses, and the 3′ end of the growing strand is transferred to the 3′ → 5′ exonuclease site (Exo) about 3 nm away, where the mispaired base, and probably other bases, are removed. Subsequently, the 3′ end flips back into the polymerase site and elongation resumes. See C. M. Joyce and T. T. Steitz, 1995, *J. Bacteriol.* **177**:6321, and S. Bell and T. Baker, 1998, *Cell* **92**:295.

chain in mitochondria and lipid oxidation in peroxisomes (see Chapter 12), produce several chemicals that react with and damage DNA, including hydroxyl radicals and superoxide ( $O_2^-$ ). These chemicals can also cause mutations, including mutations that lead to cancers.

Many spontaneous mutations are **point mutations**, which involve a change in a single base pair in the DNA sequence. A point mutation can introduce a stop codon, causing a *non-sense* mutation as discussed earlier, or a change in the amino acid sequence of an encoded protein, called a *missense* mutation. *Silent* mutations do not change the amino acid sequence (e.g., GAG to GAA; both encode glutamine). Point mutations can also occur in non-protein-coding DNA sequences that function in the regulation of a gene’s transcription, as discussed in Chapter 9. One of the most frequent causes of

point mutations is *deamination* of a cytosine (C) base, which converts it into a uracil (U) base. Another is deamination of the common modified base 5-methyl cytosine, which forms thymine when it is deaminated. If these alterations are not corrected before the DNA is replicated, the cell will use the strand containing U or T as a template to form a U·A or T·A base pair, thus creating a permanent change in the DNA sequence (Figure 5-34).

### High-Fidelity DNA Excision-Repair Systems Recognize and Repair Damage

In addition to proofreading, cells have other systems for preventing mutations due to copying errors and exposure to chemicals and radiation. Several DNA **excision-repair**

**FIGURE 5-34 Deamination leads to point mutations.** A spontaneous point mutation can be caused by deamination of 5-methylcytosine (C) to form thymine (T). If the resulting T·G base pair is not restored to the normal C·G base pair by base excision-repair mechanisms **1**, it will lead to a permanent change in sequence (i.e., a mutation) following DNA replication **2**. After one round of replication, one daughter DNA molecule will have the mutant T·A base pair and the other will have the wild-type C·G base pair.

systems that normally operate with a high degree of accuracy have been well studied. These systems were first elucidated through a combination of genetic and biochemical studies in *E. coli*. Homologs of the key bacterial proteins exist in eukaryotes from yeasts to humans, indicating that these error-free mechanisms arose early in evolution to protect DNA integrity. Each of these systems functions in a similar manner: a segment of the damaged DNA strand is excised, and the gap is filled by DNA polymerase and ligase using the complementary DNA strand as a template.

We will now take a closer look at some of the mechanisms of DNA repair, ranging from repair of single-base mutations to repair of DNA broken across both strands. Some of these mechanisms accomplish their repairs with great accuracy; others are less precise.

### Base Excision Repairs T-G Mismatches and Damaged Bases

In humans, the most common type of point mutation is a change from a C to a T, which is caused by deamination of 5-methyl C (see Figure 5-34). The conceptual problem with *base excision repair* in this case is determining which is the normal and which is the mutant DNA strand. But since a G·T mismatch is almost invariably caused by chemical conversion of C to U or 5-methyl C to T, the repair system evolved to remove the T and replace it with a C.

The G·T mismatch is recognized by a DNA glycosylase that flips the thymine base out of the helix and then hydrolyzes the bond that connects it to the sugar-phosphate DNA backbone. Following this initial incision, an endonuclease, APE1, cuts the DNA strand near the now abasic site. The deoxyribose phosphate lacking the base is then removed and replaced with a C by a specialized DNA polymerase that reads the G in the template strand (Figure 5-35).

As mentioned earlier, this repair must take place prior to DNA replication because the incorrect base in this pair, T, occurs naturally in normal DNA. Consequently, it would be able to engage in normal Watson-Crick base pairing during replication, generating a stable point mutation that would no longer be recognized by repair mechanisms (see Figure 5-34, step 2).

Human cells contain a battery of glycosylases, each of which is specific for a different set of chemically modified DNA bases. For example, one glycosylase removes 8-oxyguanine, an oxidized form of guanine, allowing its replacement by an undamaged G, and others remove bases modified by alkylating agents. The resulting abasic nucleotide is then replaced by the repair mechanism described above. A similar mechanism functions in the repair of lesions resulting from *depurination*, the loss of a guanine or adenine base from DNA caused by hydrolysis of the glycosylic bond between deoxyribose and the base. Depurination occurs spontaneously and is fairly common in mammals and birds because of their warm body temperatures. The resulting abasic sites, if left unrepaired, generate mutations during DNA replication because they cannot specify the appropriate paired base.

**FIGURE 5-35 Base excision repair of a T-G mismatch.** A DNA glycosylase specific for G·T mismatches, which are usually formed by deamination of 5-methyl C (see Figure 5-34), flips the thymine base out of the helix and then cuts it away from the sugar-phosphate DNA backbone (step 1), leaving just the deoxyribose phosphate (black dot). An endonuclease specific for the resultant abasic site (apurinic endonuclease I, APE1) then cuts the DNA backbone (step 2), and the deoxyribose phosphate is removed by an endonuclease, apurinic lyase (AP lyase) associated with DNA polymerase β, a specialized DNA polymerase used in repair (step 3). The gap is then filled in by DNA Pol β and sealed by DNA ligase (step 4), restoring the original G·C base pair. See O. Schärer, 2003, *Angewandte Chemie* 42:2946.

### Mismatch Excision Repairs Other Mismatches and Small Insertions and Deletions

Another process, also conserved in organisms from bacteria to humans, principally eliminates base-pair mismatches and insertions or deletions of one or a few nucleotides that are accidentally introduced by DNA polymerases during replication. As with base excision repair of a T in a T-G mismatch, the conceptual problem with *mismatch excision repair* is determining which is the normal and which is the mutant DNA strand. How this happens in human cells is not known with certainty. It is thought that the proteins that bind to the mismatched segment of DNA distinguish the template and daughter strands; then the mispaired segment of the daughter strand—the one with the replication error—is excised and repaired to produce an exact complement of the template strand (Figure 5-36). In contrast to base excision repair, mismatch excision repair occurs after DNA replication.

Predisposition to a colon cancer known as hereditary nonpolyposis colorectal cancer results from an inherited loss-of-function mutation in one copy of either the *MLH1* or the *MSH2* gene. The *MSH2* and *MLH1* proteins

are essential for DNA mismatch repair (see Figure 5-36). Cells with at least one functional copy of each of these genes exhibit normal mismatch repair. However, tumor cells frequently arise from individual cells that have experienced a random mutation in the second copy; when both copies of

**FIGURE 5-36 Mismatch excision repair in human cells.** The mismatch excision-repair pathway corrects errors introduced during replication. A complex of the MSH2 and MSH6 proteins (bacterial MutS homologs 1 and 6) binds to a mispaired segment of DNA in such a way as to distinguish between the template and the newly synthesized daughter strand (step **1**). This binding triggers binding of MLH1 and PMS2 (both homologs of bacterial MutL). The resulting DNA-protein complex then binds an endonuclease that cuts the newly synthesized daughter strand. Next a DNA helicase unwinds the helix, and an exonuclease removes several nucleotides from the cut end of the daughter strand, including the mismatched base (step **2**). Finally, as with base excision repair, the gap is filled in by a DNA polymerase (Pol  $\delta$ , in this case) and sealed by DNA ligase (step **3**).

one gene are nonfunctional, the mismatch repair system is lost. Inactivating mutations in these genes are also common in noninherited forms of colon cancer. ■

### Nucleotide Excision Repairs Chemical Adducts that Distort Normal DNA Shape

Cells use *nucleotide excision repair* to fix DNA regions containing chemically modified bases, often called *chemical adducts*, that distort the normal shape of DNA locally. A key to this type of repair is the ability of certain proteins to slide along the surface of a double-stranded DNA molecule looking for bulges or other irregularities in the shape of the double helix. For example, this mechanism repairs *thymine-thymine dimers*, a common type of chemical adduct caused by UV light (Figure 5-37); these dimers interfere with both replication and transcription of DNA. Figure 5-38

**FIGURE 5-37 Formation of thymine-thymine dimers.** (a) The most common type of DNA damage caused by UV irradiation is the formation of thymine-thymine dimers. (b) These lesions can be repaired by an excision-repair mechanism that recognizes the distortion they create in the shape of the DNA double helix. The red lines in (b) represent the UV-induced C—C bonds shown in (a). [Part (b) data from K. McAteer et al., 1998, *J Mol Biol.* **282**:1013, PDB ID 1ttd.]

**FIGURE 5-38 Nucleotide excision repair in human cells.** A DNA lesion that causes distortion of the double helix, such as a thymine-thymine dimer, is initially recognized by a complex of the XP-C (xeroderma pigmentosum C protein) and 23B proteins (step **1**). This complex then recruits transcription factor TFIIH, whose helicase subunits, powered by ATP hydrolysis, partially unwind the double helix. XP-G and RPA proteins then bind to the complex and further unwind and stabilize the helix until a bubble of about 25 bases is formed (step **2**). Then XP-G (now acting as an endonuclease) and XP-F, a second endonuclease, cut the damaged strand at points 24–32 bases apart on each side of the lesion (step **3**). This releases the DNA fragment with the damaged bases, which is degraded to mononucleotides. Finally the gap is filled by DNA polymerase exactly as in DNA replication, and the remaining nick is sealed by DNA ligase (step **4**). See J. Hoeijmakers, 2001, *Nature* **411**:366, and O. Schärer, 2003, *Angewandte Chemie* **42**:2946.

illustrates how the nucleotide excision-repair system repairs damaged DNA.

Some 30 proteins are involved in the nucleotide excision-repair process, the first of which were identified through a study of the defects in DNA repair in cultured cells from individuals with **xeroderma pigmentosum**, a hereditary disease associated with a predisposition to cancer. Individuals with this disease frequently develop skin cancers called melanomas and squamous cell carcinomas if their skin is exposed to the UV rays in sunlight. The cells of affected patients lack a functional nucleotide excision-repair system. Mutations in any of at least seven different genes, called XP-A through XP-G, lead to inactivation of this repair system and cause xeroderma pigmentosum; all produce the same phenotype and have the same consequences. The functions of most of these XP proteins in nucleotide excision repair are now well understood (see Figure 5-38).

Remarkably, five polypeptide subunits of TFIIH, a general transcription factor required for transcription of all genes (see Figure 9-19), are also required for nucleotide excision repair in eukaryotic cells. Two of these subunits have homology to helicases, as shown in Figure 5-38. In transcription, the helicase activity of TFIIH helps to unwind the DNA helix at the start site, allowing RNA polymerase to initiate the process (see Figure 9-19). It appears that nature has used a similar protein assembly in two different cellular processes that require helicase activity.

The use of shared subunits in transcription and in DNA repair may help explain the observation that DNA damage in higher eukaryotes is repaired at a much faster rate in regions of the genome being actively transcribed than in nontranscribed regions—a phenomenon called *transcription-coupled repair*. Since only a small fraction of the genome is transcribed in any one cell, transcription-coupled repair efficiently directs repair efforts to the most critical regions. In this system, if an RNA polymerase becomes stalled at a lesion on DNA (e.g., a thymine-thymine dimer), a complex of proteins CSA and CSB is recruited to the RNA polymerase, where they trigger opening of the DNA helix, recruitment of TFIIH, and the reactions of steps **2** through **4** depicted in Figure 5-38. CSA and CSB are named after the rare inherited developmental disorder called Cockayne syndrome that results from mutations in these proteins.

## Two Systems Use Recombination to Repair Double-Strand Breaks in DNA

Ionizing radiation (e.g., x- and  $\gamma$ -radiation) and some anticancer drugs cause double-strand breaks in DNA. These lesions are particularly severe because incorrect rejoining of double strands of DNA can lead to gross chromosomal rearrangements that can affect the functioning of genes. For example, incorrect joining could create a “hybrid” gene that codes for the N-terminal portion of one amino acid sequence fused to the C-terminal portion of a completely different

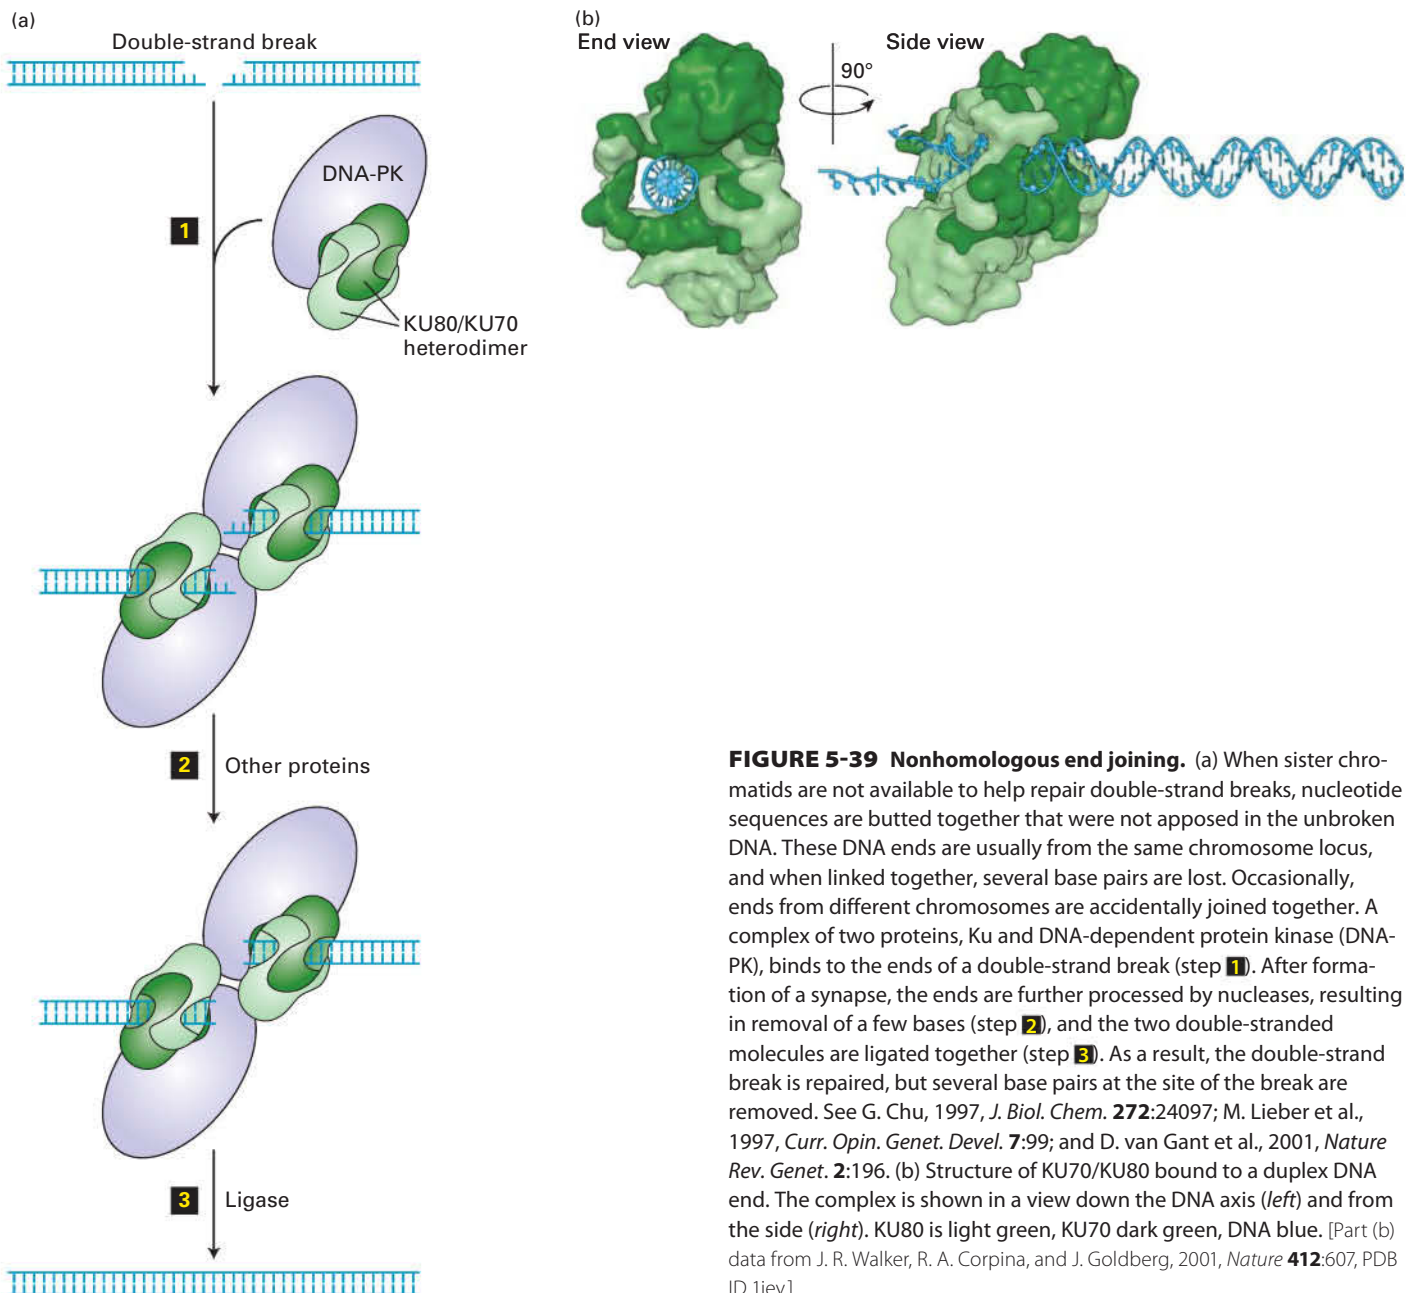

amino acid sequence; or a chromosomal rearrangement could bring the promoter of one gene close to the coding region of another gene, changing the level or cell type in which that gene is expressed.

Two systems have evolved to repair double-strand breaks: *homologous recombination*, discussed below, and *nonhomologous end joining (NHEJ)*, which is error-prone, since several nucleotides are invariably lost at the point of repair.

**Error-Prone Repair by Nonhomologous End Joining** The predominant mechanism for repairing double-strand breaks

in multicellular organisms involves rejoining of the nonhomologous ends of two DNA molecules. Even if the joined DNA fragments come from the same chromosome, the repair process results in the loss of several base pairs at the joining point (Figure 5-39). The formation of such a possibly mutagenic deletion is one example of how repair of DNA damage can introduce mutations.

Since diffusion of DNA within the viscous nucleoplasm is fairly slow, the correct ends of a broken chromosome are generally rejoined together, albeit with a loss of base pairs, before they diffuse too far apart for nonhomologous

**FIGURE 5-39 Nonhomologous end joining.** (a) When sister chromatids are not available to help repair double-strand breaks, nucleotide sequences are butted together that were not apposed in the unbroken DNA. These DNA ends are usually from the same chromosome locus, and when linked together, several base pairs are lost. Occasionally, ends from different chromosomes are accidentally joined together. A complex of two proteins, Ku and DNA-dependent protein kinase (DNA-PK), binds to the ends of a double-strand break (step 1). After formation of a synapse, the ends are further processed by nucleases, resulting in removal of a few bases (step 2), and the two double-stranded molecules are ligated together (step 3). As a result, the double-strand break is repaired, but several base pairs at the site of the break are removed. See G. Chu, 1997, *J. Biol. Chem.* **272**:24097; M. Lieber et al., 1997, *Curr. Opin. Genet. Devel.* **7**:99; and D. van Gant et al., 2001, *Nature Rev. Genet.* **2**:196. (b) Structure of KU70/KU80 bound to a duplex DNA end. The complex is shown in a view down the DNA axis (left) and from the side (right). KU80 is light green, KU70 dark green, DNA blue. [Part (b) data from J. R. Walker, R. A. Corpina, and J. Goldberg, 2001, *Nature* **412**:607, PDB ID 1jey.]

end joining to be efficient. Since most of the length of most human genes consists of introns that are spliced out of the processed mRNA, in most cases the small deletion generated is not harmful. Occasionally, however, broken ends from different chromosomes are joined together, leading to translocation of pieces of DNA from one chromosome to another. Such translocations may generate chimeric genes that can have drastic effects on normal cell function, such as uncontrollable cell growth, which is the hallmark of cancer (see Figure 8-38). The devastating effects of double-strand breaks make these the “most unkindest cuts of all,” to borrow a phrase from Shakespeare’s *Julius Caesar*.

## Homologous Recombination Can Repair DNA Damage and Generate Genetic Diversity

At one time homologous recombination was thought to be a minor repair process in human cells. This view changed when it was realized that several human cancers are potentiated by inherited mutations in genes that are essential for homologous recombination repair (see Table 24-1). For example, some women with an inherited susceptibility to breast cancer have a mutation in one allele of either the *BRCA-1* or the *BRCA-2* gene, both of which encode proteins participating in this repair process. Loss or inactivation of the second allele inhibits the homologous recombination repair pathway and thus tends to induce cancer in mammary or ovarian epithelial cells. Yeasts can use homologous recombination to repair double-strand breaks induced by  $\gamma$ -irradiation. Isolation and analysis of radiation-sensitive (*RAD*) mutants that are deficient in this repair system facilitated study of the process. Virtually all the yeast Rad proteins have homologs in the human genome, and the human and yeast proteins function in an essentially identical fashion.

A variety of DNA lesions that are not repaired by the mechanisms discussed earlier can be repaired by mechanisms in which the damaged DNA sequence is copied from an undamaged copy of the same or a highly homologous sequence on the homologous chromosome in diploid organisms or the sister chromosome following DNA replication in haploid and diploid organisms. These mechanisms involve an exchange of strands between separate DNA molecules and hence are referred to as **recombination**.

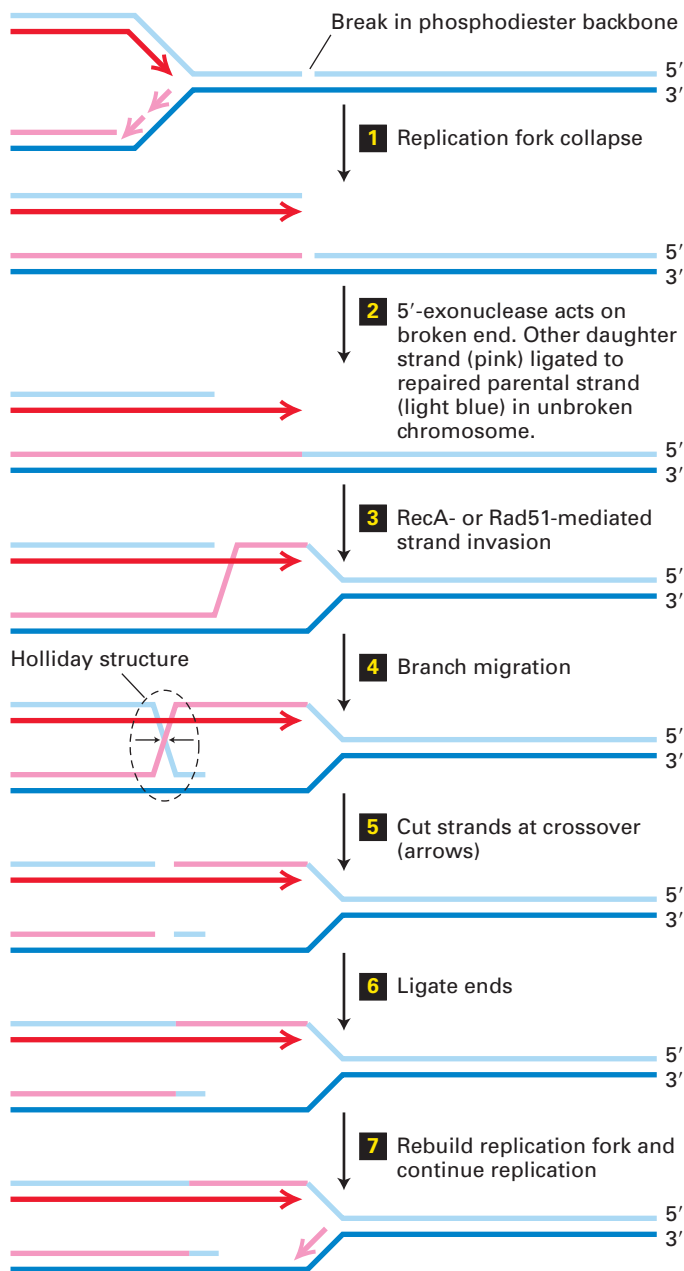

In addition to providing a mechanism for DNA repair, similar recombination mechanisms generate genetic diversity among the individuals of a species by causing the exchange of large regions of chromosomes between the maternal and paternal pair of homologous chromosomes during *meiosis*, the special type of cell division that generates germ cells (sperm and eggs) (see Figure 6-3). In fact, the exchange of regions of homologous chromosomes, called *crossing over*, is required for proper segregation of chromosomes during the first meiotic cell division. Meiosis and the consequences of generating new combinations of maternal and paternal genes by recombination are discussed further in Chapter 6, and the mechanisms leading to proper segregation of chromosomes

during meiosis are discussed in Chapter 19. Here we focus on the molecular mechanisms of DNA recombination, highlighting the exchange of DNA strands between two recombining DNA molecules.

**Repair of a Collapsed Replication Fork** An example of recombinational DNA repair is the repair of a “collapsed” replication fork. If a break in the phosphodiester backbone of one DNA strand (called a “nick”) is not repaired before a replication fork passes, the replicated portions of the daughter chromosomes become separated when the replication helicase reaches the nick in the parent strand because there are no covalent bonds between the two fragments of the parent strand on either side of the nick. This process is called *replication fork collapse* (Figure 5-40, step **1**). If the break in the double-stranded daughter DNA molecule is not repaired, it is generally lethal to at least one daughter cell following cell division because of the loss of genetic information between the break and the end of the chromosome. The recombination process that repairs the resulting double-strand break and regenerates a replication fork involves multiple enzymes and other proteins, only some of which are mentioned here.

The first step in the repair of the double-strand break is exonucleolytic digestion of the strand with its 5' end at the broken end of DNA, leaving the strand with a 3' end at the break single-stranded (Figure 5-40, step **2**). The lagging nascent strand (pink) base-paired to the unbroken parent strand (dark blue) is ligated to the unreplicated portion of the parent chromosome (light blue), as shown in Figure 5-40, step **2**. A protein required for the next step is RecA in bacteria, or the homologous Rad51 in *S. cerevisiae* and other eukaryotes. Multiple RecA/Rad51 molecules bind to the single-stranded DNA and catalyze its hybridization to a perfectly or nearly perfectly complementary sequence in another, homologous, double-stranded DNA molecule. The complementary strand of this target double-stranded DNA (dark blue) is displaced as a single-stranded loop of DNA over the region of hybridization to the invading strand (Figure 5-40, step **3**). This RecA/Rad51-catalyzed *invasion* of a duplex DNA by a single-stranded complement of one of the strands is key to the recombination process. This process is called **strand invasion**, and because there is no change in the number of base pairs, it does not require an input of energy.

Next the hybrid region between target DNA and the invading strand is extended in the direction away from the break by proteins that use energy from ATP hydrolysis. This process is called *branch migration* (Figure 5-40, step **4**) because the position where the target DNA strand crosses from one complementary strand (dark blue) to its complement in the broken DNA molecule (dark red)—that is, the pink diagonal line after step **3**—is called a *branch* in the DNA structure. In this diagram, the diagonal lines represent only one phosphodiester bond. Molecular modeling and other studies show that the first base on either side of the branch is base-paired to a complementary nucleotide. As this branch *migrates* to the left, the number of base pairs remains

**FIGURE 5-40 Recombinational repair of a collapsed replication fork.** Parent strands are light and dark blue. The leading daughter strand is dark red, and the lagging daughter strand pink. Diagonal lines in step 3 and beyond represent a single phosphodiester bond from the DNA strand of the corresponding color. Small black arrows following step 4 represent cleavage of the phosphodiester bonds at the crossover of DNA strands in the Holliday structure. See <http://www.sheffield.ac.uk/mbb/ruva> for an animation of branch migration catalyzed by *E. coli* proteins RuvA and RuvB. See the text for a discussion.

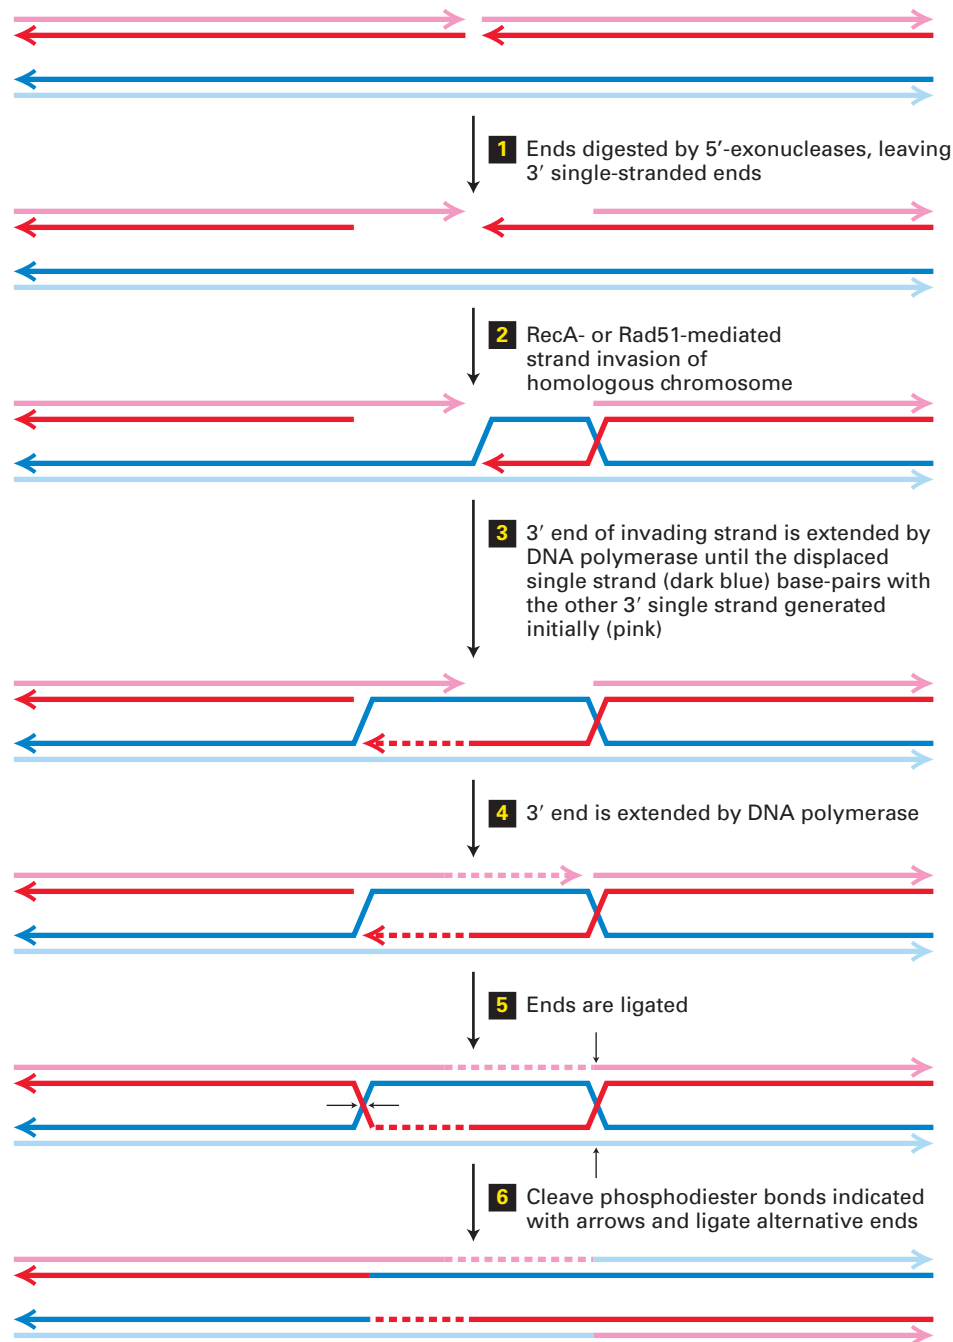

constant; one new base pair formed with the (red) invading strand is matched by the loss of one base pair with the parent (blue) strand.

When the hybrid region extends beyond the 5' end of the broken strand that was digested by the 5'-exonuclease in step 2 (light blue), the single-stranded parent DNA strand generated (light blue) base-pairs with the complementary

region of the other parent strand (dark blue), which becomes single-stranded as the branch migrates to the left (Figure 5-40, step 4). The resulting structure is called a **Holliday structure**, after Robin Holliday, the geneticist who first proposed it as an intermediate in genetic recombination. Again, the diagonal lines in the diagram following step 4 represent single phosphodiester bonds, and all bases in the Holliday structure are base-paired to complementary bases in the parent strands. Cleavage of the phosphodiester bonds that *cross over* from one parent strand to the other (step 5) and ligation of the 5' and 3' ends base-paired to the same parent strands (step 6) result in the generation of a structure similar to a replication fork. Rebinding of replication fork proteins results in extension of the leading strand past the point of the original strand break and re-initiation of lagging-strand synthesis (step 7), thus regenerating a replication fork. The overall process allows the ligated upper strand in the lower molecule following step 2 to serve as a template for extension of the leading strand in step 7.

**Repair of a Double-Strand Break by Homologous Recombination** A similar mechanism, called **homologous recombination**, can repair a double-strand break in a chromosome and can also exchange large segments of two double-stranded DNA molecules (Figure 5-41). First, the broken ends of the DNA molecule are digested by 5'-exonucleases, leaving a single-stranded region of DNA with a 3' end (step 1). RecA in bacteria or Rad51 in eukaryotes then catalyzes invasion of one of these 3' ends into the homologous region of the homologous chromosome, as described above for repair of a collapsed replication fork (step 2). The 3' end of the invading DNA strand is then extended by a DNA polymerase, displacing the parent strand as an enlarging single-stranded loop of DNA (dark blue) (step 3). When the loop extends to a sequence that is complementary to the other broken and 5'-exonuclease-digested end of DNA (the fragment on the left following step 1), the complementary sequences base-pair (diagram following step 3). This 3' end is then extended by a DNA polymerase using the displaced single-stranded loop of parent DNA (dark blue) as a template (step 4).

Next the new 3' ends are ligated (step 5) to the exonuclease-digested 5' ends. This generates two Holliday structures in the paired molecules (step 5). Branch migration of these Holliday structures can occur in either direction (not diagrammed). Finally, cleavage of the strands at the positions shown by the arrows, and ligation of the alternative 5' and 3' ends at each cleaved Holliday structure, generates two *recombinant* chromosomes that contain the DNA of one *parent* DNA molecule on one side of the initial break point (pink and red strands), and the DNA of the other parent DNA molecule on the other side of the break point (light and dark blue) (step 6). The region in the immediate vicinity of the initial break point forms a *heteroduplex*, in which one strand from one parent is base-paired to the complementary strand of the other parent (pink or red strand base-paired to light or dark blue strand). Base-pair mismatches between the two parent strands are usually repaired by the repair mechanisms discussed above to generate

**FIGURE 5-41 Repair of a double-strand break by homologous recombination.** For simplicity, each DNA double helix is represented by two parallel lines with the polarities of the strands indicated by arrowheads at their 3' ends. The upper molecule has a double-strand break.

Note that in the diagram of the upper DNA molecule, the strand with its 3' end at the right is on the top, while in the diagram of the lower DNA molecule, this strand is drawn on the bottom. See the text for discussion. See T. L. Orr-Weaver and J. W. Szostak, 1985, *Microbiol. Rev.* **49**:33.

a complementary base pair. In the process, sequence differences between the two parents are lost, a process referred to as **gene conversion**.

Figure 5-42 diagrams how cleavage of one or the other pair of strands at the four-way strand junction in the Holliday structure generates parent or recombinant molecules. This process, called *resolution* of the Holliday structure, separates DNA molecules initially joined by RecA/Rad51-catalyzed strand invasion. Each Holliday structure in the intermediate following Figure 5-41, step **5**, can be cleaved

and religated in the two possible ways shown by the two sets of small black arrows in Figure 5-42 (step **1** or step **2**). Consequently, there are four possible products of the recombination process shown in Figure 5-41. After ligation of the cleaved ends, two of these products regenerate the parent chromosomes [with the exception of the heteroduplex region at the break point that is repaired into the sequence of one parent or the other (gene conversion)]. The other two possible products generate recombinant chromosomes as shown in Figure 5-41.

**FIGURE 5-42 Alternative resolution of a Holliday structure.**

Diagonal and vertical lines represent a single phosphodiester bond. It is simplest to diagram the process by rotating the diagram of the bottom molecule 180° so that the top and bottom molecules have the same

strand orientations. Cutting the bonds as shown in **1** and ligating the ends as indicated regenerates the original chromosomes. Cutting the strands as shown in **2** and religating as shown at the bottom generates recombinant chromosomes.

## KEY CONCEPTS OF SECTION 5.6

### DNA Repair and Recombination

- Changes in the DNA sequence result from copying errors and the effects of various physical and chemical agents.
- Many copying errors that occur during DNA replication are corrected by the proofreading function of DNA polymerases, which can recognize incorrect (mismatched) bases at the 3' end of the growing strand and then remove them by means of an inherent 3'→5' exonuclease activity (see Figure 5-33).
- Eukaryotic cells have three excision-repair systems for correcting mismatched bases and for removing chemical adducts from DNA. Base excision repair, mismatch repair, and nucleotide excision repair operate with high accuracy and generally do not introduce errors.
- Repair of double-strand breaks by the nonhomologous end joining pathway can link segments of DNA from different chromosomes, possibly forming an oncogenic chromosomal translocation. This repair mechanism also produces a small deletion, even when segments from the same chromosome are joined.
- Error-free repair of double-strand breaks in DNA is accomplished by homologous recombination using the undamaged sister chromatid as a template.
- Inherited defects in the nucleotide excision-repair pathway, as in individuals with xeroderma pigmentosum, predispose them to skin cancer. Inherited colon cancer is frequently associated with mutant forms of proteins essential for the mismatch repair pathway. Defects in repair by homologous recombination are associated with inheritance of one mutant allele of the *BRCA-1* or *BRCA-2* gene and result in predisposition to breast and uterine cancer.

## 5.7 Viruses: Parasites of the Cellular Genetic System

**Viruses** are obligate, intracellular parasites. They cannot reproduce by themselves and must commandeer a host cell's machinery to synthesize viral proteins and, in some cases, to replicate the viral genome. RNA viruses, which usually replicate in the host-cell cytoplasm, have an RNA genome, and DNA viruses, which commonly replicate in the host-cell nucleus, have a DNA genome (see Figure 5-1). Viral genomes may be single- or double-stranded, depending on the specific type of virus. The entire infectious virus particle, called a **virion**, consists of nucleic acid and an outer shell of protein that both protects the viral nucleic acid and functions in the process of host-cell infection. The simplest viruses contain only enough RNA or DNA to encode four proteins; the most complex can encode some two hundred proteins. In addition to their obvious importance as causes of disease, viruses are extremely useful as research tools in the study of basic biological processes such as those discussed in this chapter.

### Most Viral Host Ranges Are Narrow

The surface of a virion contains many copies of one type of protein that binds specifically to multiple copies of a receptor protein on a host-cell surface. This interaction determines the *host range*—the group of cell types that a virus can infect—and begins the infection process. Most viruses have a rather limited host range.

A virus that infects only bacteria is called a **bacteriophage**, or simply a *phage*. Viruses that infect animal or plant cells are referred to generally as animal viruses or plant viruses. A few viruses can grow in both plants or animals and the insects that feed on them. The highly mobile insects serve as vectors for transferring such viruses between susceptible animal or plant hosts. Wide host ranges are also characteristic of some strictly animal viruses, such as vesicular stomatitis

virus, which grows in insect vectors and in many different types of mammals. Most animal viruses, however, do not cross phyla, and some (e.g., poliovirus) infect only closely related species, such as primates. The host-cell range of some animal viruses is further restricted to a limited number of cell types because only those cells have surface receptors to which the virions can attach. One example is poliovirus, which infects only cells in the intestine and, unfortunately for its host, motor neurons in the spinal cord, causing paralysis. Another is HIV-1, discussed further below, which infects cells called CD4<sup>+</sup> T lymphocytes that are essential for the immune response (see Chapter 23) as well as certain neurons and other cells of the central nervous system called glial cells.

### Viral Capsids Are Regular Arrays of One or a Few Types of Protein

The nucleic acid of a virion is enclosed within a protein coat, or **capsid**, composed of multiple copies of one protein or a few different proteins, each of which is encoded by a single viral gene. Because of this structure, a virus is able to encode all the information for making a relatively large capsid in a small number of genes. This efficient use of genetic information is important because only a limited amount of DNA or RNA, and therefore a limited number of genes, can fit into a virion capsid.

Nature has found two basic ways of arranging the multiple capsid protein subunits and the viral genome into a virion. In some viruses, multiple copies of a single capsid protein form a *helical* structure that encloses and protects the viral RNA or DNA, which runs in a helical groove within the protein tube. Viruses with such a helical structure, such as tobacco mosaic virus, have a rodlike shape (Figure 5-43a). The other major structural type is based on the *icosahedron*, a solid, approximately spherical object built of 20 identical faces, each of which is an equilateral triangle (Figure 5-43b). During infection, some icosahedral viruses interact with host-cell receptors via clefts in between the capsid subunits. Others interact via long fiberlike proteins extending from the vertices of the icosahedron.

In many DNA bacteriophages, the viral DNA is located within an icosahedral “head” that is attached to a rodlike “tail.” During infection, viral proteins at the tip of the tail bind to host-cell receptors, and the viral DNA then passes down the tail into the cytoplasm of the host cell (Figure 5-43c).

In some viruses, a symmetrically arranged **nucleocapsid** composed of the viral genome associated with multiple copies of one or a few proteins is covered by an external membrane, or **envelope**, which consists mainly of a phospholipid bilayer but also contains one or more types of virus-encoded glycoproteins (Figure 5-43d). The phospholipids in the viral envelope are similar to those in the plasma membrane of an infected host cell. The viral envelope is, in fact, derived by budding from that membrane, but contains mainly viral glycoproteins, as we will discuss shortly.

### Viruses Can Be Cloned and Counted in Plaque Assays

The number of infectious viral particles in a sample can be quantified by a **plaque assay**. This assay is performed by culturing a dilute sample of viral particles on a plate covered with host cells and then counting the number of local lesions, called *plaques*, that develop (Figure 5-44). A plaque develops on the plate wherever a single virion initially infects a single cell. The virus replicates in this initial host cell and then lyses (ruptures) the cell, releasing many progeny virions that infect the neighboring cells on the plate. After a few such cycles of infection, enough cells are lysed to produce a visible clear area, or plaque, in the layer of remaining uninfected cells. Since all the progeny virions in a plaque are derived from a single parent virus, they constitute a viral clone.

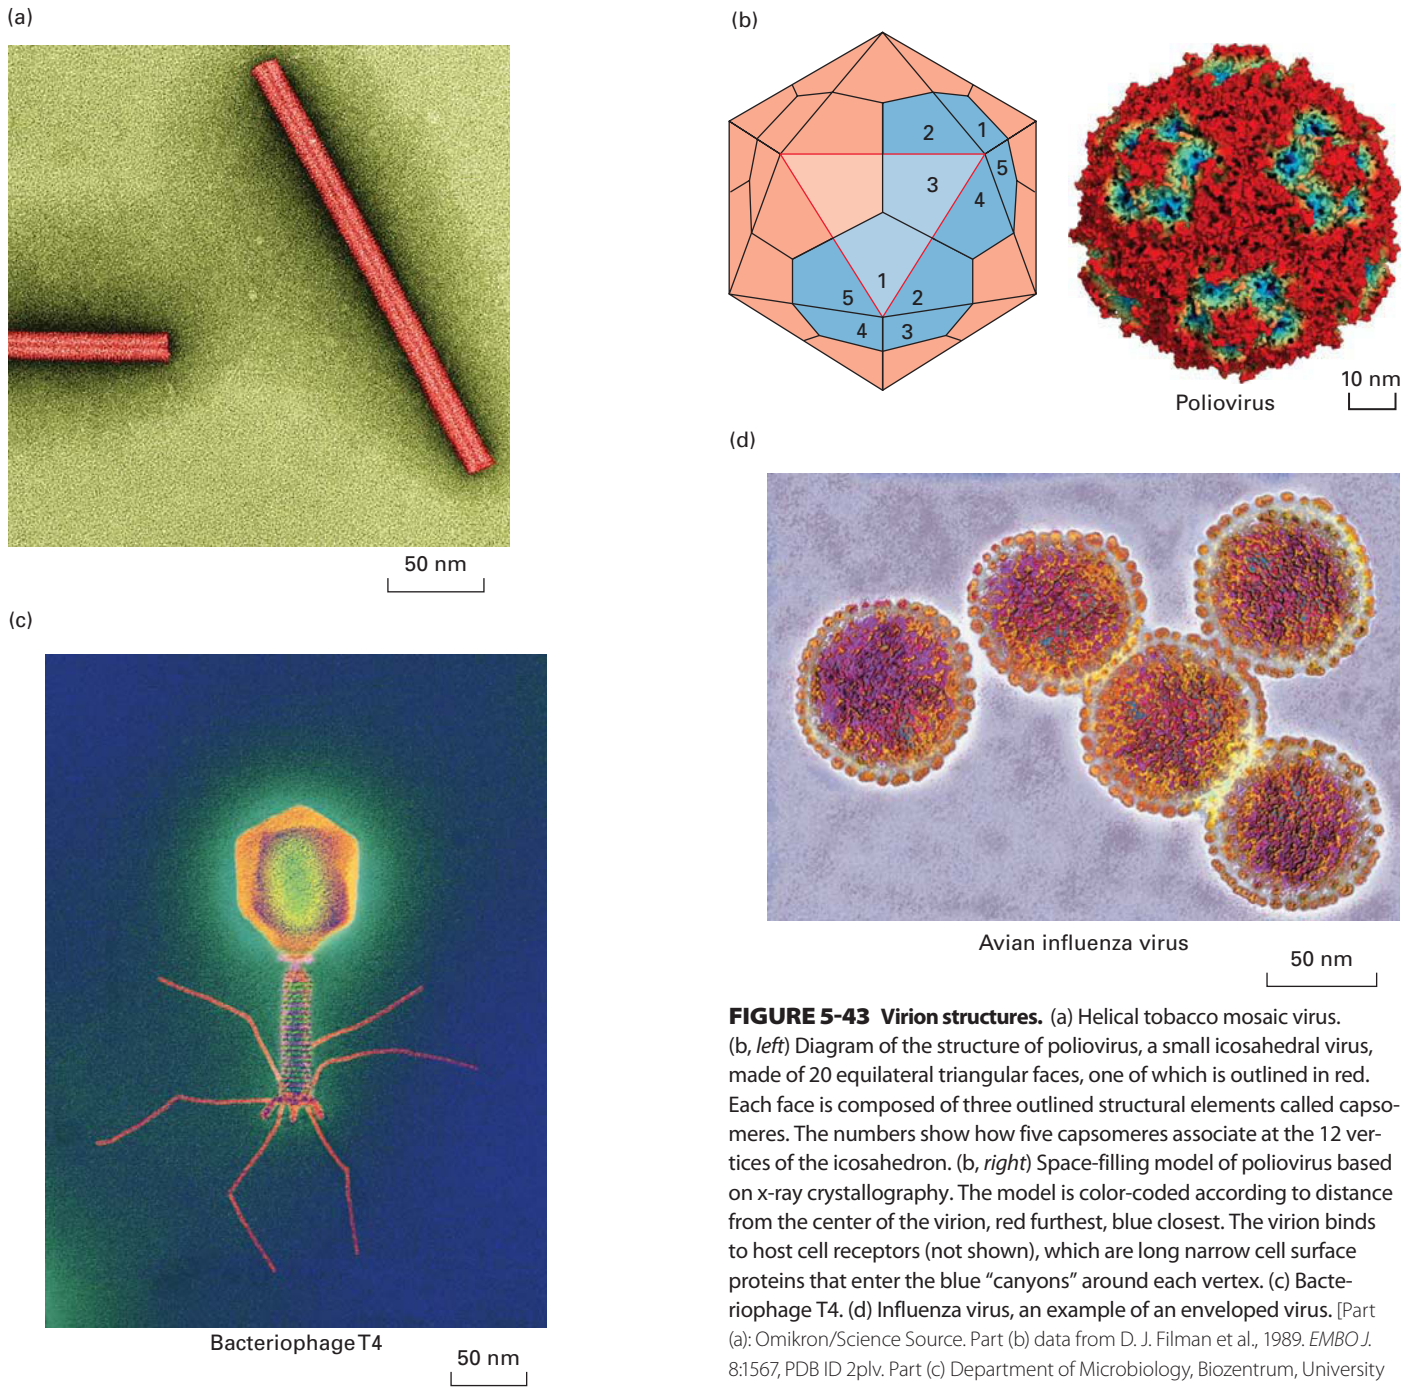

This type of plaque assay is in standard use for bacterial and animal viruses. Plant viruses can be assayed similarly by counting local lesions on plant leaves inoculated with viruses. Analysis of viral mutants, which are commonly isolated by plaque assays, has contributed extensively to our current understanding of molecular cellular processes.

### Lytic Viral Growth Cycles Lead to Death of Host Cells

Although details vary among different types of viruses, those that exhibit a *lytic cycle* of growth proceed through the following general stages:

1. **Adsorption**—Virion interacts with a host cell by binding of multiple copies of capsid protein to specific receptors on the cell surface.
2. **Penetration**—Viral genome crosses the host plasma membrane. For some viruses, viral proteins packaged inside the capsid also enter the host cell.
3. **Replication**—Viral mRNAs are produced with the aid of the host-cell transcription machinery (DNA viruses) or by viral enzymes (RNA viruses). For both types of viruses, viral mRNAs are translated by the host-cell translation machinery. Production of multiple copies of the viral genome is carried out either by viral proteins alone or with the help of host-cell proteins.
4. **Assembly**—Viral proteins and replicated genomes associate to form progeny virions.
5. **Release**—The host cell either ruptures suddenly (**lysis**), releasing all the newly formed virions at once, or disintegrates gradually, releasing the virions slowly. Both types of release lead to the death of the infected cell.

Figure 5-45 illustrates the lytic cycle for T4 bacteriophage, a nonenveloped DNA virus that infects *E. coli*. Viral capsid proteins generally are made in large amounts because many copies of them are required for the assembly of each progeny virion. In each infected *E. coli* cell, about 100–200 T4 progeny virions are produced and released by lysis.

**FIGURE 5-43 Virion structures.** (a) Helical tobacco mosaic virus. (b, *left*) Diagram of the structure of poliovirus, a small icosahedral virus, made of 20 equilateral triangular faces, one of which is outlined in red. Each face is composed of three outlined structural elements called capsomeres. The numbers show how five capsomeres associate at the 12 vertices of the icosahedron. (b, *right*) Space-filling model of poliovirus based on x-ray crystallography. The model is color-coded according to distance from the center of the virion, red furthest, blue closest. The virion binds to host cell receptors (not shown), which are long narrow cell surface proteins that enter the blue “canyons” around each vertex. (c) Bacteriophage T4. (d) Influenza virus, an example of an enveloped virus. [Part (a): Omikron/Science Source. Part (b) data from D. J. Filman et al., 1989. *EMBO J.* 8:1567, PDB ID 2plv. Part (c) Department of Microbiology, Biozentrum, University of Basel/Science Source. Part (d) James Cavallini/Science Source.]

The lytic cycle is somewhat more complicated for DNA viruses that infect eukaryotic cells. In most such viruses, the DNA genome is transported (with some associated proteins) into the cell nucleus. Once inside the nucleus, the viral DNA is transcribed into RNA by the host’s transcription machinery. Processing of the viral RNA primary transcript by host-cell enzymes yields viral mRNA, which is transported to the cytoplasm and translated into viral proteins by host-cell ribosomes, tRNA, and translation factors. The viral proteins are then transported back into the nucleus, where some of them either replicate the viral DNA directly or direct cellular proteins to replicate the viral DNA, as in the case of SV40, discussed earlier. Association

of the capsid proteins with the newly replicated viral DNA occurs in the nucleus, yielding thousands to hundreds of thousands of progeny virions. Since mammalian cells are about a thousand times larger than bacterial cells, on the order of a thousand times as many virions are produced per cell. However, since many more proteins must be synthesized and viral genomes replicated to assemble this large number of virions, one cycle of infection takes much longer for an animal virus than for bacteriophage of comparable complexity. Bacteriophage T4 replicates in and lyses *E. coli* cells in about 20 minutes, whereas replication of poliovirus and lysis of host cells requires about 8 hours. Many animal viruses are considerably slower than poliovirus, requiring

**EXPERIMENTAL FIGURE 5-44 Plaque assay.** The plaque assay determines the number of infectious particles in a viral suspension. (a) A lesion, or plaque, develops where a single virion initially infected a single cell. Each plaque constitutes a pure viral clone. (b) Plaques on a lawn of *Pseudomonas fluorescens* bacteria made by bacteriophage  $\phi$ S1. [Part (b) P. Rossi, 1994, Advances in biological tracer techniques for hydrology and hydrogeology using bacteriophages, Ph. D. thesis, University of Neuchâtel, 200 pp. [http://doc.rero.ch/record/2576/files/these\\_RossiP](http://doc.rero.ch/record/2576/files/these_RossiP)]

2 days or more for lysis of an infected cell and release of progeny virions.

Most plant and animal viruses with an RNA genome do not require nuclear functions for lytic replication. In some of these viruses, a virus-encoded enzyme that enters the host cell during penetration transcribes the viral genomic RNA into mRNA in the cell cytoplasm. The mRNA is directly translated into viral proteins by the host-cell translation machinery. One or more of these proteins then produces additional copies of the viral RNA genome. Finally, progeny genomes are associated with newly synthesized capsid proteins to form progeny virions in the cytoplasm.

After the synthesis of hundreds to hundreds of thousands of new virions has been completed, depending on the type of virus and host cell, most infected bacterial cells and some

**FIGURE 5-45 Lytic replication cycle of a nonenveloped bacterial virus.** *E. coli* bacteriophage T4 has a double-stranded DNA genome and lacks a membrane envelope. After viral capsid proteins at the tip of the tail in T4 interact with specific receptor proteins on the exterior of the host cell, the viral genome is injected into the host (step 1). Host-cell enzymes then transcribe viral “early” genes into mRNAs and subsequently translate these mRNAs into viral “early” proteins (step 2). The early proteins replicate the viral DNA and induce expression of viral “late” proteins by host-cell enzymes (step 3). The viral late proteins include capsid and assembly proteins and enzymes that degrade the host-cell DNA, supplying nucleotides for synthesis of more viral DNA. Progeny virions are assembled in the cell (step 4) and released (step 5) when viral proteins lyse the cell. Newly liberated viruses initiate another cycle of infection in other host cells.

infected plant and animal cells are lysed, releasing all the virions at once. In many plant and animal viral infections, however, no discrete lytic event occurs; rather, the dead host cell releases the virions as it gradually disintegrates.

As noted previously, enveloped animal viruses are surrounded by an outer phospholipid bilayer, derived from the plasma membrane of a host cell, that contains abundant viral glycoproteins. The processes of adsorption and release of enveloped viruses differ substantially from these processes for nonenveloped viruses. To illustrate lytic replication of enveloped viruses, we consider the rabies virus, whose nucleocapsid consists of a single-stranded RNA genome bound by multiple copies of a nucleocapsid protein. Like other lytic RNA viruses, the rabies virus is replicated in the cytoplasm and does not require host-cell nuclear enzymes. As shown in

**FIGURE 5-46 Lytic replication cycle of an enveloped animal virus.** The rabies virus is an enveloped virus with a single-stranded RNA genome. The structural components of this virus are depicted at the top. After a virion adsorbs to multiple copies of a specific host membrane protein (step **1**), the cell engulfs it in an endosome (step **2**). A cellular protein in the endosome membrane pumps  $H^+$  ions from the cytosol into the endosome interior. The resulting decrease in endosomal pH induces a conformational change in the viral glycoprotein, leading to fusion of the viral envelope with the endosomal lipid bilayer and release of the nucleocapsid into the cytosol (steps **3** and **4**). Viral RNA polymerase uses ribonucleoside triphosphates in the cytosol to replicate the viral RNA genome (step **5**) and to synthesize viral mRNAs (step **6**). One of the viral mRNAs encodes the viral transmembrane glycoprotein, which is inserted into the membrane of the endoplasmic

reticulum (ER) as it is synthesized on ER-bound ribosomes (step **7**). Carbohydrate is added to the large folded domain inside the ER lumen and is modified as the membrane and the associated glycoproteins pass through the Golgi apparatus (step **8**). Vesicles with mature glycoprotein fuse with the host-cell plasma membrane, depositing viral glycoprotein on the cell surface with the large receptor-binding domain outside the cell (step **9**). Meanwhile, other viral mRNAs are translated on host-cell ribosomes into nucleocapsid protein, matrix protein, and viral RNA polymerase (step **10**). These proteins are assembled with replicated viral genomic RNA (bright red) into progeny nucleocapsids (step **11**), which then associate with the cytosolic domain of viral transmembrane glycoproteins in the host-cell plasma membrane (step **12**). The plasma membrane is folded around the nucleocapsid, forming a “bud” that is eventually released (step **13**).

Figure 5-46, a rabies virion is adsorbed by endocytosis (see Chapter 14, Figures 14-1 and 14-2), and release of progeny virions occurs by *budding* from the host-cell plasma membrane. Budding virions are clearly visible in electron micrographs of infected cells, as illustrated in Figure 5-47. Many tens of thousands of progeny virions bud from an infected host cell before it dies.

### Viral DNA Is Integrated into the Host-Cell Genome in Some Nonlytic Viral Growth Cycles

Some bacterial viruses, called *temperate phages*, can establish a nonlytic association with their host cell that does not kill the cell. For example, when bacteriophage  $\lambda$  infects *E. coli*, most of the time it causes a lytic infection. Occasionally,

however, the viral DNA is integrated into the host-cell chromosome rather than being replicated. The integrated viral DNA, called a *prophage*, is replicated as part of the host cell’s DNA from one host-cell generation to the next. This phenomenon is referred to as *lysogeny*. If the host cell suffers extensive damage to its DNA from UV light, the prophage DNA is activated, leading to its excision from the host-cell chromosome, entrance into the lytic cycle, and subsequent production and release of progeny virions before the host cell dies.

The genomes of a number of animal viruses can also integrate into the host-cell genome. Among the most important of these are the **retroviruses**, which are enveloped viruses with a genome consisting of two identical strands of RNA. These viruses are so named because their RNA genome acts

**EXPERIMENTAL FIGURE 5-47 Release of progeny virions by budding.** Progeny virions of enveloped viruses are released by budding from infected cells. In this transmission electron micrograph of a cell infected with measles virus, virion buds are clearly visible protruding from the cell surface. Measles virus is an enveloped RNA virus with a helical nucleocapsid, like rabies virus, and replicates as illustrated in Figure 5-46. [Thomas Deerinck, NCMIR/Science Source.]

as a template for the formation of a DNA molecule—a flow of genetic information that is opposite to the more common transcription of DNA into RNA. In the retroviral life cycle (Figure 5-48), a viral enzyme called **reverse transcriptase** initially copies the viral RNA genome into single-stranded DNA that is complementary to the viral RNA; the same enzyme then catalyzes the synthesis of a complementary DNA strand. (This complex reaction is detailed in Chapter 8, where we consider closely related intracellular parasites called retrotransposons.) The resulting double-stranded DNA is integrated into the chromosomal DNA of the infected cell by an integrase enzyme in the virion. Finally, the integrated DNA, called a *provirus*, is transcribed by the host cell's own RNA polymerase into RNA, which is either translated into viral proteins or packaged within virion capsid proteins to form progeny virions that are released by budding from the host-cell membrane. Because most retroviruses do not kill their host cells, infected cells can replicate, producing daughter cells with integrated proviral DNA. These daughter cells continue to transcribe the proviral DNA and bud progeny virions.

Some retroviruses contain cancer-causing genes (*oncogenes*), and cells infected by such retroviruses are oncogenically transformed into tumor cells. Studies of oncogenic retroviruses (mostly viruses of birds and mice) have revealed a great deal about the processes that lead to transformation of a normal cell into a cancer cell (see Chapter 24).

**FIGURE 5-48 Retroviral life cycle.** Retroviruses have a genome of two identical copies of single-stranded RNA and an outer envelope. Step **1**: After viral glycoproteins in the retroviral envelope interact with a specific host-cell membrane protein, the envelope fuses directly with the plasma membrane, allowing entry of the nucleocapsid into the cytoplasm of the cell. Step **2**: Viral reverse transcriptase and other proteins copy the viral ssRNA genome into a double-stranded DNA. Step **3**: The viral dsDNA is transported into the nucleus and integrated

into one of many possible sites in the host-cell chromosomal DNA. For simplicity, only one host-cell chromosome is depicted. Step **4**: The integrated viral DNA (provirus) is transcribed by the host-cell RNA polymerase, generating viral mRNAs (dark red) and viral genomic RNA molecules (bright red). The host-cell machinery translates the viral mRNAs into glycoproteins and nucleocapsid proteins. Step **5**: Progeny virions then assemble and are released by budding, as illustrated in Figure 5-46.

Among the known human retroviruses are human T-cell lymphotropic virus (HTLV), which causes a form of leukemia, and human immunodeficiency virus (HIV-1), which causes acquired immune deficiency syndrome (AIDS). Both of these viruses can infect only specific cell types, primarily certain cells of the immune system and, in the case of HIV-1, some central nervous system neurons and glial cells. Only those cells have cell-surface receptors that interact with viral envelope proteins. Unlike most other retroviruses, HIV-1 eventually kills its host cells. The eventual death of large numbers of immune-system cells results in the defective immune response characteristic of AIDS.

Some DNA viruses can also integrate into a host-cell chromosome. One example is the human papillomaviruses (HPVs), which most commonly cause warts and other benign skin lesions. These viruses replicate without integrating into a host-cell chromosome. However, the genomes of certain HPV serotypes occasionally integrate into the chromosomal DNA of infected cervical epithelial cells. Unlike retroviruses and temperate bacteriophages, this integration is not carried out by viral proteins, but rather is the consequence of host-cell DNA repair processes. Integration is a dead-end for HPV. The integrated viral DNA cannot replicate and generate progeny virions. But oncogenic (cancer-causing) viral proteins can be expressed from the integrated viral genome, initiating development of cervical cancer. Routine Pap smears can detect cells in the early stages of the transformation process initiated by HPV integration, permitting effective treatment before cancer develops. A vaccine for the types of HPV associated with cervical cancer has been developed and can protect against the initial infection by these viruses, and consequently, against development of cervical cancer. However, once an individual is infected with these HPVs, the “window of opportunity” is missed, and the vaccine does not protect against the development of cancer. Because the vaccine is not 100 percent effective, even vaccinated women should have regular Pap smears. ■

- Most animal and plant DNA viruses require host-cell nuclear enzymes to carry out transcription of the viral genome into mRNA and production of progeny genomes. In contrast, most RNA viruses encode enzymes that can transcribe the RNA genome into viral mRNA and produce new copies of the RNA genome.
- Host-cell ribosomes, tRNAs, and translation factors are used in the synthesis of all viral proteins in infected cells.
- Lytic viral infection entails adsorption, penetration, synthesis of viral proteins and progeny genomes (replication), assembly of progeny virions, and release of hundreds to thousands of virions, leading to death of the host cell (see Figure 5-45). Release of enveloped viruses occurs by budding through the host-cell plasma membrane (see Figure 5-46).
- Nonlytic infection occurs when the viral genome is integrated into the host-cell DNA and generally does not lead to cell death.
- Retroviruses are enveloped animal viruses containing a single-stranded RNA genome. After a host cell is penetrated, reverse transcriptase, a viral enzyme carried in the virion, converts the viral RNA genome into double-stranded DNA, which is integrated into chromosomal DNA by an integrase enzyme that enters the cell inside the virion (see Figure 5-48).
- Unlike infection by other retroviruses, HIV-1 infection eventually kills host cells, causing the defects in the immune response characteristic of AIDS.
- Tumor viruses, which contain oncogenes, may have an RNA genome (e.g., human T-cell lymphotropic virus) or a DNA genome (e.g., human papillomaviruses). Integration of the genomes of these viruses into a host-cell chromosome can cause transformation of the host cell into a tumor cell.

## KEY CONCEPTS OF SECTION 5.7

### Viruses: Parasites of the Cellular Genetic System

- Viruses are small parasites that can replicate only in host cells. Viral genomes may be either DNA (DNA viruses) or RNA (RNA viruses) and may be either single- or double-stranded.
- The capsid, which surrounds the viral genome, is composed of multiple copies of one or a small number of virus-encoded proteins. Some viruses also have an outer envelope, which is similar to the plasma membrane of the host cell but contains viral transmembrane proteins.

## Key Terms

anticodon 183	Okazaki fragments 199
codon 183	phosphodiester bond 170
complementary 171	polyribosome 195
DNA polymerase 198	primer 198
double helix 170	promoter 176
excision-repair systems 204	reading frame 184
gene conversion 211	recombination 209
genetic code 183	replication fork 199
Holliday structure 210	retroviruses 216
homologous recombination 208	reverse transcriptase 217
isoform 182	ribosomal RNA (rRNA) 168
lagging strand 199	ribosome 183
leading strand 199	RNA polymerase 176
messenger RNA (mRNA) 168	transcription 168
mutation 203	transfer RNA (tRNA) 168
	translation 168

## Review the Concepts

1. What are Watson-Crick base pairs? Why are they important?
2. Preparing plasmid (double-stranded, circular) DNA for sequencing involves annealing a complementary, short, single-stranded oligonucleotide DNA primer to one strand of the plasmid template. This is routinely accomplished by heating the plasmid DNA and primer to 90 °C and then slowly bringing the temperature down to 25 °C. Why does this protocol work?
3. What difference between RNA and DNA helps to explain the greater stability of DNA? What implications does this have for the function of DNA?
4. What are the major differences in the synthesis and structure of prokaryotic and eukaryotic mRNAs?
5. While investigating the function of a specific growth factor receptor gene from humans, researchers found that two types of proteins are synthesized from this gene. A larger protein containing a membrane-spanning domain recognizes growth factors at the cell surface, stimulating a specific downstream signaling pathway. In contrast, a related, smaller protein is secreted from the cell and binds available growth factor circulating in the blood, thus inhibiting the downstream signaling pathway. Speculate on how the cell synthesizes these disparate proteins.
6. The transcription of many bacterial genes relies on functional groups called *operons*, such as the tryptophan operon (see Figure 5-13a). What is an operon? What advantages are there to having genes arranged in an operon, compared with the arrangement in eukaryotes?

7. How would a mutation in the poly(A)-binding protein gene affect translation? How would an electron micrograph of polyribosomes from such a mutant differ from the normal pattern?

8. What characteristic of DNA results in the requirement that some DNA synthesis be discontinuous? How are Okazaki fragments and DNA ligase used by the cell?

9. Eukaryotes have repair systems that prevent mutations due to copying errors and exposure to mutagens. What are the three excision-repair systems found in eukaryotes, and which one is responsible for correcting thymine-thymine dimers that form as a result of UV light damage to DNA?

10. DNA repair systems are responsible for maintaining genomic fidelity in normal cells despite the high frequency with which mutational events occur. What type of DNA mutation is generated by (a) UV radiation and (b) ionizing radiation? Describe the system responsible for repairing each of these types of mutations in mammalian cells. Postulate why a loss of function in one or more DNA repair systems typifies many cancers.

11. What is the name given to the process that can repair DNA damage *and* generate genetic diversity? Briefly describe the similarities and differences of the two processes.

12. The genome of a retrovirus can integrate into the host-cell genome. What gene is unique to retroviruses, and why is the protein encoded by this gene absolutely necessary for maintaining the retroviral life cycle? A number of retroviruses can infect certain human cells. List two of them, briefly describe the medical implications resulting from these infections, and describe why only certain cells are infected.

13. a. Which of the following DNA strands, the top or bottom, would serve as a template for RNA transcription if the DNA molecule were to unwind in the indicated direction?

5' ACGGACTGTACCGCTGAAGTCATGGACGCTCGA 3'  
3' TGCCTGACATGGCGACTTCAGTACCTGCGAGCT 5'

—————→

Direction of DNA unwinding

b. What would be the resulting RNA sequence (written 5'→3')?

14. Contrast prokaryotic and eukaryotic gene characteristics.

15. You have learned about the events surrounding DNA replication and the central dogma. Identify the steps associated with these processes that would be adversely affected in the following scenarios.

a. Helicases unwind the DNA, but stabilizing proteins are mutated and cannot bind to the DNA.

b. The mRNA molecule forms a hairpin loop on itself via complementary base pairing in an area spanning the AUG start site.

c. The cell is unable to produce functional tRNA<sub>i</sub><sup>Met</sup>.

16. Use the key provided below to determine the amino acid sequence of the polypeptide produced from the following DNA sequence. Intron sequences are highlighted. Note: Not all amino acids in the key will be used.

5' TTCTAAACGCATGAAGCACCGTCTCAGAGCCAGTGA 3'  
3' AAGATTTGCGTACTTCGTGGCAGAGTCTCGGTCCT 5'

—————→

Direction of DNA unwinding

Asn = AAU Cys = TCG Gly = CAG His = CAU Lys = AAG

Met = AUG Phe = UUC Ser = AGC Tyr = UAC Val = GUC; GUA

17. a. Look at the figure above. Explain why it is necessary for Okazaki fragments to be formed as the lagging strand is produced (instead of a continuous strand).

b. If the DNA polymerase in the figure above could bind only to the lower template strand, under what condition(s) would it be able to produce a leading strand?

18. The DNA repair systems preferentially target the newly synthesized strand. Why is this important?

19. Identify the specific types of point mutations below (you are viewing the direct DNA version of the RNA sequence).

Original sequence: 5' AUG TCA GGA CGT CAC TCA GCT 3'

Mutation A: 5' AUG TCA GGA CGT CAC TGA GCT 3'

Mutation B: 5' AUA TCA GGA CGT CAC TCA GCT 3'

20. a. Detail the key differences between lytic and nonlytic viral infection and provide an example of each.

b. Which of the following processes occurs in both lytic and nonlytic viral infections?

(i) Infected cell ruptures to release viral particles.

(ii) Viral mRNAs are transcribed by the host-cell translation machinery.

(iii) Viral proteins and nucleic acids are packaged to produce virions.

The mouse on the right has cataracts because it carries a single copy of a dominant mutant allele of the gene for gamma-crystallin. The mouse on the left, with normal eyes, was produced from a zygote in which the mutant allele was corrected back to the wild-type state by the CRISPR-Cas9 genome editing method. [Jinsong Li]

# Molecular Genetic Techniques

In the field of molecular cell biology, reduced to its most basic elements, we seek an understanding of the biological behavior of cells in terms of the underlying chemical and molecular mechanisms. Often the investigation of a new molecular process focuses on the function of a particular protein or set of proteins. There are three fundamental questions that cell biologists usually ask about a newly discovered protein: What is the function of the protein in the context of a living cell? What is the biochemical function of the purified protein? Where is the protein located? To answer these questions, investigators employ three molecular genetic tools: the gene that encodes the protein, a mutant cell line or organism that lacks the functional protein, and a source of the purified protein itself. In this chapter, we consider various aspects of two basic experimental strategies for obtaining all three tools (Figure 6-1).

The first strategy, often referred to as *classical genetics*, begins with isolation of a mutant that appears to be defective in some process of interest. Genetic methods are then used to identify and isolate the affected gene. The isolated gene can

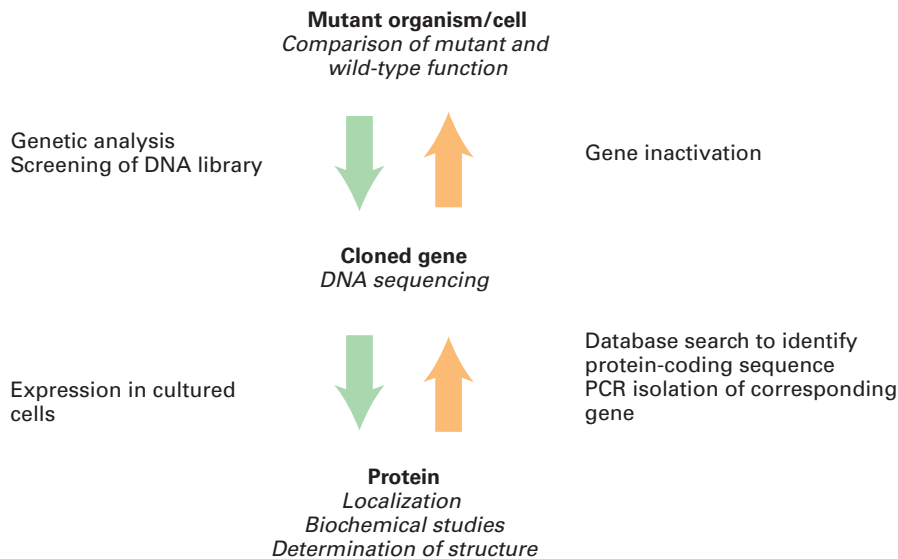

be manipulated to produce large quantities of the protein it encodes for biochemical experiments and to design probes for studies of where and when the protein is expressed in an organism. The second strategy follows essentially the same steps as the classical approach, but in the reverse order, beginning with isolation of an interesting protein or its identification based on analysis of an organism's genomic sequence. Once the corresponding gene has been isolated, that gene can be altered and then reinserted into an organism. With both strategies, by examining the phenotypic consequences of mutations that inactivate a particular gene, geneticists are able to connect knowledge about the sequence, structure, and biochemical activity of the encoded protein to its function in the context of a living cell or multicellular organism.

An important component in both strategies for studying a protein and its biological function is isolation of the corresponding gene. Thus we discuss various techniques by which researchers can isolate, sequence, and manipulate specific regions of an organism's DNA. Next we introduce

## OUTLINE

- 6.1** Genetic Analysis of Mutations to Identify and Study Genes
- 6.2** DNA Cloning and Characterization
- 6.3** Using Cloned DNA Fragments to Study Gene Expression

- 6.4** Locating and Identifying Human Disease Genes
- 6.5** Inactivating the Function of Specific Genes in Eukaryotes

**FIGURE 6-1 Overview of two strategies for relating the function, location, and structure of gene products.** A mutant organism is the starting point for the classical genetic strategy (green arrows). The reverse strategy (orange arrows) usually begins with identification of a protein-coding sequence by analysis of genomic sequence databases. In both strategies, the actual gene is isolated either from a DNA library or by specific amplification of the gene sequence from genomic DNA. Once a cloned gene is isolated, it can be used to produce the encoded protein in bacterial or eukaryotic expression systems. Alternatively, a cloned gene can be inactivated by one of various techniques and used to generate mutant cells or organisms.

a variety of techniques that are commonly used to analyze where and when a particular gene is expressed and where in the cell its protein is localized. In some cases, knowledge of protein function can lead to significant medical advances, and the first step in developing treatments for an inherited disease is to identify and isolate the affected gene, a process we describe here. Finally, we discuss techniques that abolish normal protein function in order to analyze the role of the protein in the cell.

## 6.1 Genetic Analysis of Mutations to Identify and Study Genes

As described in Chapter 5, the information encoded in the DNA sequence of genes specifies the sequence—and therefore the structure and function—of every protein molecule in a cell. The power of genetics as a tool for studying cells and organisms lies in the ability of researchers to selectively alter every copy of one specific type of protein in a cell by making a change in the gene for that protein. Genetic analyses of mutants defective in a particular process can reveal (1) genes required for the process to occur, (2) the order in which gene products act in the process, and (3) whether and how the proteins encoded by different genes interact with one another. Before we see how genetic studies of this type can provide insights into the mechanism of a complicated cellular or developmental process, let's first review some basic genetic terms used throughout our discussion.

The different forms or variants of a gene are referred to as **alleles**. Geneticists commonly refer to the numerous naturally occurring genetic variants that exist in populations, particularly human populations, as alleles. The term **mutation** is usually reserved for instances in which an allele is known to have been newly formed, such as after treatment of an experimental organism with a **mutagen**, an agent that causes a heritable change in the DNA sequence.

Strictly speaking, the particular set of alleles for all the genes carried by an individual constitutes its **genotype**. However, this term is most often used in a more restricted sense to denote the alleles of a particular gene or genes under examination. For experimental organisms, the term **wild type** is often used to designate a standard genotype for use as a reference in breeding experiments. Thus the normal, nonmutant allele is usually designated as the wild type. Because of the enormous allelic variation that naturally exists in human populations, the term *wild type* usually denotes an allele that is present at a much higher frequency than any of the other possible alternatives.

Geneticists draw an important distinction between the *genotype* and the *phenotype* of an organism. The term **phenotype** refers to all the physical attributes or traits of an individual that are the consequence of a given genotype. In practice, however, the term *phenotype* is usually used to denote the consequences that result from the particular alleles that are under experimental study. Readily observable phenotypic characteristics are critical in the genetic analysis of mutations.

### Recessive and Dominant Mutant Alleles Generally Have Opposite Effects on Gene Function

A fundamental genetic difference between experimental organisms is whether their cells carry two copies of each chromosome or only one copy of each chromosome. The former are referred to as *diploid*; the latter as *haploid*. Most complex multicellular organisms (e.g., fruit flies, mice, humans) are diploid, whereas some simple unicellular organisms are haploid. Some organisms, notably the yeast *Saccharomyces cerevisiae*, can exist in either haploid or diploid states. The normal cells of some organisms, both plants and animals, carry more than two copies of each chromosome and are thus designated *polyploid*. Moreover, cancer cells begin as diploid cells, but through the process of transformation into

DIPLOID GENOTYPE					
DIPLOID PHENOTYPE	Wild type	Mutant	Mutant	Wild type	Mutant

**FIGURE 6-2 Effects of dominant and recessive mutant alleles on phenotype in diploid organisms.** A single copy of a dominant mutant allele is sufficient to produce a mutant phenotype, whereas both

copies of a recessive mutant allele must be present to cause a mutant phenotype. Recessive mutations usually cause a loss of function; dominant mutations usually cause a gain of function or an altered function.

cancer cells, can gain extra copies of one or more chromosomes and are thus designated as *aneuploid*. However, our discussion of genetic techniques and analysis relates to diploid organisms, including diploid yeasts.

Although many different alleles of a gene might occur in different organisms in a population, any individual diploid organism will carry two copies of each gene and thus at most can have two different alleles. A diploid individual with two different alleles is **heterozygous** for a gene, whereas a diploid individual that carries two identical alleles is **homozygous** for a gene. A **recessive** mutant allele is defined as one in which both alleles must be mutant in order for the mutant phenotype to be observed; that is, the individual must be homozygous for the mutant allele to show the mutant phenotype. In contrast, the phenotypic consequences of a **dominant** mutant allele can be observed in a heterozygous individual carrying one mutant and one wild-type allele (Figure 6-2).

Whether a mutant allele is recessive or dominant provides valuable information about the function of the affected gene and the nature of the causative mutation. Recessive alleles usually result from a mutation that inactivates the affected gene, leading to a partial or complete *loss of function*. Such recessive mutations may remove part of the gene or the entire gene from the chromosome, disrupt expression of the gene, or alter the structure of the encoded protein, thereby altering its function. Conversely, dominant alleles are often the consequence of a mutation that causes some kind of *gain of function*. Such dominant mutations may increase the activity of the encoded protein, confer a new function on it, or lead to a new spatial or temporal pattern of expression.

In some rare cases, dominant mutations are associated with a loss of function. For instance, some genes are *haplo-insufficient*, in that removing or inactivating one of the two alleles of such a gene leads to a mutant phenotype because not enough gene product is made. In other rare instances, a dominant mutation in one allele may lead to a structural change in the protein that interferes with the function of the wild-type protein encoded by the other allele. This type of mutation, referred to as a *dominant-negative*, produces a phenotype similar to that obtained from a loss-of-function mutation.

Some alleles can exhibit both recessive and dominant properties. In such cases, statements about whether an allele is dominant or recessive must specify the phenotype. For example, the allele of the hemoglobin gene in humans designated  $Hb^s$  has more than one phenotypic consequence. Individuals who are homozygous for this allele ( $Hb^s/Hb^s$ )

have debilitating anemia caused by sickle-cell disease, but heterozygous individuals ( $Hb^s/Hb^a$ ) do not have the disease. Therefore,  $Hb^s$  is *recessive* for the trait of sickle-cell disease. On the other hand, heterozygous ( $Hb^s/Hb^a$ ) individuals are more resistant to malaria than are homozygous ( $Hb^a/Hb^a$ ) individuals, revealing that  $Hb^s$  is *dominant* for the trait of malaria resistance. ■

A mutagen commonly used in experimental organisms is ethylmethane sulfonate (EMS). Although this mutagen can alter DNA sequences in several ways, its most common effect is to chemically modify guanine bases in DNA, ultimately leading to the conversion of a G·C base pair into an A·T base pair. Such an alteration in the sequence of a gene that involves only a single base pair is known as a **point mutation**. A *silent* point mutation causes no change in the amino acid sequence or activity of a gene's encoded protein. However, observable phenotypic consequences due to changes in a protein's activity can arise from point mutations that result in substitution of one amino acid for another (*missense* mutations) or introduction of a premature stop codon (*nonsense* mutations). Addition or deletion of bases may change the reading frame of a gene (*frameshift* mutations). Because alterations in the DNA sequence leading to a decrease in protein activity are much more likely than alterations leading to an increase or qualitative change in protein activity, mutagenesis usually produces many more recessive mutations than dominant mutations.

## Segregation of Mutations in Breeding Experiments Reveals Their Dominance or Recessivity

Geneticists exploit the normal life cycle of an organism to test for the dominance or recessivity of alleles. To see how this is done, we must first review the type of cell division that gives rise to gametes (sperm and egg cells in higher plants and animals). Whereas the body (somatic) cells of most multicellular organisms divide by mitosis, the germ cells that give rise to gametes undergo meiosis. Like somatic cells, pre-meiotic germ cells are diploid, containing two homologs of each morphological type of chromosome. The two homologs that constitute each pair of homologous chromosomes are descended from different parents, and thus their genes may exist in different allelic forms. Figure 6-3 depicts the major events in mitotic and meiotic cell division. In mitosis, DNA replication is always followed by cell division, yielding two

## MITOTIC CELL DIVISION

## MEIOTIC CELL DIVISION

**FIGURE 6-3 Comparison of mitosis and meiosis.** Both somatic cells and pre-meiotic germ cells have two copies of each chromosome ( $2n$ ), one maternal and one paternal. In mitosis, the replicated chromosomes, each composed of two sister chromatids, align at the cell center in such a way that both daughter cells receive a maternal and a paternal homolog of each morphological type of chromosome. During the first *meiotic* division, however, each replicated chromosome pairs with its homologous partner at the cell center; this pairing off is referred to as *synapsis*, and crossing over between homologous chromosomes is evident at this stage. One replicated

chromosome of each morphological type then goes into each daughter cell. The resulting cells undergo a second division without intervening DNA replication, so that one of the sister chromatids of each morphological type is apportioned to the daughter cells. In the second meiotic division, the alignment of chromatids and their equal segregation into daughter cells is the same as in mitotic division. The alignment of pairs of homologous chromosomes in metaphase I is random with respect to other chromosome pairs, resulting in a mix of paternally and maternally derived chromosomes in each daughter cell.

diploid daughter cells. In meiosis, *one* round of DNA replication is followed by *two* separate cell divisions, yielding haploid ( $1n$ ) cells known as gametes that contain only one chromosome of each homologous pair. The apportionment, or **segregation**, of the replicated homologous chromosomes to daughter cells during the first meiotic division is random and different chromosomes segregate independently of one another, yielding gametes with different mixes of paternal and maternal chromosomes.

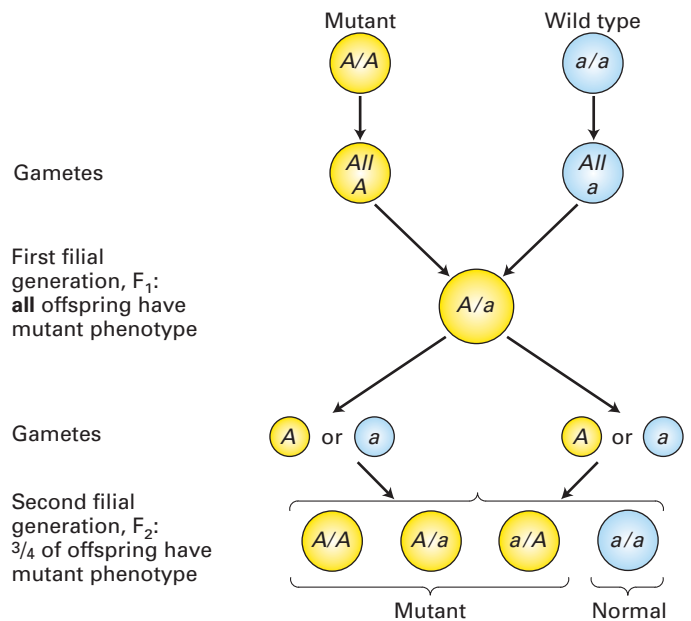

As a way to avoid unwanted complexity, geneticists usually strive to begin breeding experiments with strains of organisms that are homozygous for the genes under examination. In such *true-breeding* strains, every individual will receive the same allele from each parent, and therefore the composition of alleles will not change from one generation to the next. When a true-breeding mutant strain is mated to a true-breeding wild-type strain, all the first filial ( $F_1$ ) progeny will be heterozygous (Figure 6-4). If the  $F_1$  progeny exhibit the mutant trait, then the mutant allele is dominant; if the  $F_1$  progeny exhibit the wild-type trait, then the mutant allele is recessive. Further crossing between  $F_1$  individuals will also reveal different patterns of inheritance according to whether the mutation is dominant or recessive. When  $F_1$  individuals that are heterozygous for a dominant allele are crossed among themselves, three-fourths of the resulting  $F_2$  progeny will exhibit the mutant trait. In contrast, when  $F_1$  individuals that are heterozygous for a recessive allele are crossed among themselves, only one-fourth of the resulting  $F_2$  progeny will exhibit the mutant trait.

As noted earlier, the yeast *S. cerevisiae*, an important experimental organism, can exist in either a haploid or a diploid state. In these unicellular eukaryotes, crosses between haploid cells can determine whether a mutant allele is dominant or recessive. Haploid yeast cells, which carry one copy of each chromosome, can be of two different mating types, known as  $a$  and  $\alpha$ . Haploid cells of opposite mating type can mate to produce  $a/\alpha$  diploids, which carry two copies of each chromosome. If a new mutation with an observable phenotype is isolated in a haploid strain, the mutant strain can be mated to a wild-type strain of the opposite mating type to produce  $a/\alpha$  diploids that are heterozygous for the mutant allele. If these diploids exhibit the mutant trait, then the mutant allele is dominant, but if the diploids exhibit the wild-type trait, then the mutant allele is recessive. When  $a/\alpha$  diploids are placed under starvation conditions, the cells undergo meiosis, each giving rise to a tetrad of four haploid spores, two of type  $a$  and two of type  $\alpha$ . Sporulation of a heterozygous diploid cell yields two spores carrying the mutant allele and two carrying the wild-type allele (Figure 6-5). Under appropriate conditions, yeast spores will germinate, producing vegetative haploid strains of both mating types.

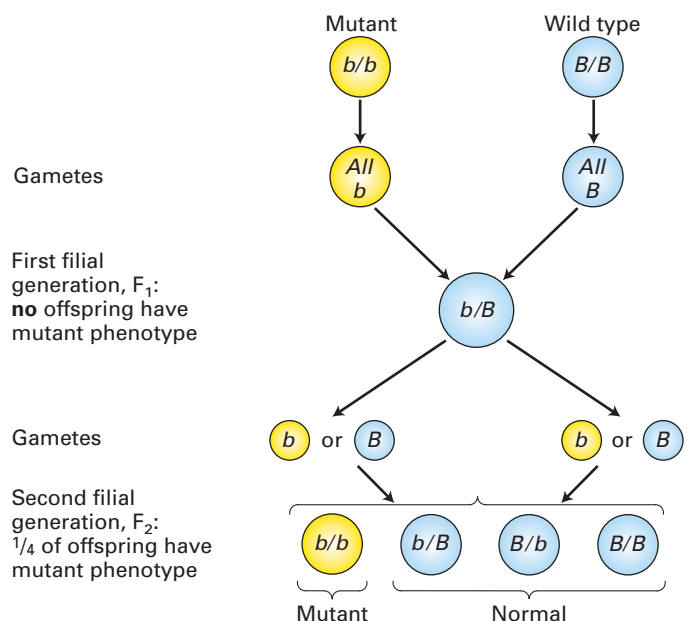

## Conditional Mutations Can Be Used to Study Essential Genes in Yeast

The procedures used to identify and isolate mutants, referred to as *genetic screens*, depend on whether the experimental

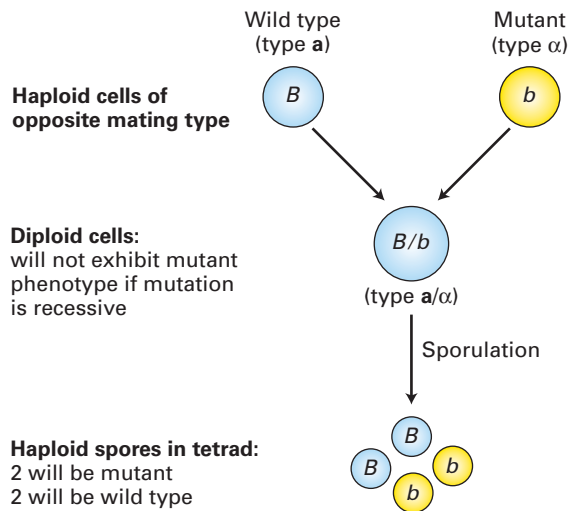

(a) Segregation of **dominant** mutation

(b) Segregation of **recessive** mutation

**FIGURE 6-4 Segregation patterns of dominant and recessive mutations in crosses between true-breeding strains of diploid organisms.** All the offspring in the first ( $F_1$ ) generation are heterozygous. If the mutant allele is dominant, the  $F_1$  offspring will exhibit the mutant phenotype, as in part (a). If the mutant allele is recessive, the  $F_1$  offspring will exhibit the wild-type phenotype, as in part (b). Crossing of the  $F_1$  heterozygotes among themselves also produces different segregation ratios for dominant and recessive mutant alleles in the  $F_2$  generation.

**FIGURE 6-5 Segregation of alleles in yeast.** Haploid *Saccharomyces* cells of opposite mating type (i.e., one of mating type  $a$  and one of mating type  $\alpha$ ) can mate to produce an  $a/\alpha$  diploid. If one haploid carries a dominant wild-type allele and the other carries a recessive mutant allele of the same gene, the resulting heterozygous diploid will express the dominant trait. Under certain conditions, a diploid cell will form a tetrad of four haploid spores. Two of the spores in the tetrad will express the recessive trait and two will express the dominant trait.

organism is haploid or diploid and, if the latter, whether the mutation is recessive or dominant. Genes that encode proteins essential for life are among the most interesting and important ones to study. Since phenotypic expression of a mutation in an essential gene leads to death of the individual, clever genetic screens are needed to isolate and maintain organisms with a lethal mutation.

In haploid yeast cells, essential genes can be studied through the use of *conditional mutations*. Among the most common conditional mutations are *temperature-sensitive mutations*, which are useful in organisms, such as bacteria and lower eukaryotes, that can grow at a range of temperatures. For instance, a single missense mutation may cause the resulting mutant protein to have reduced thermal stability, such that the protein is fully functional at one temperature (e.g., 23 °C) but begins to denature and is thus inactive at another temperature (e.g., 36 °C), whereas the normal protein would be fully stable and functional at both temperatures. A temperature at which the mutant phenotype is observed is called *nonpermissive*; a *permissive* temperature is one at which the mutant phenotype is not observed even though the mutant allele is present. Thus mutant strains can be maintained at a permissive temperature and then subcultured at a nonpermissive temperature for analysis of the mutant phenotype.

An example of a particularly important screen for temperature-sensitive mutants in the yeast *S. cerevisiae* comes from the studies of L. H. Hartwell and colleagues in the late 1960s and early 1970s. They set out to identify genes important in regulation of the cell cycle (during which a cell synthesizes proteins, replicates its DNA, and then undergoes mitotic cell division). Exponential growth of a single yeast

cell for 20–30 cell divisions forms a visible yeast colony on solid agar medium. Because mutants with a complete block in the cell cycle would not be able to form colonies, conditional mutants were required to study mutations that affect this basic cellular process. To screen for such mutants, the researchers first exposed yeast cells to mutagens and then identified mutant yeast cells that could grow normally at 23 °C, but could not form a colony when placed at 36 °C (Figure 6-6a).

Once temperature-sensitive mutants were isolated, further analysis revealed that some indeed were defective in cell division. In *S. cerevisiae*, cell division occurs through a budding process, and the size of the bud, which is easily visualized by light microscopy, indicates a cell's position in the cell cycle. Each of the mutants that could not grow at 36 °C was examined by microscopy after several hours at the nonpermissive temperature. Examination of many different temperature-sensitive mutants revealed a set that exhibited a distinct block in the cell cycle. These mutants were therefore designated *cdc* (cell division cycle) *mutants*. Importantly, these yeast mutants did not simply fail to grow, as they might have if they carried a mutation affecting general cellular metabolism. Rather, at the nonpermissive temperature, the mutants grew normally for part of the cell cycle, but then arrested at a particular stage of the cell cycle, so that many cells at that stage were seen (Figure 6-6b). Most *cdc* mutations in yeast are recessive; that is, when haploid *cdc* strains are mated to wild-type haploids, the resulting heterozygous diploids are neither temperature sensitive nor defective in cell division.

### Recessive Lethal Mutations in Diploids Can Be Identified by Inbreeding and Maintained in Heterozygotes

In diploid organisms, phenotypes resulting from recessive mutations can be observed only in individuals that are homozygous for the mutant alleles. Since mutagenesis in a diploid organism typically changes only one allele of a gene, yielding heterozygous mutants, genetic screens must include inbreeding steps to generate progeny that are homozygous for the mutant allele. The geneticist H. Muller developed a general and efficient procedure for carrying out such inbreeding experiments in the fruit fly *Drosophila*. By using such procedures, recessive lethal mutations in *Drosophila* and other diploid organisms can be maintained in heterozygous individuals and their phenotypic consequences analyzed in homozygotes.

The Muller approach was used to great effect by C. Nüsslein-Volhard and E. Wieschaus, who systematically screened for recessive lethal mutations affecting embryogenesis in *Drosophila*. Dead homozygous embryos carrying recessive lethal mutations identified by this screen were examined under the microscope for specific morphological defects. Current understanding of the molecular mechanisms underlying the development of multicellular organisms is based, in large part, on the detailed picture of embryonic development revealed by characterization of these *Drosophila* mutants.

### EXPERIMENTAL FIGURE 6-6 Haploid yeast cells carrying temperature-sensitive lethal mutations can be maintained at permissive temperature and analyzed at nonpermissive temperature.

(a) Genetic screen for temperature-sensitive cell division cycle (*cdc*) mutants in *S. cerevisiae*. Yeast cells that grow and form colonies at 23 °C (permissive temperature) but not at 36 °C (nonpermissive temperature) may carry a lethal mutation that blocks cell division. See L. H. Hartwell, 1967, *J. Bacteriol.* **93**:1662. (b) Assay of temperature-sensitive colonies for blocks at specific stages in the cell cycle. Shown here are micrographs of wild-type yeast and two different temperature-sensitive mutants after incubation at the nonpermissive temperature for 6 hours. Wild-type cells, which continue to grow, can be seen with all different sizes of buds, reflecting different stages of the cell cycle. In contrast, cells in the lower two micrographs exhibit a block at a specific stage in the cell cycle. The *cdc28* mutants arrest at a point before emergence of a new bud and therefore appear as unbudded cells. The *cdc7* mutants, which arrest just before separation of the mother cell and bud (emerging daughter cell), appear as cells with large buds. ### Complementation Tests Determine Whether Different Recessive Mutations Are in the Same Gene

Researchers using the classical genetic approach to studying a particular cellular process often isolate multiple recessive mutations that produce the same phenotype. A common test for determining whether these mutations are in the same gene or in different genes exploits the phenomenon of genetic complementation; that is, restoration of the wild-type phenotype by mating two different mutants. If two recessive mutations, *a* and *b*, are in the *same* gene, then a diploid organism carrying one *a* allele and one *b* allele will exhibit the mutant phenotype because neither allele provides a functional copy of the gene. In contrast, if mutations *a* and *b* are in *separate* genes, then heterozygotes carrying a single copy of each mutant allele will not exhibit the mutant phenotype because a wild-type allele of each gene is also present. In this case, the mutations are said to *complement* each other. Complementation analysis cannot be performed on dominant mutations because the phenotype conferred by the mutant allele is displayed even in the presence of a wild-type allele of the gene.

Complementation analysis of a set of mutants exhibiting the same phenotype can distinguish the individual genes in a set of functionally related genes, all of which must function to produce a given phenotypic trait. For example, the screen for *cdc* mutations in *Saccharomyces* described previously yielded many recessive temperature-sensitive mutants that appeared to be arrested at the same cell cycle stage. To determine how many genes were affected by these mutations, Hartwell and his colleagues performed complementation

tests on all of the pair-wise combinations of their *cdc* mutants, following the general protocol outlined in Figure 6-7. These tests organized more than 100 *cdc* mutations into about 20 different *CDC* genes. The subsequent molecular characterization of the *CDC* genes and their encoded proteins, as described in detail in Chapter 19, has provided a framework for understanding how cell division is regulated in organisms ranging from yeast to humans.

## Double Mutants Are Useful in Assessing the Order in Which Proteins Function

By careful analysis of mutant phenotypes associated with a particular cellular process, researchers can often deduce the order in which a set of genes and their protein products function. Two general types of processes are amenable to such analysis: (1) biosynthetic pathways in which a precursor material is converted via one or more intermediates to a final product, and (2) signaling pathways that regulate other processes and involve the flow of information rather than chemical intermediates.

**Ordering of Biosynthetic Pathways** A simple example of the first type of process is the biosynthesis of a metabolite such as the amino acid tryptophan in bacteria. In this case, each of the enzymes required for synthesis of tryptophan catalyzes the conversion of one of the intermediates in the biosynthetic pathway to the next. In *E. coli*, the genes encoding these enzymes lie adjacent to one another in the genome, constituting the *trp* operon (see Figure 5-13). The order of action of the different genes for these enzymes, and hence the order of the biochemical reactions in the pathway, was initially deduced from the types of intermediate compounds that accumulated in each mutant. In the case of complex synthetic pathways, however, phenotypic analysis of mutants defective in a single step may give ambiguous results that do not permit conclusive ordering of the steps. Double mutants defective in two steps in the pathway are particularly useful in ordering such pathways (Figure 6-8a).

In Chapter 14, we discuss the classic use of the double-mutant strategy to help elucidate the secretory pathway. In this pathway, proteins to be secreted from the cell move from their site of synthesis on the rough endoplasmic reticulum

**EXPERIMENTAL FIGURE 6-7** Complementation analysis determines whether recessive mutations are in the same or different genes. Complementation tests in yeast are performed by mating haploid *a* and  $\alpha$  cells carrying different recessive mutations to produce diploid cells. In the analysis of *cdc* mutations, pairs of different haploid temperature-sensitive *cdc* strains were systematically mated and the resulting diploids tested for growth at the permissive and nonpermissive temperatures. In this hypothetical example, the *cdcX* and *cdcY* mutants complement each other, and thus have mutations in different genes, whereas the *cdcX* and *cdcZ* mutants have mutations in the same gene.

### (a) Analysis of a biosynthetic pathway

- A mutation in **A** accumulates intermediate 1.
- A mutation in **B** accumulates intermediate 2.

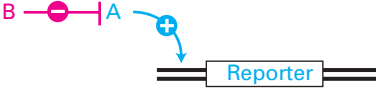

PHENOTYPE OF DOUBLE MUTANT:	A double mutation in A and B accumulates intermediate 1.
INTERPRETATION:	<i>The reaction catalyzed by A precedes the reaction catalyzed by B.</i>

### (b) Analysis of a signaling pathway

- A mutation in **A** gives repressed reporter expression.
- A mutation in **B** gives constitutive reporter expression.

PHENOTYPE OF DOUBLE MUTANT:	A double mutation in A and B gives repressed reporter expression.
INTERPRETATION:	<i>A positively regulates reporter expression and is negatively regulated by B.</i>

PHENOTYPE OF DOUBLE MUTANT:	A double mutation in A and B gives constitutive reporter expression.
INTERPRETATION:	<i>B negatively regulates reporter expression and is negatively regulated by A.</i>

**FIGURE 6-8 Analysis of double mutants can often order the steps in biosynthetic or signaling pathways.** When mutations in two different genes affect the same cellular process but produce distinctly different phenotypes, the phenotype of the double mutant can often reveal the order in which the two genes must function. (a) In the case of mutations that affect the same biosynthetic pathway, a double mutant will accumulate the intermediate immediately preceding the step catalyzed by the protein that acts earlier in the wild-type organism. (b) Double-mutant analysis of a signaling pathway is possible if two mutations have opposite effects on expression of a reporter gene. In this case, the observed phenotype of the double mutant provides information about the order in which the proteins act and whether they are positive or negative regulators.

(ER) to the Golgi complex, then to secretory vesicles, and finally to the cell surface.

**Ordering of Signaling Pathways** As we will learn in later chapters, the expression of many eukaryotic genes is regulated by signaling pathways that are initiated by extracellular hormones, growth factors, or other signals. Such signaling pathways may include numerous components, and double-mutant analysis can often provide insight into the functions and interactions of these components. The only prerequisite for obtaining useful information from this type of analysis is that the two mutations must have very different, or even

opposite, effects on the output of the same regulated pathway as measured by expression of a reporter gene. Most commonly, one mutation represses expression of a particular reporter gene even when the signal is present, while another mutation results in reporter gene expression even when the signal is absent (i.e., constitutive expression). As illustrated in Figure 6-8b, two simple regulatory mechanisms are consistent with such single mutants, but the double-mutant phenotype can distinguish between them. This general approach has enabled geneticists to delineate many of the key steps in a variety of different regulatory pathways, setting the stage for more specific biochemical assays.

Note that this technique differs from the complementation analysis just described in that both dominant and recessive mutants can be subjected to double-mutant analysis. When two recessive mutations are tested, the double mutant created must be *homozygous* for both mutations.

## Genetic Suppression and Synthetic Lethality Can Reveal Interacting or Redundant Proteins

Two other types of genetic analysis can provide additional clues about how proteins that function in the same cellular process may interact with one another in the living cell. Both of these methods, which are applicable in many experimental organisms, involve the use of double mutants in which the phenotypic effects of one mutation are changed by the presence of a second mutation.

**Suppressor Mutations** The first type of analysis is based on *genetic suppression*. To understand this phenomenon, suppose that point mutations lead to structural changes in one protein (A) that disrupt its ability to associate with another protein (B) involved in the same cellular process. Similarly, mutations in protein B lead to small structural changes that inhibit its ability to interact with protein A. Assume, furthermore, that the normal functioning of proteins A and B depends on their interacting. In theory, a specific structural change in protein A might be suppressed by compensatory changes in protein B, allowing the mutant proteins to interact. In the rare cases in which such suppressor mutations occurred, strains carrying both mutant alleles would be normal, whereas strains carrying only one or the other mutant allele would have a mutant phenotype (Figure 6-9a).

The observation of genetic suppression in yeast strains carrying a mutant actin allele (*act1-1*) and a second mutation in another gene (*sac6*) provided early evidence for a direct interaction *in vivo* between the proteins encoded by the two genes. Later biochemical studies showed that these two proteins—Act1 and Sac6—do indeed interact in the construction of functional actin structures within the cell.

**Synthetic Lethal Mutations** Another phenomenon, called *synthetic lethality*, produces a phenotypic effect opposite to that of suppression. In this case, the deleterious effect of one mutation is greatly exacerbated (rather than suppressed) by a second mutation in a related gene. One situation in which

### (a) Suppression

### (b) Synthetic lethality 1

### (c) Synthetic lethality 2

**FIGURE 6-9 Mutations that result in genetic suppression or synthetic lethality reveal interacting or redundant proteins.** (a) The observation that double mutants with two defective proteins (A and B) have a wild-type phenotype but that single mutants have a mutant phenotype indicates that the function of each protein depends on interaction with the other. (b) The observation that double mutants have a more severe phenotypic defect than single mutants is also evidence that two proteins (e.g., subunits of a heterodimer) must interact to function normally. (c) The observation that a double mutant is nonviable but that the corresponding single mutants have the wild-type phenotype indicates that two proteins function in redundant pathways to produce an essential product.

such synthetic lethal mutations can occur is illustrated in Figure 6-9b. In this example, a heterodimeric protein is partially, but not completely, inactivated by mutations in either one of its nonidentical subunits. However, in double mutants carrying specific mutations in the genes encoding both subunits, little interaction between subunits occurs, resulting in severe phenotypic effects. Synthetic lethal mutations can also reveal nonessential genes whose encoded proteins function in redundant pathways for producing an essential cell component. As depicted in Figure 6-9c, if either pathway alone is inactivated by a mutation, the other pathway will be able to supply the needed product. However, if both pathways are inactivated at the same time, the essential product cannot be synthesized, and the double mutants will be nonviable.

## Genes Can Be Identified by Their Map Position on the Chromosome

We will now consider a fundamentally different type of genetic analysis based on *gene position*. Studies designed to determine the position of a gene on a chromosome, often referred to as *genetic mapping studies*, can be used to identify the gene affected by a particular mutation or to determine whether two mutations are in the same gene.

In many organisms, genetic mapping studies rely on exchanges of genetic information that occur during meiosis. As shown in Figure 6-10a, genetic **recombination** takes place in germ cells after the chromosomes of each homologous pair have replicated, but before the first meiotic cell division. At this time, homologous DNA sequences on maternally and paternally derived chromatids can be exchanged with each other in a process known as crossing over. We now know that the resulting crossovers between homologous chromosomes provide structural links that are important for the proper segregation of pairs of homologous chromatids to opposite poles during the first meiotic cell division (for further discussion, see Chapter 19).

Consider an individual with two different mutations, one inherited from each parent, that are located close to each other on the same chromosome. That individual can produce two different types of gametes according to whether a crossover occurs between the mutations during meiosis. If no crossover occurs between them, gametes known as *parental types*, which contain either one or the other mutation, will be produced. In contrast, if a crossover occurs between the two mutations, gametes known as *recombinant types* will be produced. In this example, recombinant chromosomes would contain either both mutations or neither of them. Recombination events occur more or less at random along the length of chromosomes; thus the closer together two genes are, the less likely that recombination will happen to occur between them during meiosis. Thus *the less frequently recombination is observed to occur between two genes on the same chromosome, the closer together they must be*. Two genes that are on the same chromosome and that are sufficiently close together that significantly fewer recombinant gametes than parental gametes are produced are considered to exhibit genetic **linkage**. If the number of recombinant gametes produced is not significantly less than the number of parental gametes, the two loci under consideration are considered to be *unlinked* and could be far apart on the same chromosome, or they could be on different chromosomes.

The technique of recombination mapping was devised in 1911 by A. Sturtevant while he was an undergraduate working in the laboratory of T. H. Morgan at Columbia University. Originally used in studies on *Drosophila*, this technique is still used today to assess the distance between two genetic loci on the same chromosome in many experimental organisms. A typical experiment designed to determine the *map distance* between two genetic positions involves two steps. In the first step, a strain is constructed that carries a different mutation at each of two positions, or *loci*. In the second step, the progeny of this strain are assessed to determine

**FIGURE 6-10 Recombination during meiosis can be used to map the positions of genes.** (a) Consider the gametes produced by an individual that carries two mutations, designated *m1* (yellow) and *m2* (green), that are on the maternal and paternal versions of the same chromosome, respectively. If crossing over occurs at an interval between *m1* and *m2* before the first meiotic division, then two types of recombinant gametes are produced; one carries both *m1* and *m2*, whereas the other carries neither mutation. The longer the distance between two

the relative frequency of inheritance of parental or recombinant types. A typical way to determine the frequency of recombination between two genes is to cross one of these heterozygous progeny with another individual that is homozygous for each gene. For such a cross, the proportion of recombinant progeny is readily determined because recombinant phenotypes will differ from the parental phenotypes. By convention, one *genetic map unit* is defined as the distance between two positions along a chromosome that results in 1 recombinant individual in 100 total progeny. The distance corresponding to this 1 percent recombination frequency is called a *centimorgan* (cM) in honor of Sturtevant's mentor, Morgan (Figure 6-10b).

A complete discussion of the methods of genetic mapping is beyond the scope of this introductory discussion; however, two features of recombination mapping need particular emphasis. First, the frequency of genetic exchange between two loci is proportional to the physical distance in base pairs separating them only for loci that are relatively close together (say, less than about 10 cM). For linked loci that are farther apart than this, a distance measured by the frequency of genetic exchange tends to underestimate the physical distance because of the possibility of two or more crossovers occurring within an interval.

(b) Consider two linked genes *A* and *B* with recessive alleles *a* and *b*.

Cross of two mutants to construct a doubly heterozygous strain:

$$A/A\ b/b \times a/a\ B/B$$

$$\downarrow$$

$$\frac{A}{a} \quad \frac{b}{B}$$

Cross of double heterozygote to test strain:

$$\frac{A}{a} \quad \frac{b}{B} \times \frac{a}{a} \quad \frac{b}{b}$$

$$\downarrow$$

$\frac{A}{a} \quad \frac{b}{b}$	$\frac{a}{a} \quad \frac{B}{b}$	$\frac{A}{a} \quad \frac{B}{b}$	$\frac{a}{a} \quad \frac{b}{b}$
Parental types		Recombinant types	

Genetic distance between *A* and *B* can be determined from frequency of parental and recombinant gametes:

$$\text{Genetic distance in cM} = 100 \times \frac{\text{recombinant gametes}}{\text{total gametes}}$$

mutations on a chromatid, the more likely they are to be separated by recombination, and the greater the proportion of recombinant gametes produced. (b) In a typical mapping experiment, a strain that is heterozygous for two different genes is constructed. The frequency of parental or recombinant gametes produced by this strain can be determined from the phenotypes of the progeny in a testcross to a homozygous recessive strain. The genetic map distance in centimorgans (cM) is given as the percentage of the gametes that are recombinant.

A second important concept needed for interpreting genetic mapping experiments in different types of organisms is that although genetic distance is defined in the same way for different organisms, the relationship between recombination frequency (i.e., genetic map distance) and physical distance varies between organisms. For example, a 1 percent recombination frequency (i.e., a genetic distance of 1 cM) represents a physical distance of about 2.8 kb in yeast, compared with a distance of about 400 kb in *Drosophila* and about 780 kb in humans.

One of the chief uses of genetic mapping studies is to locate the gene that is affected by a mutation of interest. The presence of many different already mapped genetic traits, or *genetic markers*, distributed along the length of a chromosome permits the position of an unmapped mutation to be determined by assessing its segregation with respect to these marker genes during meiosis. Thus the more markers that are available, the more precisely a mutation can be mapped. In Section 6.4, we will see how the genes affected in inherited human diseases can be identified using such methods. A second general use of mapping experiments is to determine whether two different mutations are in the same gene. If two mutations are in the same gene, they will exhibit tight linkage in mapping experiments, but if they are in different genes, they will usually be unlinked or exhibit weak linkage.

## KEY CONCEPTS OF SECTION 6.1

### Genetic Analysis of Mutations to Identify and Study Genes

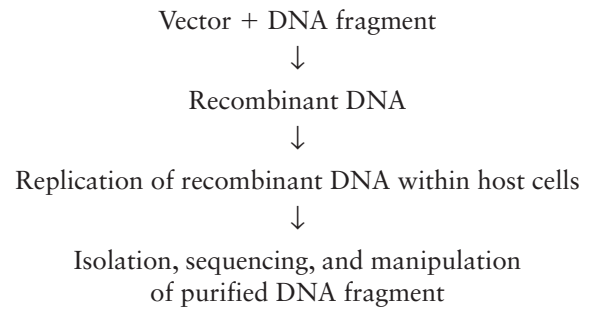

- Diploid organisms carry two copies (alleles) of each gene, whereas haploid organisms carry only one copy.
- Recessive mutations often lead to a loss of function, which is masked if a wild-type allele of the gene is present. For the mutant phenotype to be observed, both alleles must carry the mutation.
- Dominant mutations lead to a mutant phenotype in the presence of a wild-type allele of the gene. The phenotypes associated with dominant mutations often represent a gain of function.
- In meiosis, a diploid cell undergoes one DNA replication and two cell divisions, yielding four haploid cells in which maternal and paternal chromosomes and their associated alleles are randomly assorted (see Figure 6-3).
- Dominant and recessive mutations exhibit characteristic segregation patterns in genetic crosses (see Figure 6-4).
- In haploid yeast, temperature-sensitive mutations are particularly useful for identifying and studying genes essential to survival.
- The number of functionally related genes involved in a process can be defined by complementation analysis (see Figure 6-7).
- The order in which genes function in a biosynthetic or signaling pathway can be deduced from the phenotype of double mutants defective in two steps in the affected process.
- Functionally significant interactions between proteins can be deduced from the phenotypic effects of allele-specific suppressor mutations or synthetic lethal mutations.
- Genetic mapping experiments make use of crossing over between homologous chromosomes during meiosis to measure the genetic distance between two different mutations on the same chromosome.

## 6.2 DNA Cloning and Characterization

Detailed studies of the structure and function of a gene at the molecular level require large quantities of the individual gene in pure form. A variety of techniques, often referred to as *recombinant DNA technology*, are used in **DNA cloning**, which permits researchers to prepare large numbers of identical DNA molecules. **Recombinant DNA** is simply any DNA molecule composed of sequences derived from different sources.

The key to cloning a DNA fragment of interest is to link it to a **vector** DNA molecule that can replicate within a host cell. After a single recombinant DNA molecule, composed of a vector plus an inserted DNA fragment, is introduced into a host cell, the inserted DNA is replicated along with

the vector, generating a large number of identical DNA molecules. The basic scheme can be summarized as follows:

Although investigators have devised numerous experimental variations, this flow diagram indicates the essential steps in DNA cloning.

In this section, we first describe methods for isolating a specific sequence of DNA from a sea of other DNA sequences. This process often involves cutting the genome into fragments and then placing each fragment in a vector so that the entire collection can be propagated as recombinant molecules in separate host cells. While many different types of vectors exist, our discussion will mainly focus on plasmid vectors in *E. coli* host cells, which are commonly used. Various techniques can then be employed to identify the sequence of interest from this collection of DNA fragments. Once a specific DNA fragment is isolated, the exact sequence of nucleotides in the fragment can be determined. We end with a discussion of the polymerase chain reaction (PCR). This powerful and versatile technique can be used in many ways to generate large quantities of a specific sequence and to manipulate DNA in the laboratory. The various uses of cloned DNA fragments are discussed in subsequent sections.

### Restriction Enzymes and DNA Ligases Allow Insertion of DNA Fragments into Cloning Vectors

A major objective of DNA cloning is to obtain discrete, small regions of an organism's DNA that constitute specific genes. In addition, only relatively small DNA molecules can be inserted into any of the available vectors. For these reasons, the very long DNA molecules that compose an organism's genome must be cleaved into fragments that can be inserted into the vector DNA. Two types of enzymes—restriction enzymes and DNA ligases—facilitate production of such recombinant DNA molecules.

**Cutting DNA Molecules into Small Fragments** **Restriction enzymes** are endonucleases produced by bacteria that typically recognize specific 4–8-bp sequences, called *restriction sites*, and cleave both DNA strands at these sites. Restriction sites commonly are short *palindromic* sequences; that is, the restriction-site sequence is the same on each DNA strand when read in the 5' to 3' direction (Figure 6-11).

For each restriction enzyme, bacteria also produce a *modification enzyme*, which protects a host bacterium's own DNA from cleavage by modifying the host DNA at or near each potential cleavage site. The modification

**FIGURE 6-11 Cleavage of DNA by the restriction enzyme *EcoRI*.** This restriction enzyme from *E. coli* makes staggered cuts at the specific 6-bp palindromic sequence shown, yielding fragments with single-stranded, complementary 4-base “sticky” ends. Many other restriction enzymes also produce fragments with sticky ends.

enzyme adds a methyl group to one or two bases, usually within the restriction site. When a methyl group is present there, the restriction endonuclease is prevented from cutting the DNA. Together with the restriction endonuclease, the modification enzyme forms a restriction-modification system that protects the host DNA while it destroys incoming foreign DNA (e.g., bacteriophage DNA or DNA taken

up during transformation) by cleaving it at all the available restriction sites.

Many restriction enzymes make staggered cuts in the two DNA strands at the corresponding restriction site, generating fragments that have a single-stranded “tail” at both ends (see Figure 6-11). The tails on the fragments generated at a given restriction site are complementary to those on all other fragments generated by the same restriction enzyme. At room temperature, these *sticky ends* can transiently base-pair with those on other DNA fragments generated with the same restriction enzyme.

The DNA isolated from an individual organism has a specific sequence that, purely by chance, contains a specific set of restriction sites. Thus a given restriction enzyme will cut the DNA from a particular source into a reproducible set of fragments called *restriction fragments*. The frequency with which a restriction enzyme cuts DNA, and thus the average size of the resulting restriction fragments, depends largely on the length of the recognition site. For example, a restriction enzyme that recognizes a 4-bp site will cleave DNA an average of once every 4<sup>4</sup>, or 256, base pairs, whereas an enzyme that recognizes an 8-bp sequence will cleave DNA an average of once every 4<sup>8</sup> base pairs (65 kb). The hundreds of different restriction enzymes that have been identified from different species of bacteria allow DNA molecules to be cut at a large number of different sequences corresponding to the recognition sites of these enzymes (Table 6-1).

**TABLE 6-1 Selected Restriction Enzymes and Their Recognition Sequences**

Enzyme	Source Microorganism	Recognition Site*	Ends Produced
<i>Bam</i> HI	<i>Bacillus amyloliquefaciens</i>	↓ -G-G-A-T-C-C- -C-C-T-A-G-G- ↑	Sticky

\*Many of these recognition sequences are included in a common polylinker sequence (see Figure 6-13).

**Inserting DNA Fragments into Vectors** DNA fragments with either sticky ends or blunt ends can be inserted into vector DNA with the aid of *DNA ligase*. During normal DNA replication, DNA ligase catalyzes the end-to-end joining (ligation) of short fragments of DNA. For purposes of DNA cloning, purified DNA ligase is used to covalently join the ends of a restriction fragment and vector DNA that have complementary ends (Figure 6-12). The vector DNA and restriction fragment are covalently ligated together through the standard phosphodiester bonds of DNA. In addition to ligating complementary sticky ends, the DNA ligase from bacteriophage T4 can ligate any two blunt DNA ends. However, blunt-end ligation is inherently inefficient and requires a higher concentration of both DNA and DNA ligase than does ligation of sticky ends.

## Isolated DNA Fragments Can Be Cloned into *E. coli* Plasmid Vectors

**Plasmids** are circular, double-stranded DNA (dsDNA) molecules that replicate separately from a cell's chromosomal

DNA. These extrachromosomal DNAs, which occur naturally in bacteria and in lower eukaryotic cells (e.g., yeast), exist in a symbiotic relationship with their host cell. Like the host-cell chromosomal DNA, plasmid DNA is duplicated before every cell division. During cell division, copies of the plasmid DNA segregate to each daughter cell, ensuring continued propagation of the plasmid through successive generations of the host cell.

The plasmids most commonly used in recombinant DNA technology are those that replicate in *E. coli*. Investigators have engineered these plasmids to optimize their use as vectors in DNA cloning. For instance, removal of unneeded portions from naturally occurring *E. coli* plasmids yields plasmid vectors about 1.2–3 kb in circumferential length that contain three regions essential for DNA cloning: a replication origin (ORI); a marker that permits selection, usually a drug-resistance gene; and a region in which exogenous DNA fragments can be inserted (Figure 6-13).

Figure 6-14 outlines the general procedure for cloning a DNA fragment using *E. coli* plasmid vectors. When *E. coli* cells are mixed with recombinant vector DNA and subjected to a stress such as heat shock, a small fraction of the cells will take up the plasmid DNA, a process known as **transformation**. Typically, 1 cell in about 10,000 incorporates a *single* plasmid DNA molecule and thus becomes transformed. The rare transformed cells can be easily selected by use of a selectable marker. For instance, if the plasmid carries a gene that confers resistance to the antibiotic ampicillin, transformed cells can be selected by growing them in an ampicillin-containing medium. All the antibiotic-resistant progeny cells that arise from the initial transformed cell will contain plasmids with the same inserted DNA. Since all the cells in a colony arise from a single transformed parent cell,

**FIGURE 6-12** Ligation of restriction fragments with complementary sticky ends. In this example, vector DNA cut with *EcoRI* is mixed with a sample containing restriction fragments produced by cleaving genomic DNA with several different restriction enzymes. The short base sequences composing the sticky ends of each fragment type are shown. The sticky end on the cut vector DNA (a') base-pairs only with the complementary sticky ends on the *EcoRI* fragment (a) in the genomic sample. The adjacent 3' hydroxyl and 5' phosphate groups (red) on the base-paired fragments are then covalently joined (ligated) by T4 DNA ligase.

**FIGURE 6-13** Basic components of a plasmid cloning vector that can replicate within an *E. coli* cell. Plasmid vectors contain a selectable gene, such as *amp<sup>r</sup>*, which encodes the enzyme  $\beta$ -lactamase and confers resistance to ampicillin. Exogenous DNA can be inserted into the bracketed region without disturbing the ability of the plasmid to replicate or express the *amp<sup>r</sup>* gene. Plasmid vectors also contain a replication origin (ORI) sequence where DNA replication can be initiated by host-cell enzymes. Inclusion of a synthetic polylinker containing the recognition sequences for several different restriction enzymes increases the versatility of a plasmid vector. The vector is designed so that each site in the polylinker is unique on the plasmid.

they constitute a **clone** of cells, and the initial fragment of DNA inserted into the parental plasmid is referred to as *cloned DNA* or a *DNA clone*.

The versatility of an *E. coli* plasmid vector is increased by the addition of a *polylinker*, a synthetically generated sequence containing one copy of each of several different restriction sites that are not present elsewhere in the plasmid sequence (see Figure 6-13). Typically, the polylinker is cleaved with two different restriction enzymes in preparation to accept a DNA fragment prepared with two different sticky ends corresponding to the same two enzymes. Such a strategy eliminates unwanted by-products such as reclosing

of the cleaved plasmid vector and greatly increases the efficiency of cloning DNA fragments.

Plasmid cloning vectors are useful for propagating DNA fragments up to about 20 kb in length, but fragments longer than this cannot be reliably replicated within one cell-division cycle. For some purposes, such as the isolation and manipulation of large segments of the human genome, it is desirable to clone DNA segments as large as several megabases [1 megabase (Mb) = 1 million base pairs]. For this purpose, specialized plasmid vectors known as *BACs* (*bacterial artificial chromosomes*) have been developed. One type of BAC uses a replication origin derived from an endogenous plasmid of *E. coli* known as the *F factor*. The F factor, and cloning vectors derived from it, can be stably maintained at a single copy per *E. coli* cell even when they contain inserted sequences of up to about 2 Mb. Production of BAC libraries requires special methods for the isolation, ligation, and transformation of large segments of DNA because segments of DNA larger than about 20 kb are highly vulnerable to mechanical breakage even by standard manipulations such as pipetting.

### Yeast Genomic Libraries Can Be Constructed with Shuttle Vectors and Screened by Functional Complementation

A collection of DNA molecules each cloned into a vector molecule is known as a **DNA library**. When genomic DNA from a particular organism is the source of the starting DNA, the set of clones that collectively represent all the DNA sequences in the genome is known as a *genomic library*. In some cases, a DNA library can be screened for the ability to express a functional protein that complements a recessive mutation. Such a screening strategy would be an efficient way to isolate a cloned gene that corresponds to an interesting recessive mutation identified in an experimental organism. To illustrate this method, referred to as **functional complementation**, we describe how yeast genes cloned in special *E. coli* plasmids can be introduced into mutant yeast cells to identify the wild-type gene that is defective in the mutant strain. Because *Saccharomyces* genes do not contain multiple introns, they are sufficiently compact that the entire sequence of as many as 10 genes can be included in a genomic DNA fragment inserted into a plasmid vector.

To construct a plasmid genomic library that is to be screened by functional complementation in yeast cells,

**EXPERIMENTAL FIGURE 6-14 DNA cloning in a plasmid vector permits amplification of a DNA fragment.** A fragment of DNA to be cloned is first inserted into a plasmid vector containing an ampicillin-resistance gene (*amp<sup>r</sup>*), such as that shown in Figure 6-13. Only the few cells transformed by incorporation of a plasmid will survive on ampicillin-containing medium. In transformed cells, the plasmid DNA replicates and segregates into daughter cells, resulting in the formation of an ampicillin-resistant colony in which each cell contains the cloned DNA.

the plasmid vector must be capable of replication in both *E. coli* cells and yeast cells. This type of vector, capable of propagation in two different hosts, is called a *shuttle vector*. The structure of a typical yeast shuttle vector is shown in Figure 6-15a. This vector contains the basic elements that permit cloning of DNA fragments in *E. coli* as well as sequences required for its propagation in yeast.

To increase the probability that all regions of the yeast genome will be successfully cloned and represented in the plasmid library, the genomic DNA is usually only partially digested to yield overlapping restriction fragments of ~10 kb. These fragments are then ligated into a shuttle

vector in which the polylinker has been cleaved with a restriction enzyme that produces sticky ends complementary to those on the yeast DNA fragments (Figure 6-15b). Because the 10-kb restriction fragments of yeast DNA are incorporated into the shuttle vectors randomly, at least  $10^5$  *E. coli* colonies, each containing a particular recombinant shuttle vector, are necessary to ensure that each region of yeast DNA has a high probability of being represented in the library at least once.

Figure 6-16 outlines how such a yeast genomic library can be screened to isolate the wild-type gene corresponding to one of the temperature-sensitive *cdc* mutations mentioned earlier in this chapter. The starting yeast strain is a double mutant that requires uracil for growth due to a *ura3<sup>-</sup>* mutation and is temperature sensitive due to a *cdc28* mutation identified by its phenotype (see Figure 6-6b). Recombinant plasmids isolated from the yeast genomic library are mixed with yeast cells under conditions that promote transformation of the cells with foreign DNA. Since transformed yeast cells carry a plasmid-borne copy of the wild-type *URA3* gene, they can be selected by their ability to grow in the absence of uracil. Typically, about 20 petri dishes, each containing about 500 yeast transformants, are sufficient to represent the entire yeast genome. This collection of yeast transformants can be maintained at 23 °C, a temperature permissive for growth of the *cdc28* mutant. The entire collection on 20 plates is then transferred to replica plates, which are maintained at 36 °C, a nonpermissive temperature for *cdc* mutants. Yeast colonies that carry recombinant plasmids expressing a wild-type copy of the *CDC28* gene will be able to grow at 36 °C. Once temperature-resistant yeast colonies have been identified, plasmid DNA can be extracted from the cultured yeast cells and analyzed by DNA sequencing, a topic we take up shortly.

## cDNA Libraries Represent the Sequences of Protein-Coding Genes

Genomic libraries are ideal for representing the genetic content of relatively simple organisms such as bacteria or yeast,

**EXPERIMENTAL FIGURE 6-15** A yeast genomic library can be constructed in a plasmid shuttle vector that can replicate in yeast and in *E. coli*. (a) Components of a typical plasmid shuttle vector for cloning *Saccharomyces* genes. The presence of a yeast replication origin (ARS) and a yeast centromere (CEN) allows stable replication and segregation in yeast. Also included is a yeast selectable marker such as *URA3*, which allows a *ura3* mutant to grow on medium lacking uracil. Finally, the vector contains sequences for replication and selection in *E. coli* (ORI and *amp<sup>r</sup>*) and a polylinker for easy insertion of yeast DNA fragments. (b) Typical protocol for constructing a yeast genomic library. Partial digestion of total yeast genomic DNA with *Sau*3A is adjusted to generate fragments with an average size of ~10 kb. The vector is prepared to accept the genomic fragments by digestion with *Bam*HI, which produces the same sticky ends as *Sau*3A. Each transformed clone of *E. coli* that grows after selection for ampicillin resistance contains a single type of yeast DNA fragment.

**EXPERIMENTAL FIGURE 6-16** Screening of a yeast genomic library by functional complementation can identify clones carrying the normal form of a mutant yeast gene. In this example, a wild-type *CDC* gene is isolated by complementation of a *cdc* yeast mutant. The yeast genomic library prepared as shown in Figure 6-15 is transformed into a *ura3<sup>-</sup>*, temperature-sensitive *cdc* mutant strain. The relatively few transformed yeast cells, which contain recombinant plasmid DNA, can grow in the absence of uracil at 23 °C. When these colonies are replica-plated and incubated at 36 °C (a nonpermissive temperature), only clones carrying a library plasmid that contains the wild-type copy of the *CDC* gene will survive. LiOAC = lithium acetate; PEG = polyethylene glycol.

but present certain experimental difficulties for higher eukaryotes. First, the genes of eukaryotes usually contain extensive intron sequences and can therefore be too large to be inserted intact into plasmid vectors. As a result, the sequences of individual genes are broken apart and carried in more than one clone. Moreover, the presence of introns and long intergenic regions in genomic DNA often makes it difficult to identify the important parts of a gene that actually encode protein sequences. For example, only about 1.5 percent of the human genome actually represents protein-coding gene sequences. Thus for many studies, cellular mRNAs, which lack the noncoding regions present in genomic DNA, are a more useful starting material for generating a DNA library. In this approach, DNA copies of mRNAs, called **complementary DNAs (cDNAs)**, are synthesized and cloned into plasmid vectors. A large collection of the resulting cDNA clones, representing all the mRNAs expressed in a cell type, is called a *cDNA library*.

The first step in preparing a cDNA library is to isolate the total mRNA from the cell type or tissue of interest. Because of their poly(A) tails, mRNAs are easily separated from the much more prevalent rRNAs and tRNAs present in a cell extract by use of a matrix to which short strings of thymidylate (oligo-dTs) are linked. The general procedure for preparing a cDNA library from a mixture of cellular mRNAs is outlined in Figure 6-17. The enzyme reverse transcriptase, which is found in retroviruses, is used to synthesize a strand of DNA complementary to each mRNA molecule, starting from an oligo-dT primer (steps 1 and 2). The resulting cDNA-mRNA hybrid molecules are converted in several steps into double-stranded cDNA molecules corresponding to all the mRNA molecules in the original preparation (steps 3–5). Each double-stranded cDNA contains an oligo-dC-oligo-dG double-stranded region at one end and an oligo-dT-oligo-dA double-stranded region at the other end. Methylation of the cDNA protects it from subsequent restriction enzyme cleavage (step 6).

To prepare double-stranded cDNAs for cloning, short double-stranded DNA molecules containing the recognition site for a particular restriction enzyme (called *linkers*) are ligated to both ends of the cDNAs using DNA ligase from bacteriophage T4 (Figure 6-17, step 7). As noted earlier, this ligase can join “blunt-ended” double-stranded DNA molecules lacking sticky ends. The resulting molecules are then treated with the restriction enzyme specific for the attached linker, generating cDNA molecules with sticky ends (step 8a). In a separate procedure, plasmid DNA is treated with the same restriction enzyme to produce the appropriate sticky ends (step 8b).

The plasmid vector and the collection of cDNAs, all containing complementary sticky ends, are then mixed and joined covalently by DNA ligase (Figure 6-17, step 9). The resulting DNA molecules are introduced into *E. coli* cells to generate individual clones; each clone carries a cDNA derived from a single mRNA.

Because different genes are transcribed at very different rates, cDNA clones corresponding to abundantly transcribed genes will be represented many times in a cDNA library, whereas cDNAs corresponding to infrequently transcribed genes will be extremely rare or not present at all. To have a reasonable chance of including clones corresponding to slowly transcribed genes, mammalian cDNA libraries must contain  $10^6$ – $10^7$  individual recombinant clones.

## The Polymerase Chain Reaction Amplifies a Specific DNA Sequence from a Complex Mixture

If the nucleotide sequences at the ends of a particular DNA region are known, the intervening fragment can be amplified directly by the **polymerase chain reaction (PCR)**. Here we describe the basic PCR technique and three situations in which it is used.

**FIGURE 6-17 A cDNA library contains representative copies of cellular mRNA sequences.** A mixture of mRNAs is the starting point for preparing recombinant plasmid clones, each containing a cDNA. Transforming *E. coli* with the recombinant plasmids generates a set of cDNA clones representing all the cellular mRNAs. See the text for a step-by-step discussion.

The PCR depends on the ability to alternately denature (melt) double-stranded DNA molecules and hybridize complementary single strands in a controlled fashion. As outlined in Figure 6-18, a typical PCR procedure begins with

heat-denaturation of a DNA sample into single strands at 95 °C. Next, two synthetic oligonucleotides complementary to the 3' ends of the DNA segment of interest (the target sequence) are added in great excess to the denatured DNA,

and the temperature is lowered to 50–60 °C. These specific oligonucleotides, which are present at a very high concentration, hybridize to their complementary sequences in the DNA sample, whereas the long strands of the sample DNA remain apart because of their comparatively low concentration. The hybridized oligonucleotides then serve as primers for DNA chain synthesis in the presence of deoxynucleotides (dNTPs) and a temperature-resistant DNA polymerase such as that from *Thermus aquaticus*, a bacterium that lives in hot springs. This enzyme, called *Taq polymerase*, can

**FIGURE 6-18 The polymerase chain reaction (PCR) is widely used to amplify DNA regions with known flanking sequences.** To amplify a specific region of DNA, an investigator chemically synthesizes two different oligonucleotide primers complementary to sequences of approximately 18 bases flanking the region of interest (shown here as light blue and dark blue bars). The complete reaction is composed of a complex mixture of double-stranded DNA (usually genomic DNA containing the target sequence of interest), a stoichiometric excess of both primers, the four dNTPs, and a heat-stable DNA polymerase known as *Taq polymerase*. During each PCR cycle, the reaction mixture is first heated to separate the strands and then cooled to allow the primers to bind to complementary sequences flanking the region to be amplified. *Taq polymerase* then extends each primer from its 3' end, generating newly synthesized strands that extend in the 3' direction to the 5' end of the template strand. During the third cycle, two double-stranded DNA molecules are generated equal in length to the sequence of the region to be amplified. In each successive cycle, the target sequence, which anneals to the primers, is duplicated, so it eventually vastly outnumbers all other DNA sequences in the reaction mixture. Successive PCR cycles can be automated by cycling the reaction at timed intervals between a high temperature for DNA melting and a lower temperature for the annealing and elongation parts of the cycle. A reaction that cycles 20 times will amplify the specific target sequence 1-million-fold.

remain active even after being heated to 95 °C and can extend the primers at temperatures up to 72 °C. When synthesis is complete, the whole mixture is reheated to 95 °C to denature the newly formed DNA duplexes. After the temperature is lowered again, another cycle of synthesis takes place because excess primer is still present. Repeated cycles of denaturation (heating) followed by hybridization and synthesis (cooling) quickly amplify the sequence of interest. At each cycle, the number of copies of the sequence between the primer sites is doubled; therefore, the target sequence increases exponentially—about 1-million-fold after 20 cycles—whereas all other sequences in the original DNA sample remain unamplified.

**Direct Isolation of a Specific Segment of Genomic DNA** For organisms in which all or most of the genome has been sequenced, PCR amplification starting with the total genomic DNA is often the easiest way to obtain a specific DNA region of interest for cloning. In this application of the PCR, the two oligonucleotide primers are designed to hybridize to sequences flanking the genomic region of interest and to include sequences that are recognized by specific restriction enzymes (Figure 6-19). For an oligonucleotide to be useful as a PCR primer, it must be long enough for its sequence to occur uniquely in the genome. For most purposes, this condition is satisfied by oligonucleotides containing about 20 nucleotides. Any given 20-nucleotide sequence occurs once in every  $4^{20}$  ( $\sim 10^{12}$ ) nucleotides by chance, so it is usually possible to identify two specific 20-nucleotide sequences flanking the target sequence that each occur only once in the genome.

After amplification of the target sequence for about 20 PCR cycles, cleavage with the appropriate restriction

**EXPERIMENTAL FIGURE 6-19 A specific target sequence in genomic DNA can be amplified by PCR for use in cloning.** Each primer for PCR is complementary to one end of the target sequence and includes the recognition site for a restriction enzyme that does not have a recognition site within the target region. In this example, primer 1 contains a *Bam*HI recognition sequence, whereas primer 2 contains a *Hind*III recognition sequence. (Note that for clarity, in any round, amplification of only one of the two strands—the one in brackets—is shown.) After amplification, the target segments are treated with appropriate restriction enzymes, generating fragments with sticky ends. These fragments can be incorporated into complementary plasmid vectors and cloned in *E. coli* by the usual procedure (see Figure 6-14).

A variation on the PCR method allows PCR amplification of a specific cDNA sequence made from cellular mRNAs. This method, known as *reverse transcriptase-PCR* (*RT-PCR*), begins with the same procedure described previously for isolation of cDNA from a collection of cellular mRNAs. Typically, an oligo-dT primer, which hybridizes to the 3' poly(A) tail of the mRNA, is used as the primer for the first strand of cDNA synthesis by reverse transcriptase. A specific cDNA can then be isolated from this complex mixture of cDNAs by PCR amplification using two oligonucleotide primers designed to match sequences at the 5' and 3' ends of the corresponding mRNA. As described previously, these primers can be designed to include restriction sites to facilitate the insertion of the amplified cDNA into a suitable plasmid vector.

RT-PCR can be performed so that the starting amount of a particular cellular mRNA can be determined accurately. To carry out quantitative RT-PCR, the amount of double-stranded DNA sequence produced by each amplification cycle is determined as the amplification of a particular mRNA sequence proceeds. By extrapolation from these amounts, an estimate of the starting amount of the mRNA sequence can be obtained. Such quantitative RT-PCR analyses carried out on tissues or whole organisms using primers targeted to genes of interest provide one of the most accurate means to follow changes in gene expression.

**Tagging of Genes by Insertion Mutations** Another useful application of the PCR is the amplification of a “tagged” gene from the genomic DNA of a mutant strain. This approach is a simpler method for identifying genes associated with a particular mutant phenotype than the screening of a library by functional complementation (see Figure 6-16).

The key to this use of the PCR is the ability to produce mutations by inserting a known DNA sequence into the genome of an experimental organism. Such insertion mutations can be generated by the use of DNA transposons, which can move (or transpose) from one chromosomal site

enzymes produces sticky ends that allow efficient ligation of the fragment to a plasmid vector whose polylinker has been cleaved by the same restriction enzymes. The resulting recombinant plasmids, all carrying the identical genomic DNA segment, can then be cloned in *E. coli* cells. With certain refinements of the PCR, even DNA segments greater than 10 kb in length can be amplified and cloned in this way.

Note that this method does not require the cloning of large numbers of restriction fragments derived from genomic DNA and their subsequent screening to identify the specific fragment of interest. In effect, the PCR method inverts this traditional approach and so avoids its most tedious aspects. The PCR method is useful for isolating gene sequences to be manipulated in a variety of useful ways described later. In addition, the PCR method can be used to isolate gene sequences from mutant organisms to determine how they differ from the wild type.

to another. As discussed in more detail in Chapter 8, these DNA sequences occur naturally in the genomes of most organisms and may give rise to loss-of-function mutations if they transpose into a protein-coding region.

For example, researchers have modified a *Drosophila* DNA transposon, known as the *P element*, to optimize its use in the experimental generation of insertion mutations. Once it has been demonstrated that insertion of a *P element* causes a mutation with an interesting phenotype, the genomic sequences adjacent to the insertion site can be amplified by a variation of the standard PCR protocol that uses synthetic primers complementary to the known *P-element* sequence, but allows unknown neighboring sequences to be amplified. One such method, depicted in Figure 6-20, begins by cleaving *Drosophila* genomic DNA containing a *P-element* insertion with a restriction enzyme that makes a single cut within the *P-element* DNA. The resulting collection of cleaved DNA fragments, when treated with DNA ligase, yields circular molecules, some of which contain *P-element* DNA. The chromosomal region flanking the *P element* can then be amplified by PCR using primers that match *P-element* sequences and are elongated in opposite directions. The sequence of the resulting amplified fragment can then be determined using a third DNA primer. The crucial sequence for identifying the site of *P-element* insertion is

the junction between the end of the *P-element* and genomic sequences. Overall, this approach avoids the cloning of large numbers of DNA fragments and their screening to detect a cloned DNA corresponding to a mutated gene of interest.

Similar methods have been applied to other organisms for which insertion mutations can be generated using either DNA transposons or viruses with sequenced genomes that can insert randomly into the genome.

## Cloned DNA Molecules Can Be Sequenced Rapidly by Methods Based on PCR

The complete characterization of any cloned DNA fragment requires determination of its nucleotide sequence. The technology used to determine the sequence of a DNA segment represents one of the most rapidly developing fields in molecular biology. In the 1970s, F. Sanger and his colleagues developed the chain-termination procedure, which served as the basis for most DNA sequencing methods for the next 30 years. The idea behind this method is to synthesize from the DNA fragment to be sequenced a set of daughter strands that are labeled at one end and terminate at one of the four nucleotides. Separation of the truncated daughter strands by gel electrophoresis, which can resolve strands that differ in length by a single nucleotide, can then reveal the lengths of

**FIGURE 6-20 The genomic sequence at the insertion site of a DNA transposon is revealed by PCR amplification and sequencing.** To obtain the DNA sequence of the insertion site of a *P element*, it is necessary to amplify the junction between known transposon sequences and unknown flanking chromosomal sequences. One way to achieve this is to cleave genomic DNA with a restriction enzyme that cuts once within the transposon sequence. Ligation of the resulting restriction fragments will generate circular DNA molecules. By using appropriately designed DNA primers that match transposon sequences, it is possible to amplify the desired junction fragment using PCR. Finally, a DNA sequencing reaction (see Figures 6-21 and 6-22) is performed using the amplified fragment as a template and an oligonucleotide primer that matches sequences near the end of the transposon to obtain the sequence of the junction between the transposon and chromosome.

all strands ending in G, A, T, or C. From these collections of strands of different lengths, the nucleotide sequence of the original DNA fragment can be established. The Sanger method has undergone many refinements and can now be fully automated, but because each DNA fragment requires a separate individual sequencing reaction, the overall rate at which new DNA sequences can be produced by this method is limited by the total number of reactions that can be performed at one time.

A breakthrough in sequencing technology occurred when methods were devised to allow a single sequencing instrument to carry out billions of sequencing reactions simultaneously by localizing them in tiny clusters on the surface of a solid substratum. In 2007, when these so-called *next-generation*

**EXPERIMENTAL FIGURE 6-21** Generation of clusters of identical DNA fragments attached to a solid support. A large collection of DNA fragments to be sequenced is ligated to double-stranded linkers, which become attached to each end of each fragment. The DNA is then amplified by PCR using primers matching the sequences of the linkers that are covalently attached to a solid substratum. Ten cycles of amplification yield about a thousand identical copies of each DNA fragment localized in a small cluster and attached at both ends to the solid substratum. These reactions are optimized to produce as many as  $3 \times 10^9$  discrete, non-overlapping clusters that are ready to be sequenced.

sequencers became commercially available, the capacity for new sequence production increased enormously, and since then, because of improvements in the technology, it has been further increasing at an amazing pace—doubling every few months. In one popular sequencing method, billions of different DNA fragments to be sequenced are prepared by ligating double-stranded linkers to their ends (Figure 6-21). Next the DNA fragments are amplified by PCR using primers that match the linker sequences. This reaction differs from the standard PCR amplification shown in Figure 6-19 in that the primers used are covalently attached to a solid substratum. Thus, as the PCR amplification proceeds, one end of each daughter DNA strand is covalently linked to the substratum, and at the end of the amplification about a thousand identical PCR products are linked to the surface in a tight cluster.

These clusters can then be sequenced by using a special microscope to image fluorescently labeled deoxyribonucleotide triphosphates (dNTPs) as they are incorporated by DNA polymerase one at a time into a growing DNA chain (Figure 6-22). First, one strand is cut and washed out, leaving a single-stranded DNA template. Then sequencing is carried out on the thousand or so identical templates in each cluster, one nucleotide at a time. All four dNTPs are fluorescently labeled and added to the sequencing reaction. After they are allowed to anneal, the substratum is imaged and the color of each cluster is recorded. Next the fluorescent tag is chemically removed and a new dNTP is allowed to bind. This cycle is repeated about a hundred times, resulting in billions of hundred-nucleotide-long sequences. The entire procedure may take about one day and yield some  $10^{11}$  bases of sequence information.

In order to sequence a long continuous region of genomic DNA, or even the entire genome of an organism, researchers usually employ one of the strategies outlined in Figure 6-23. The first method requires the isolation of a collection of cloned DNA fragments whose sequences overlap. Once the sequence of one of these fragments is determined, oligonucleotides based on that sequence can be chemically synthesized for use as primers in sequencing the adjacent overlapping fragments. In this way, the sequence of a long stretch of DNA is determined incrementally by sequencing of the overlapping cloned DNA fragments that compose it. A second method, which is called *whole genome shotgun sequencing*, bypasses the time-consuming step of isolating an ordered collection of DNA segments that span the genome. This method involves simply sequencing random clones from a genomic library. A sufficient number of clones are chosen for sequencing so that on average, each segment of the genome is sequenced about 10 times. This degree of coverage ensures that each segment of the genome is sequenced more than once. The entire genomic sequence is then assembled using a computer algorithm that aligns all the segments using their regions of overlap. Whole genome shotgun sequencing is the fastest and most cost-effective method for sequencing long stretches of DNA, and most genomes, including the human genome, have been sequenced by this method.

### EXPERIMENTAL FIGURE 6-22 Using fluorescent-tagged deoxyribonucleotide triphosphates for sequence determination.

(a) The reaction begins with the cleaving of one strand of the amplified, clustered DNA (see Figure 6-21). After denaturation, a single DNA strand remains attached to the substratum. A synthetic oligodeoxynucleotide is used as the primer for the polymerization reaction, which also contains dNTPs, each fluorescently tagged with a different color. The fluorescent tag is designed to block the 3' OH group on the dNTP so that once the fluorescent dNTP has been incorporated, further elongation is not possible. Because DNA polymerase will incorporate the same fluorescently labeled dNTP into each of the thousand or so identical DNA copies in a cluster, the entire cluster will be uniformly labeled with the same fluorescent color, which can be imaged in a special microscope. (b) Five images from the same field of view, each corresponding to an individual cycle of dNTP addition. Each colored dot represents a cluster of identical DNA fragments. After each image is made, the fluorescent tags are removed by a chemical reaction that leaves a new primer terminus available for the next cycle of dNTP addition. As can be seen for the circled colored dot, the color changes in each reaction cycle according to which nucleotide is added to the DNA fragments. A typical sequencing reaction may carry out a hundred polymerization cycles, allowing a hundred bases of sequence for each cluster to be determined. Thus a total sequencing reaction of this type may generate as much as  $3 \times 10^{11}$  bases of sequence information in about two days. [Part (b) A. Loehr and A.W. Zaranek for the Harvard Personal Genome Project.]

**EXPERIMENTAL FIGURE 6-23 Two strategies for assembling whole genome sequences.** One method (*left*) depends on isolating and assembling a set of cloned DNA fragments that span the genome. This can be done by matching cloned fragments by hybridization or by alignment of restriction-site maps. The DNA sequence of the ordered clones can then be assembled into a complete genomic sequence. The alternative method (*right*) depends on the relative ease of automated DNA sequencing and bypasses the laborious step of ordering a DNA library. By sequencing enough random clones from the library so that each segment of the genome is represented from 3 to 10 times, it is possible to reconstruct the genomic sequence by computer alignment of the very large number of sequence fragments.

## KEY CONCEPTS OF SECTION 6.2

### DNA Cloning and Characterization

- In DNA cloning, recombinant DNA molecules are formed *in vitro* by inserting DNA fragments into vector DNA molecules. The recombinant DNA molecules are then introduced into host cells, where they replicate, producing large numbers of recombinant DNA molecules.
- Restriction enzymes (endonucleases) typically cut DNA at specific 4–8-bp palindromic sequences, producing defined fragments that often have self-complementary single-stranded tails (sticky ends).
- Two restriction fragments with complementary ends can be joined with DNA ligase to form a recombinant DNA molecule (see Figure 6-12).
- *E. coli* cloning vectors are small circular DNA molecules (plasmids) that include three functional regions: a replication origin, a selectable marker gene, and a site where a DNA fragment can be inserted. Transformed cells carrying a vector grow into colonies on the selection medium (see Figure 6-14).
- A genomic library is a set of clones carrying restriction fragments produced by cleavage of the entire genome.
- Shuttle vectors that can replicate in both yeast and *E. coli* can be used to construct a yeast genomic library. Specific genes can be isolated by their ability to complement the corresponding mutant genes in yeast cells (see Figure 6-16).
- In cDNA cloning, expressed mRNAs are reverse-transcribed into complementary DNAs, or cDNAs. A cDNA library is a set of cDNA clones prepared from the mRNAs isolated from a particular type of cell or tissue (see Figure 6-17).
- The polymerase chain reaction (PCR) permits exponential amplification of a specific segment of DNA from a single initial template DNA molecule if the sequence flanking the DNA region to be amplified is known (see Figure 6-19).
- PCR is a highly versatile method that can be programmed to amplify a specific genomic DNA sequence, a cDNA, or a sequence at the junction between a DNA transposon and flanking chromosomal sequences.
- DNA fragments up to about 100 nucleotides long can be sequenced by generating clusters of identical fragments by PCR and imaging fluorescently labeled nucleotide precursors incorporated by DNA polymerase (see Figures 6-21 and 6-22).
- Whole genome sequences can be assembled from the sequences of a large number of overlapping clones from a genomic library (see Figure 6-23).

## 6.3 Using Cloned DNA Fragments to Study Gene Expression

In the last section, we described the basic techniques for using recombinant DNA technology to isolate specific DNA clones and ways in which those clones can be further characterized.

Here we consider how an isolated DNA clone can be used to study gene expression. We discuss several widely used general techniques that rely on nucleic acid hybridization to elucidate when and where genes are expressed, as well as methods for generating large quantities of protein and otherwise manipulating amino acid sequences to determine their expression patterns, structure, and function. More specific applications of all these basic techniques are examined in the following sections.

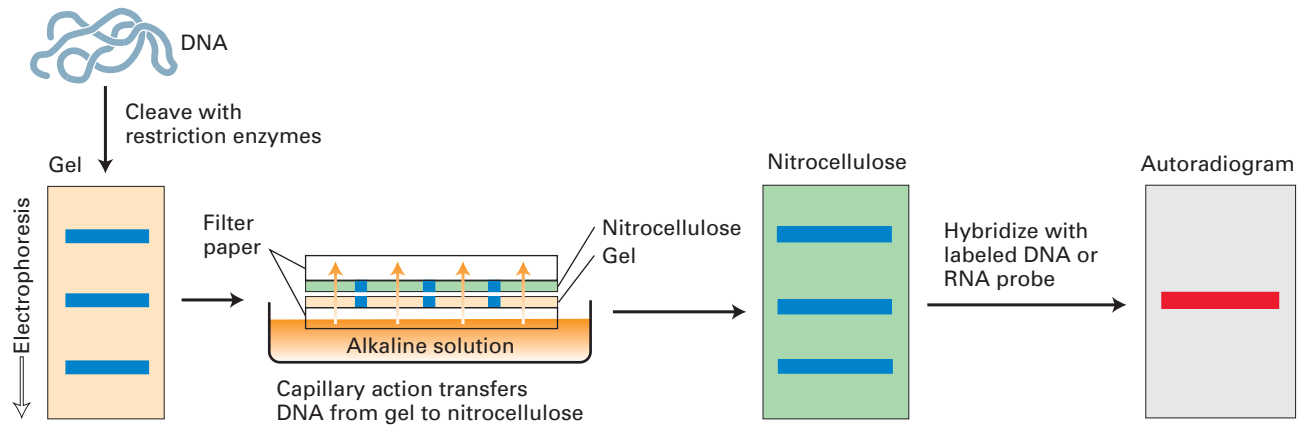

### Hybridization Techniques Permit Detection of Specific DNA Fragments and mRNAs

**Hybridization** depends on the ability of complementary single-stranded DNA or RNA molecules to associate (hybridize) specifically with each other via base pairing. As discussed in Chapter 4, double-stranded (duplex) DNA can be denatured (melted) into single strands by heating in a dilute salt solution. If the temperature is then lowered and the ion concentration raised, complementary single strands will reassociate (hybridize) into duplexes. In a mixture of nucleic acids, only complementary single strands (or strands containing complementary regions) will reassociate; moreover, the extent of their reassociation is virtually unaffected by the presence of noncomplementary strands.

Two very sensitive methods for detecting a particular DNA or RNA sequence within a complex mixture combine separation by gel electrophoresis and hybridization to a complementary DNA probe that is either radioactively or fluorescently labeled. A third method involves hybridizing labeled probes directly to a prepared tissue sample. We will encounter references to all three of these techniques, which have numerous applications, in other chapters.

**Southern Blotting** The first hybridization technique developed to detect DNA fragments of a specific sequence is known as **Southern blotting**, after its originator, E. M. Southern. This technique is capable of detecting a single specific restriction fragment in the highly complex mixture of fragments produced by cleavage of the entire human genome with a restriction enzyme. A common procedure for separating DNA fragments of different sizes is *gel electrophoresis*. Near neutral pH, DNA molecules carry a large negative charge and therefore move toward the positive electrode during gel electrophoresis. Because the gel matrix restricts random diffusion, molecules of the same length migrate together as distinct bands. Smaller molecules move through the gel matrix more readily than larger molecules. Larger DNA molecules from about 200 bp to more than 20 kb can be separated electrophoretically on *agarose gels*, and smaller DNA molecules from about 10 to 2000 bp can be separated on *polyacrylamide gels*.

When DNA from a whole genome is fragmented by digestion with a restriction enzyme, the mixture of DNA fragments that is produced is so complex that even after gel electrophoresis, so many different fragments of nearly the same length are present that it is not possible to resolve any particular DNA fragment as a discrete band on the gel. Nevertheless, it is possible to identify a particular fragment migrating as a band on the gel by its ability to hybridize to

**EXPERIMENTAL FIGURE 6-24** Southern blotting can detect a specific DNA fragment in a complex mixture of restriction fragments. The diagram depicts three different restriction fragments in the gel, but the procedure can be applied to a mixture of millions of DNA

fragments. Only fragments that hybridize to a labeled probe will give a signal on an autoradiogram. A similar technique, called Northern blotting, detects specific mRNAs within a mixture. See E. M. Southern, 1975, *J. Mol. Biol.* **98**:508.

a specific DNA probe. To accomplish this, the restriction fragments present in the gel are denatured with alkali and transferred onto a nitrocellulose filter or nylon membrane by blotting (Figure 6-24). This procedure preserves the distribution of the fragments in the gel, creating a replica of the gel on the filter. (The blot is used because probes do not readily diffuse into the original gel.) The filter is then incubated under hybridization conditions with a specific labeled DNA probe, which is usually generated from a cloned restriction fragment. The DNA restriction fragment that is complementary to the probe hybridizes to it, and its location on the filter can be revealed by autoradiography (for a radio-labeled probe) or by fluorescent imaging (for a fluorescently labeled probe). Although PCR is now more commonly used to detect the presence of a particular sequence in a complex mixture, Southern blotting is still useful for reconstructing the relationship between genomic sequences that are too far apart to be amplified by PCR in a single reaction.

**Northern Blotting** One of the most basic ways to characterize a cloned gene is to determine when and where in an organism the gene is expressed. The expression of a particular gene can be followed by assaying for the corresponding mRNA by **Northern blotting**, named, in a play on words, after the related method of Southern blotting. An RNA sample, often the total cellular RNA, is denatured by treatment with an agent such as formaldehyde that disrupts the hydrogen bonds between base pairs, ensuring that all the RNA molecules have an unfolded, linear conformation. The individual RNAs are separated according to size by gel electrophoresis and transferred to a nitrocellulose filter to which the extended denatured RNAs adhere. As in Southern blotting, the filter is then exposed to a labeled DNA probe that is complementary to the gene of interest; finally, the labeled filter is subjected to autoradiography. Because the amount of a specific RNA in a sample can be estimated from a Northern blot, the procedure is widely used to compare the amounts of a particular mRNA in cells under different conditions.

**In Situ Hybridization** Northern blotting requires extracting the mRNA from a cell or mixture of cells, which means that the cells are removed from their normal location within an organism or tissue. As a result, the location of a cell and its relation to its neighbors is lost. To retain such positional information in precise studies of gene expression, a whole or sectioned tissue, or even a whole permeabilized embryo, may be subjected to **in situ hybridization** to detect the mRNA encoded by a particular gene. This technique allows gene transcription to be monitored in both time and space (Figure 6-25).

## DNA Microarrays Can Be Used to Evaluate the Expression of Many Genes at One Time

Monitoring the expression of thousands of genes simultaneously is possible with DNA microarray analysis, another technique based on the concept of nucleic acid hybridization. A **DNA microarray** consists of an organized array of thousands of individual, closely packed, gene-specific sequences attached to the surface of a glass microscope slide. By coupling microarray analysis with the results from genomic sequencing projects, researchers can analyze the global patterns of gene expression in an organism during specific physiological responses or developmental processes.

**Preparation of DNA Microarrays** In one method of preparing microarrays, a DNA segment of about 1 kb corresponding to part of the coding region of each gene to be analyzed is individually amplified by PCR. A robotic device is used to apply each amplified DNA sample to the surface of a glass microscope slide, which is then chemically processed to permanently attach the DNA sequences to the glass surface and to denature them. A typical array might contain some 6000 spots of DNA in a  $2 \times 2$ -cm grid.

In an alternative method, multiple DNA oligonucleotides, usually at least 20 nucleotides in length, are synthesized from an initial nucleotide that is covalently bound to the surface of a glass slide. The synthesis of an oligonucleotide of specific

**EXPERIMENTAL FIGURE 6-25 In situ hybridization can detect activity of specific genes in whole and sectioned embryos.** The specimen is permeabilized by treatment with detergent and a protease to expose the mRNA to the probe. A DNA or RNA probe, specific for the mRNA of interest, is made with nucleotide analogs containing chemical groups that can be recognized by antibodies. After the permeabilized specimen has been incubated with the probe under conditions that promote hybridization, the excess probe is removed with a series of washes. The specimen is then incubated in a solution containing an antibody that binds to the probe. This antibody is covalently joined to a reporter enzyme (e.g., horseradish peroxidase or alkaline phosphatase) that produces a colored reaction product. After excess antibody

has been removed, substrate for the reporter enzyme is added. A colored precipitate forms where the probe has hybridized to the mRNA being detected. (a) A whole mouse embryo at about 10 days of development probed for *Sonic hedgehog* mRNA. The stain marks the notochord (red arrow), a rod of mesoderm running along the future spinal cord. (b) A cross section of a mouse embryo similar to that in part (a). The dorsal/ventral axis of the neural tube (NT) can be seen, with the *Sonic hedgehog*-expressing notochord (red arrow) below it and the endoderm (blue arrow) still farther ventral. (c) A whole *Drosophila* embryo probed for an mRNA produced during trachea development. The repeating pattern of body segments is visible. Anterior (head) is up; ventral is to the left. [Ljiljana Milenkovic and Matthew P. Scott.]

sequence can be programmed in a small region on the surface of the slide. Several oligonucleotide sequences from a single gene are thus synthesized in neighboring regions of the slide. With this method, oligonucleotides representing thousands of genes can be produced on a single glass slide. Because the methods for constructing these arrays of synthetic oligonucleotides were adapted from methods for manufacturing microscopic integrated circuits used in computers, these types of oligonucleotide microarrays are often called *DNA chips*.

**Using Microarrays to Compare Gene Expression Under Different Conditions** The initial step in a microarray expression study is to prepare cDNAs from the mRNAs expressed by the cells under study and attach fluorescent labels to them. When the cDNA preparation is applied to a microarray under appropriate conditions, DNA spots representing genes that are expressed will hybridize to their complementary cDNAs in the labeled probe mix and can subsequently be detected in a scanning laser microscope.

Figure 6-26 depicts how this method can be applied to examine the changes in gene expression observed after starved human fibroblasts are transferred to a rich, serum-containing growth medium. In this type of experiment, the separate cDNA preparations from starved and from serum-grown fibroblasts are labeled with differently colored fluorescent dyes. A DNA microarray comprising 8600 mammalian genes is then incubated with a mixture containing equal amounts of the two cDNA preparations under hybridization conditions. After unhybridized cDNA is washed away, the

intensity of green and red fluorescence at each DNA spot is measured using a fluorescence microscope and is recorded under the name of each gene according to its known position on the slide. The relative intensities of red and green fluorescence signals at each spot provide a measure of the relative level of expression of that gene in response to serum. Genes that are not transcribed under these growth conditions give no detectable signal. Genes that are transcribed at the same level under both conditions hybridize equally to both red- and green-labeled cDNA preparations. Microarray analysis of gene expression in fibroblasts showed that transcription of about 500 of the 8600 genes examined changed substantially after addition of serum.

### Cluster Analysis of Multiple Expression Experiments Identifies Co-regulated Genes

Firm conclusions about whether genes that exhibit similar changes in expression are co-regulated, and hence likely to be closely related functionally, rarely can be drawn from a single microarray experiment. For example, many of the observed differences in gene expression just described in fibroblasts could be indirect consequences of the many different changes in cell physiology that occur when cells are transferred from one medium to another. In other words, genes that appear to be co-regulated in a single microarray expression experiment may undergo changes in expression for very different reasons and may actually have very different biological functions. A solution to this problem is to

combine the information from a set of microarray expression experiments to find genes that are similarly regulated under a variety of conditions or over a period of time.

**EXPERIMENTAL FIGURE 6-26 DNA microarray analysis can reveal differences in gene expression in fibroblasts under different experimental conditions.** (a) In this example, cDNA prepared from mRNA isolated from fibroblasts either starved for serum or after serum addition is labeled with different fluorescent dyes. A microarray composed of DNA spots representing 8600 mammalian genes is exposed to an equal mixture of the two cDNA preparations under hybridization conditions. The ratio of the intensities of red and green fluorescence over each spot, detected with a scanning confocal laser microscope, indicates the relative expression of each gene in response to serum. (b) A micrograph of a small segment of an actual DNA microarray. Each spot in this  $16 \times 16$  array contains DNA from a different gene hybridized to control and experimental cDNA samples labeled with red and green fluorescent dyes. (A yellow spot indicates equal hybridization of green and red fluorescence, indicating no change in gene expression.) [Part (b) Alfred Pasieka/Science Source.]

This more informative use of multiple microarray expression experiments is illustrated by an examination of the relative expression of the 8600 genes mentioned above at different times after serum addition to fibroblasts, which generated more than  $10^4$  individual pieces of data. A computer program, related to the one used to determine the relatedness of different protein sequences, can organize these data and cluster genes that show similar expression over the time course after serum addition. Remarkably, such *cluster analysis* groups sets of genes whose encoded proteins participate in a common cellular process, such as cholesterol biosynthesis or the cell cycle (Figure 6-27).

 Microarray analysis is a powerful diagnostic tool in medicine. For instance, particular sets of mRNAs have been found to distinguish tumors with a poor prognosis from those with a good prognosis. Previously indistinguishable disease variations are now detectable. Analysis of tumor biopsies for these distinguishing mRNAs will help physicians to select the most appropriate treatment. As more patterns of gene expression characteristic of various diseased tissues are recognized, the diagnostic use of DNA microarrays will be extended to other conditions. ■

### **E. coli Expression Systems Can Produce Large Quantities of Proteins from Cloned Genes**

 Many protein hormones and other signaling or regulatory proteins are normally expressed at very low concentrations, which precludes their isolation and purification in large quantities by standard biochemical techniques. Widespread therapeutic use of such proteins, as well as basic research on their structure and functions, depends on efficient procedures for producing them in large amounts at reasonable cost. Recombinant DNA techniques that turn *E. coli* cells into factories for synthesizing low-abundance proteins are now used to produce granulocyte colony-stimulating factor (G-CSF), insulin, growth hormone, erythropoietin, and other human proteins with therapeutic uses commercially. For example, G-CSF stimulates the production of

**EXPERIMENTAL FIGURE 6-27 Cluster analysis of data from multiple microarray expression experiments can identify co-regulated genes.** The expression of 8600 mammalian genes was detected by microarray analysis at time intervals over a 24-hour period after serum-starved fibroblasts were provided with serum. The cluster diagram shown here is based on a computer algorithm that groups genes showing similar changes in expression compared with a serum-starved control sample over time. Each column of colored boxes represents a single gene, and each row represents a time point. A red box indicates an increase in expression relative to the control; a green box, a decrease

in expression; and a black box, no significant change in expression. The “tree” diagram at the top shows how the expression patterns for individual genes can be organized in a hierarchical fashion to group together the genes with the greatest similarity in their patterns of expression over time. Five clusters of coordinately regulated genes were identified in this experiment, as indicated by the bars at the bottom. Each cluster contains multiple genes whose encoded proteins function in a particular cellular process: cholesterol biosynthesis (A), the cell cycle (B), the immediate-early response (C), signaling and angiogenesis (D), and wound healing and tissue remodeling (E). [Michael B. Eisen, University of California, Berkeley.]

granulocytes, the phagocytic white blood cells that are critical to defense against bacterial infections. Administration of G-CSF to cancer patients helps offset the reduction in granulocyte production caused by chemotherapeutic agents, thereby protecting patients against serious infection while they are receiving chemotherapy. ■

The first step in producing large amounts of a low-abundance protein is to obtain a cDNA clone encoding the full-length protein by the methods discussed previously. The second step is to engineer plasmid vectors that will express large amounts of the encoded protein when they are inserted into *E. coli* cells. The key to designing such expression vectors is inclusion of a promoter, a DNA sequence from which transcription of the cDNA can begin. Consider, for example, the relatively simple system for expressing G-CSF shown in Figure 6-28. In this case, G-CSF is expressed in *E. coli* transformed with plasmid vectors that contain the *lac* promoter

adjacent to the cloned cDNA encoding G-CSF. Transcription from the *lac* promoter occurs at high rates only when lactose, or a lactose analog such as isopropylthiogalactoside (IPTG),

**EXPERIMENTAL FIGURE 6-28 Some eukaryotic proteins can be produced in *E. coli* cells from plasmid vectors containing the *lac* promoter.** (a) This plasmid expression vector contains a fragment of the *E. coli* chromosome containing the *lac* promoter and the neighboring *lacZ* gene. In the presence of the lactose analog IPTG, RNA polymerase normally transcribes the *lacZ* gene, producing *lacZ* mRNA, which is translated into the encoded protein,  $\beta$ -galactosidase. (b) The *lacZ* gene can be cut out of the expression vector with restriction enzymes and replaced by a cloned cDNA, in this case, one encoding granulocyte colony-stimulating factor (G-CSF). When the resulting plasmid is inserted into *E. coli* cells, addition of IPTG and subsequent transcription from the *lac* promoter produce G-CSF mRNA, which is translated into G-CSF protein.

is added to the culture medium. Even larger quantities of a desired protein can be produced in more complicated *E. coli* expression systems.

To aid in purification of a eukaryotic protein produced in an *E. coli* expression system, researchers often modify the cDNA encoding the recombinant protein to facilitate its separation from endogenous *E. coli* proteins. A commonly used modification of this type is the addition of a short nucleotide sequence to the end of the cDNA, so that the expressed protein will have six histidine residues at the C-terminus. Proteins modified in this way bind tightly to an affinity matrix that contains chelated nickel atoms, whereas *E. coli* proteins do not bind to such a matrix. The bound proteins can be released from the nickel atoms by decreasing the pH of the surrounding medium. In most cases, this procedure yields a pure recombinant protein that is functional, since addition of short amino acid sequences to either the C-terminus or the N-terminus of a protein usually does not interfere with the protein's biochemical activity.

### Plasmid Expression Vectors Can Be Designed for Use in Animal Cells

Although bacterial expression systems can be used successfully to create large quantities of some proteins, bacteria cannot be used in all cases. Many experiments designed to examine the function of a protein in an appropriate cellular context require expression of a genetically modified protein in cultured animal cells. To accomplish this, genes are cloned into specialized eukaryotic expression vectors and are introduced into cultured animal cells by a process called **transfection**. Two common methods for transfecting animal cells differ in whether the recombinant vector DNA is or is not integrated into the host-cell genomic DNA.

In both methods, cultured animal cells must be treated to facilitate their initial uptake of the recombinant plasmid vector. This can be done by exposing cells to a preparation of lipids that penetrates the plasma membrane, increasing its permeability to DNA. Alternatively, subjecting cells to a brief electric shock of several thousand volts, a technique known as *electroporation*, makes them transiently permeable to DNA. Usually the plasmid DNA is added in sufficient concentration to ensure that a large proportion of the cultured cells will receive at least one copy. Researchers have also harnessed viruses for transfection; viruses can be modified to contain DNA of interest, which is then introduced into host cells by simply infecting them with the recombinant virus.

**Transient Transfection** The simpler of the two transfection methods, called *transient transfection*, employs a plasmid vector similar to the yeast shuttle vectors described previously. For use in mammalian cells, plasmid vectors are engineered to carry a replication origin derived from a virus that infects mammalian cells, a strong promoter recognized by mammalian RNA polymerase, and the cloned cDNA encoding the protein to be expressed adjacent to the promoter (Figure 6-29a). Once such a plasmid vector enters a mammalian cell, the viral

**EXPERIMENTAL FIGURE 6-29 Transient and stable transfection with specially designed plasmid vectors permits expression of cloned genes in cultured animal cells.** Both methods employ plasmid vectors that contain the usual elements—replication origin, selectable marker (e.g., *amp<sup>r</sup>*), and polylinker—that permit propagation in *E. coli* as well as a cloned cDNA with an adjacent animal promoter. For simplicity, these elements are not depicted. (a) In transient transfection, the plasmid vector contains a replication origin from a virus that can replicate in the cultured animal cells. Since the vector is not incorporated into the genome of the cultured cells, production of the cDNA-encoded protein continues for only a limited time. (b) In stable transfection, the vector carries a selectable marker such as *neo<sup>r</sup>*, which confers resistance to G-418. The relatively few transfected animal cells that integrate the exogenous DNA into their genomes are selected on medium containing G-418. Because the vector is integrated into the genome, these stably transfected, or transformed, cells will continue to produce the cDNA-encoded protein as long as the culture is maintained. See the text for discussion.

replication origin allows it to replicate efficiently, generating numerous plasmids from which the protein is expressed. However, during cell division, such plasmids are not faithfully segregated into both daughter cells, and in time, a substantial fraction of the cells in a culture will not contain a plasmid, hence the name *transient transfection*.

**Stable Transfection (Transformation)** If an introduced vector integrates into the genome of the host cell, that genome is permanently altered, and the cell is said to be *transformed*. Integration is most likely accomplished by endogenous enzymes that normally function in DNA repair and recombination. A commonly used selectable marker is the gene for neomycin phosphotransferase (designated *neo<sup>r</sup>*), which confers resistance to a toxic compound chemically related to neomycin, known as G-418. The basic procedure for expressing a cloned cDNA by *stable transfection* is outlined in Figure 6-29b. Only those cells that have integrated the expression vector into the host chromosome will survive and give rise to a clone in the presence of a high concentration of G-418. Because integration occurs at random sites in the genome, individual transformed G-418-resistant clones will differ in their rates of transcribing the inserted cDNA. Therefore, the stable transfectants are usually screened to identify those that produce the protein of interest at the highest levels.

**Retroviral Expression Systems** Researchers have exploited the basic mechanisms used by viruses for introduction of their genetic material into animal cells and its subsequent insertion into chromosomal DNA to greatly increase the efficiency by which a modified gene can be stably expressed in animal cells. One such viral expression system is derived from a class of retroviruses known as *lentiviruses*. As shown

in Figure 6-30, three different plasmids, introduced into cells by transient transfection, are used to produce recombinant lentivirus particles suitable for efficient introduction of a cloned gene into target animal cells. The first plasmid, known as the *vector plasmid*, contains a cloned gene of interest next to a selectable marker such as *neo<sup>r</sup>* flanked by lentivirus LTR sequences. The left LTR sequence directs synthesis of an RNA molecule that carries lentiviral LTR sequences at either end and thus has many of the properties of native retroviral RNA. In an appropriate host, this LTR-bearing RNA can be packaged into viral particles and then introduced into a target cell by viral infection. In the target cell, the LTR sequences direct the copying of the RNA into double-stranded DNA by reverse transcription and the integration of that DNA into chromosomal DNA following a sequence of events depicted in Figure 8-14. A second plasmid, known as the packaging plasmid, carries all the viral genes except for the major viral envelope protein, necessary for packaging LTR-containing viral RNA into a functional lentivirus particle. The final plasmid allows expression of a viral envelope protein that, when incorporated into a recombinant lentivirus, allows the resulting hybrid virus particles to infect a desired target cell type. A common envelope protein used in this context is the glycoprotein of the vesicular stomatitis virus (VSV-G protein), which can readily replace the normal lentivirus envelope protein on the surface of completed virus particles and allows the resulting virus particles to infect a wide variety of mammalian cell types, including hematopoietic stem cells, neurons, and muscle and liver cells. After cell infection, the cloned gene flanked by the viral LTR sequences is reverse-transcribed into DNA, which is transported into the nucleus and then integrated into the host genome. If necessary, as in the case of stable transfection, cells with a stably integrated cloned gene and *neo<sup>r</sup>* marker can be selected by resistance to G-418. Many of the techniques for inactivating the function of specific genes (see Section 6.5) require that an entire population of cultured cells be genetically modified simultaneously. Engineered lentiviruses are particularly useful for such experiments because they infect cells with such high efficiency that every cell in a population will receive at least one copy of the lentivirus-borne plasmid.

**Gene and Protein Tagging** Expression vectors can provide a way to study the expression and intracellular localization of eukaryotic proteins. Such studies often rely on the use of a reporter protein, such as *green fluorescent protein (GFP)*,

**EXPERIMENTAL FIGURE 6-30** Retroviral vectors can be used for efficient integration of cloned genes into the mammalian genome. See text for discussion.

that can be conveniently detected in cells (see Figure 4-16). Here we describe two ways to create a hybrid gene that connects expression of the reporter protein to that of the protein of interest. When the hybrid gene is reintroduced into cells, either by transfection with a plasmid expression vector containing the modified gene or by creation of a transgenic animal as described in Section 6.5, the expression of the reporter protein can be used to determine where and when a gene is expressed. This method provides data similar to that from the *in situ* hybridization experiments described previously, but often with greater resolution and sensitivity.

Figure 6-31 illustrates the use of two different types of GFP-tagging experiments to study the expression of an odorant receptor protein in *C. elegans*. When the promoter for the

odorant receptor is linked directly to the coding sequence of GFP in a configuration usually known as a *promoter-fusion*, GFP is expressed in specific neurons, filling the cytoplasm of those neurons. In contrast, when the hybrid gene is constructed by linking GFP to the coding sequence of the odorant receptor, the resulting *protein-fusion* can be localized by GFP fluorescence at the distal cilia in sensory neurons, the site at which the receptor protein is normally located.

An alternative to GFP tagging for detecting the intracellular location of a protein is to modify the gene of interest by appending to it a short DNA sequence that encodes a short stretch of amino acids recognized by a known monoclonal antibody. Such a short peptide that can be bound by an antibody is called an epitope; hence this method is known as *epitope tagging*. After transfection of cells with a plasmid expression vector containing the modified gene, the expressed epitope-tagged form of the protein can be detected by immunofluorescence labeling of the cells with the monoclonal antibody specific for the epitope. The choice of whether to use a short epitope or GFP to tag a given protein often depends on what types of modification a cloned gene can tolerate and still remain functional.

(a) Promoter-fusion; ODR10 promoter fused to GFP

(b) Protein-fusion; ODR10-GFP fusion protein

#### EXPERIMENTAL FIGURE 6-31 Gene and protein tagging facilitate cellular localization of proteins expressed from cloned genes.

In this experiment, the gene encoding a chemical odorant receptor, *Odr10*, of *C. elegans* was fused to the gene encoding green fluorescent protein (GFP). (a) A promoter-fusion was generated by linking just the promoter of *Odr10* to the coding sequence for GFP. The result is that GFP is expressed in the cytoplasm of the same specific sensory neurons in the head of *C. elegans* where *Odr10* is expressed. (b) A protein-fusion was constructed by linking GFP to the end of the full-length *Odr10* coding sequence. In this case, the Odr10-GFP fusion protein is targeted to the membrane at the tip of the sensory neurons and is apparent only at the distal end of the sensory cilia. The observed distribution can be inferred to reflect the normal location of *Odr10* protein in specific neurons. Because the promoter-fusion shown in (a) lacks the *Odr10* localization sequences, the expressed GFP fills the entire cell cytoplasm rather than being localized just to the distal tip of the sensory cilia. [Courtesy Ashish Maurya.]

### KEY CONCEPTS OF SECTION 6.3

#### Using Cloned DNA Fragments to Study Gene Expression

- Southern blotting, which can detect a single specific DNA fragment within a complex mixture, combines gel electrophoresis, transfer (blotting) of the separated bands to a filter, and hybridization with a complementary labeled DNA probe (see Figure 6-24). The similar technique of Northern blotting can detect a specific RNA within a mixture.
- The presence and distribution of specific mRNAs can be detected in living cells by *in situ* hybridization.
- DNA microarray analysis simultaneously detects the relative levels of expression of thousands of genes in different types of cells or in the same cells under different conditions (see Figure 6-26).
- Cluster analysis of the data from multiple microarray expression experiments can identify genes that are similarly regulated under various conditions. Such co-regulated genes commonly encode proteins that have biologically related functions.
- Expression vectors derived from plasmids allow the production of abundant amounts of a protein from a cloned gene.
- Eukaryotic expression vectors can be used to express cloned genes in yeast or mammalian cells. An important application of these methods is the tagging of proteins with GFP or an epitope for antibody detection.

## 6.4 Locating and Identifying Human Disease Genes

Inherited human diseases are the phenotypic consequence of defective human genes. Table 6-2 lists several of the most commonly occurring inherited diseases. Although a “disease” gene may result from a new mutation that arose in the preceding generation, most cases of inherited diseases are caused by preexisting mutant alleles that have been passed from one generation to the next for many generations. ■

The typical first step in deciphering the underlying cause of any inherited human disease is to identify the affected gene and its encoded protein. Comparison of the sequences of a disease gene and its product with those of genes and proteins whose sequence and function are known can provide clues to the molecular and cellular cause of the disease. Historically, researchers have used whatever phenotypic clues might be relevant to make guesses about the molecular basis of inherited diseases. An early example of successful guesswork was the hypothesis that sickle-cell disease, known to be a disease of blood cells, might be caused by defective hemoglobin. This idea led to the identification of a specific amino acid substitution in hemoglobin that causes polymerization of the

defective hemoglobin molecules, causing the sickle-like deformation of red blood cells in individuals who have inherited two copies of the *Hb<sup>s</sup>* allele for sickle-cell hemoglobin.

Most often, however, the genes responsible for inherited diseases must be found without any prior knowledge or reasonable hypotheses about the nature of the affected gene or its encoded protein. In this section, we see how human geneticists can find the gene responsible for an inherited disease by following the segregation of the disease in families. The segregation of the disease can be correlated with the segregation of many other genetic markers, eventually leading to identification of the chromosomal position of the affected gene. This information, along with knowledge of the sequence of the human genome, can ultimately allow the affected gene and the disease-causing mutations to be pinpointed.

### Monogenic Diseases Show One of Three Patterns of Inheritance

Human genetic diseases that result from mutation in one specific gene, referred to as *monogenic diseases*, display different inheritance patterns depending on the nature and chromosomal location of the alleles that cause them. One

**TABLE 6-2** Common Inherited Human Diseases

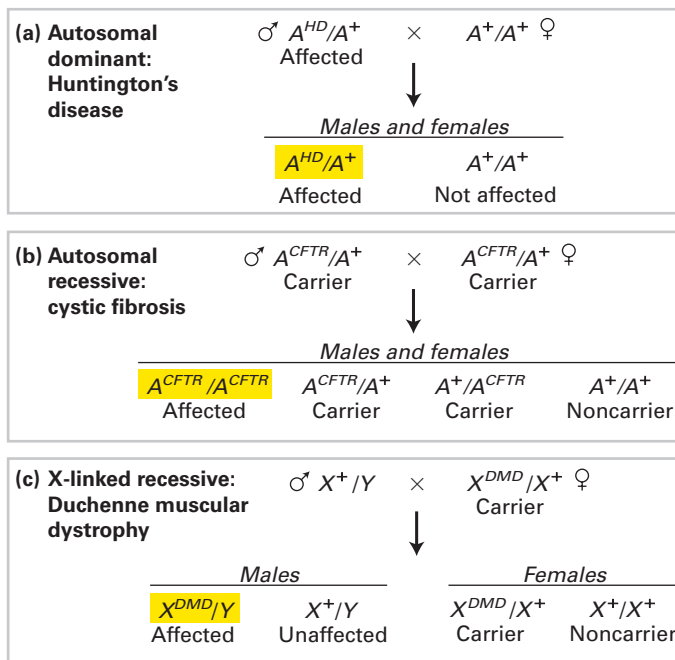

Disease	Molecular and Cellular Defect	Incidence
<b>Autosomal Recessive</b>		
Sickle-cell disease	Abnormal hemoglobin causes deformation of red blood cells, which can become lodged in capillaries; also confers resistance to malaria.	1/625 of sub-Saharan African origin
Cystic fibrosis	Defective chloride channel (CFTR) in epithelial cells leads to excessive mucus in lungs.	1/2500 of European origin
Phenylketonuria (PKU)	Defective enzyme in phenylalanine metabolism (tyrosine hydroxylase) results in excess phenylalanine leading to mental retardation, unless restricted by diet.	1/10,000 of European origin
Tay-Sachs disease	Defective hexosaminidase enzyme leads to accumulation of excess sphingolipids in the lysosomes of neurons, impairing neural development.	1/1000 eastern European Jews
<b>Autosomal Dominant</b>		
Huntington's disease	Defective neural protein (huntingtin) may assemble into aggregates, causing damage to neural tissue.	1/10,000 of European origin
Hypercholesterolemia	Defective LDL receptor leads to excessive cholesterol in blood and early heart attacks.	1/122 French Canadians
<b>X-Linked Recessive</b>		
Duchenne muscular dystrophy (DMD)	Defective cytoskeletal protein (dystrophin) leads to impaired muscle function.	1/3500 males
Hemophilia A	Defective blood clotting factor VIII leads to uncontrolled bleeding.	1–2/10,000 males

characteristic pattern is that exhibited by a dominant allele in an autosome (that is, one of the 22 human chromosomes that is not a sex chromosome). Because an *autosomal dominant* allele is expressed in the heterozygote, usually at least one of the parents of an affected individual will also have the disease. Diseases caused by dominant alleles often appear later in life, after reproductive age. If this were not the case, natural selection would have eliminated these alleles during human evolution. An example of an autosomal dominant disease is Huntington's disease, a neural degenerative disease that generally strikes in mid- to late life. If either parent carries a mutant *HD* allele, each of his or her children (regardless of sex) has a 50 percent chance of inheriting the mutant allele and being affected (Figure 6-32a).

A recessive allele in an autosome exhibits quite a different segregation pattern. Both parents must be heterozygous *carriers* of an autosomal recessive allele in order for their children to be at risk of the disease. Each child of heterozygous

parents has a 25 percent chance of receiving both recessive alleles, and thus being affected; a 50 percent chance of receiving one normal and one mutant allele, and thus being a carrier; and a 25 percent chance of receiving two normal alleles. A clear example of an autosomal recessive disease is cystic fibrosis, which results from a defective chloride-channel gene known as *CFTR* (Figure 6-32b). Related individuals (e.g., first or second cousins) have a relatively high probability of being carriers for the same recessive alleles. Thus children born to related parents are much more likely than those born to unrelated parents to be homozygous for, and therefore affected by, a rare autosomal recessive disorder.

The third common pattern of inheritance is that of an *X-linked recessive* allele. A recessive allele on the X chromosome will most often be expressed in males, who receive only one X chromosome from their mother, but not in females, who receive an X chromosome from both their mother and their father. This leads to a distinctive sex-linked segregation pattern in which the disease is exhibited much more frequently in males than in females. For example, Duchenne muscular dystrophy (DMD), a muscle degenerative disease that specifically affects males, is caused by a recessive allele on the X chromosome. DMD exhibits the typical sex-linked segregation pattern in which mothers who are heterozygous, and therefore phenotypically normal, can act as carriers, transmitting the DMD allele, and therefore the disease, to 50 percent of their male progeny (Figure 6-32c).

**FIGURE 6-32 Three common inheritance patterns for human monogenic diseases.** Wild-type autosomes (A) and sex chromosomes (X and Y) are indicated by superscript plus signs. (a) In an autosomal dominant disorder such as Huntington's disease, only one mutant allele is needed to confer the disease. If either parent is heterozygous for the mutant *HD* allele, his or her children have a 50 percent chance of inheriting the mutant allele and getting the disease. (b) In an autosomal recessive disorder such as cystic fibrosis, two mutant alleles must be present to confer the disease. Both parents must be heterozygous carriers of the mutant *CFTR* gene for their children to be at risk of being affected or being carriers. (c) An X-linked recessive disease such as Duchenne muscular dystrophy is caused by a recessive mutation on the X chromosome and exhibits the typical sex-linked segregation pattern. Males born to mothers heterozygous for a mutant *DMD* allele have a 50 percent chance of inheriting the mutant allele and being affected. Females born to heterozygous mothers have a 50 percent chance of being carriers.

## DNA Polymorphisms Are Used as Markers for Linkage Mapping of Human Mutations

Once the mode of inheritance has been determined, the next step in finding a disease allele is to map its position with respect to known genetic markers using the basic principle of genetic linkage, as described in Section 6.1. The presence of many different already mapped genetic traits, or markers, distributed along the length of a chromosome facilitates the mapping of a new mutation. The more markers that are available, the more precisely a mutation can be mapped. The density of genetic markers needed for a high-resolution human genetic map is about one marker every 5 centimorgans (cM) (as discussed previously, one genetic map unit, or centimorgan, is defined as the distance between two positions along a chromosome that results in 1 recombinant individual in 100 progeny). Thus a high-resolution genetic map requires 25 or so genetic markers of known position distributed along the length of each human chromosome.

In the experimental organisms commonly used in genetic studies, numerous markers with easily detectable phenotypes are available for genetic mapping of mutations. For humans, there are not nearly enough phenotypic markers to carry out genetic mapping studies. Instead, recombinant DNA technology has made available a wealth of useful DNA-based molecular markers. Because most of the human genome does not encode proteins, a large amount of phenotypically inconsequential sequence variation exists between individuals. Indeed, it has been estimated that nucleotide

differences between unrelated individuals occur on an average of 1 of every  $10^3$  nucleotides. Since variations in DNA sequence, referred to as *DNA polymorphisms*, can be followed from one generation to the next by sequencing the DNA of individuals, they can serve as ideal genetic markers for linkage studies. Currently, a panel of as many as  $10^4$  different known polymorphisms whose locations have been mapped in the human genome is used for genetic linkage studies in humans.

*Single-nucleotide polymorphisms (SNPs)* constitute the most abundant type of DNA polymorphism and are therefore useful for constructing genetic maps of maximum resolution (Figure 6-33). Another useful type of DNA polymorphism consists of a variable number of repetitions of a two-, three-, or four-base sequence. Such polymorphisms, known as *short tandem repeats (STRs)* or *microsatellites*, presumably are formed by recombination or by slippage of either the template or newly synthesized strand during DNA replication. A useful property of STRs is that different individuals often have different numbers of repeats. The existence of multiple versions of an STR makes it more likely to produce an informative segregation pattern in a given pedigree and therefore to be of more general use in mapping the positions of disease genes. These polymorphisms can be detected by PCR amplification and DNA sequencing.

### Linkage Studies Can Map Disease Genes with a Resolution of About 1 Centimorgan

Without going into all the technical considerations, let's see how the allele conferring a particular dominant disease trait (e.g., familial hypercholesterolemia) might be mapped. The first step is to obtain DNA samples from all the members of a family containing individuals that exhibit the disease. The DNA from each affected and unaffected individual is then analyzed to determine that individual's genotype for a large number of known DNA polymorphisms (either STR or SNP markers can be used). The segregation pattern of each DNA polymorphism within the family is then compared with the segregation pattern of the disease under study. Polymorphisms that are not linked to the disease allele will not show any significant tendency to co-segregate along with the disease, whereas polymorphisms that are closely linked to it will almost always co-segregate with the disease, because recombination events that would separate the disease allele and the polymorphism will be rare. Computer analysis of the segregation data is used to calculate the likelihood of linkage between each DNA polymorphism and the disease-causing allele. Under ideal circumstances, the segregation patterns from at least 10 individuals in a family are needed to establish statistically significant evidence for linkage.

In practice, segregation data are usually collected from different families exhibiting the same disease and pooled. The more families that can be examined, the greater the statistical significance of any evidence for linkage that can be obtained, and the greater the precision with which the distance between a linked DNA polymorphism and a disease

**EXPERIMENTAL FIGURE 6-33 Single-nucleotide polymorphisms (SNPs) can be followed like genetic markers.** A hypothetical pedigree based on SNP analysis of the DNA from a region of a chromosome. In this family, the SNP exists as an A, T, or C nucleotide. Each individual has two alleles: some contain an A on both chromosomes, and others are heterozygous at this site. Circles indicate females; squares indicate males. Blue indicates unaffected individuals; orange indicates individuals with the trait of interest. Analysis reveals that the trait segregates with a C at the SNP.

allele can be measured. Most family studies have a maximum of about 100 individuals in whom linkage between a disease gene and a panel of DNA polymorphisms can be tested. This number of individuals sets the practical upper limit on the resolution of such a mapping study to about 1 centimorgan, or a physical distance of about  $7.5 \times 10^5$  bp.

A phenomenon called *linkage disequilibrium* is the basis for an alternative mapping strategy, which can often afford a higher degree of resolution. This approach can be applied to a genetic disease commonly found in a particular population that results from a single mutation that occurred many generations in the past. The DNA polymorphisms carried by the ancestral chromosome in which the mutation occurred are collectively known as the *haplotype* of that chromosome. As the disease allele is passed from one generation to the next, only the polymorphisms that are closest to the disease gene will not be separated from it by recombination. After many generations, the region that contains the disease gene will be evident because it will be the only region of the chromosome that will carry the haplotype of the ancestral chromosome conserved through many generations (Figure 6-34). By assessing the distribution of specific markers in all affected individuals in a population, geneticists can identify DNA markers tightly associated with the disease, thus localizing the disease-associated gene to a relatively small region. Under ideal circumstances, linkage-disequilibrium studies can improve the resolution of mapping studies to less than 0.1 centimorgans. The resolving power of this method comes from its ability to determine whether a polymorphism and the disease allele were ever separated by a meiotic recombination event at any time since the disease allele first appeared on the ancestral chromosome—in some cases, this can amount to finding markers that are so closely linked to the disease gene that even after hundreds of meioses, they have never been separated from it by recombination.

**FIGURE 6-34 Linkage-disequilibrium studies of human populations can be used to map genes at high resolution.** A new disease mutation arises in the context of an ancestral chromosome among a set of polymorphisms known as the *haplotype* of that chromosome (indicated by red shading; the blue segments of chromosomes represent general haplotypes derived from the general population and not from the ancestral haplotype in which the mutation originally arose). After many generations, chromosomes that carry the disease mutation will also carry segments of the ancestral haplotype that have not been separated from the disease mutation by recombination. The regions closest to the disease mutation are the most likely to be the ancestral haplotype. This phenomenon is known as *linkage disequilibrium*. The position of the disease mutation can be located by scanning chromosomes that contain it for highly conserved polymorphisms corresponding to the ancestral haplotype.

### Further Analysis Is Needed to Locate a Disease Gene in Cloned DNA

Although linkage mapping can usually locate a human disease gene to a region containing about  $10^5$  bp, as many as 10 different genes may be located in a region of this size. The ultimate objective of a mapping study is to locate the gene of interest within a cloned segment of DNA and then to determine the nucleotide sequence of this fragment. The relative scales of a chromosomal genetic map and physical maps corresponding to ordered sets of plasmid clones and the nucleotide sequence are shown in Figure 6-35.

One strategy for further localizing a disease gene within the genome is to identify mRNA encoded by DNA in the region under study. Comparison of gene expression in tissues from normal and affected individuals may suggest tissues in which a particular disease gene is normally expressed. For instance, a mutation that phenotypically affects muscle, but no other tissue, might be in a gene that is expressed only in muscle tissue. The expression of mRNA in both normal and affected individuals is generally determined by Northern blotting, microarray analysis, or in situ hybridization

of labeled DNA or RNA to tissue sections. Northern blots, in situ hybridization, or microarray experiments permit comparison of both the level of expression and the sizes of mRNAs in mutant and wild-type tissues. Although the sensitivity of in situ hybridization is lower than that of Northern blot analysis, it can be very helpful in identifying an mRNA that is expressed at low levels in a given tissue but at very high levels in a subclass of cells within that tissue. An mRNA that is altered or missing in various individuals affected with a disease compared with wild-type individuals would be an excellent candidate for encoding the protein whose disrupted function causes that disease.

In many cases, point mutations that give rise to disease-causing alleles result in no detectable change in the level of expression or electrophoretic mobility of mRNAs. Thus, if comparison of the mRNAs expressed in normal and affected individuals reveals no detectable differences in the candidate mRNAs, a search for point mutations in the DNA regions encoding the mRNAs is undertaken. Now that highly efficient methods for sequencing DNA are available, researchers frequently determine the sequences of candidate regions of DNA isolated from affected individuals to identify point mutations. The overall strategy is to search for a coding sequence that consistently shows possibly deleterious alterations in DNA from individuals that exhibit the disease. A limitation of this approach is that the region near the affected gene may carry naturally occurring polymorphisms unrelated to the gene of interest. Such polymorphisms, not functionally related to the disease, can lead to misidentification of the DNA fragment carrying the gene of interest. For this reason, the more mutant alleles available for analysis, the more likely that a gene will be correctly identified.

### Many Inherited Diseases Result from Multiple Genetic Defects

Most of the inherited human diseases that are now understood at the molecular level are monogenic diseases; that is, a clearly discernible disease state is produced by a defect in a single gene. Monogenic diseases caused by mutation in one specific gene exhibit one of the characteristic inheritance patterns shown in Figure 6-32. The genes associated with most of the common monogenic diseases have already been mapped using DNA-based markers as described previously.

However, many other inherited diseases show more complicated patterns of inheritance, making the identification of the underlying genetic cause much more difficult. One type of added complexity that is frequently encountered is *genetic heterogeneity*. In such cases, mutations in any one of several different genes can cause the same disease. For example, retinitis pigmentosa, which is characterized by degeneration of the retina usually leading to blindness, can be caused by mutations in any one of more than 60 different genes. In human linkage studies, data from multiple families must usually be combined to determine whether a statistically significant linkage exists between a disease gene and known molecular markers. Genetic heterogeneity such as that exhibited by

**FIGURE 6-35 Relationship between genetic and physical maps of a human chromosome.** The diagram depicts a human chromosome analyzed at different levels of detail. The chromosome as a whole can be viewed in the light microscope when it is in a condensed state that occurs at metaphase, and the approximate location of specific sequences can be determined by fluorescence in situ hybridization

(FISH). At the next level of detail, genetic traits can be mapped relative to DNA-based genetic markers. Local segments of the chromosome can be analyzed at the level of DNA sequences identified by Southern blotting or PCR. Finally, important genetic differences can be most precisely defined by differences in the nucleotide sequence of the chromosomal DNA.

retinitis pigmentosa can confound such an approach because any statistical trend in the mapping data from one family tends to be canceled out by the data obtained from another family with an unrelated causative gene.

Human geneticists used two different approaches to identify the many genes associated with retinitis pigmentosa. The first approach relied on mapping studies of exceptionally large families that contained a sufficient number of affected individuals to provide statistically significant evidence for linkage between known DNA polymorphisms and a single causative gene. The genes identified in such studies showed that several of the mutations that cause retinitis pigmentosa lie within genes that encode proteins that are abundant in the retina. Following up on this clue, geneticists concentrated their attention on those genes that are highly expressed in the retina when screening other individuals with retinitis pigmentosa. This approach of using additional information to focus screening efforts on a subset of candidate genes led to

identification of additional rare causative mutations in many different genes encoding retinal proteins.

A further complication in the genetic dissection of human diseases is posed by diabetes, heart disease, obesity, predisposition to cancer, and a variety of mental disorders that have at least some heritable properties. These and many other diseases can be considered to be *polygenic diseases* in the sense that alleles of multiple genes, acting together within an individual, contribute to both the occurrence and the severity of disease. How to systematically map complex polygenic traits in humans is one of the most important and challenging problems in human genetics today.

One of the most promising methods of studying diseases that exhibit genetic heterogeneity or are polygenic is to seek a statistical correlation between inheritance of a particular region of a chromosome and the propensity to have a disease using a procedure known as a **genome-wide association study (GWAS)**. The identification of disease-causing genes

by GWAS relies on the phenomenon of linkage disequilibrium described previously. If an allele that causes, or even predisposes an individual to, a disease has originated relatively recently during human evolution, that disease-causing allele will tend to remain associated with the particular set of DNA-based markers in the neighborhood of its chromosomal location. By examining a large number of DNA markers in populations of individuals with a particular disease as well as in control populations of individuals without the disease, researchers can identify chromosomal regions that tend to be correlated with occurrence of the disease. The power of this approach lies in computer algorithms that scan data from large numbers of individuals to identify small but significant correlations between a disease and inheritance of a particular region of the genome. Genomic sequencing and other methods can then be used to identify possible disease-causing mutations in these regions. In this way, alleles that cause a predisposition to the disease in some, but not necessarily all, individuals with the disease can be identified. Although GWAS can be a powerful tool to identify candidate disease genes, much further work is needed to determine how an individual carrying a particular mutation might be predisposed to the disease.

Models of human disease in experimental organisms may also contribute to unraveling the genetics of complex traits such as obesity or diabetes. For instance, large-scale controlled breeding experiments in mice can identify mouse genes associated with diseases analogous to those in humans. The human orthologs of the mouse genes identified in such studies would be likely candidates for involvement in the corresponding human disease. DNA from human populations can then be examined to determine if particular alleles of the candidate genes show a tendency to be present in individuals affected with the disease but absent from unaffected individuals. This “candidate gene” approach is currently being used intensively to search for genes that may contribute to the major polygenic diseases in humans.

## KEY CONCEPTS OF SECTION 6.4

### Locating and Identifying Human Disease Genes

- Inherited diseases and other traits in humans show three major patterns of inheritance: autosomal dominant, autosomal recessive, and X-linked recessive (see Figure 6-32).
- Genes for human diseases and other traits can be mapped by determining their co-segregation with markers whose locations in the genome are known. The closer a gene is to a particular marker, the more likely they are to co-segregate.
- Mapping of human genes with great precision requires thousands of molecular markers distributed along the chromosomes. The most useful markers are differences in the DNA sequence (polymorphisms) between individuals in noncoding regions of the genome.

- DNA polymorphisms useful in mapping human genes include single-nucleotide polymorphisms (SNPs) and short tandem repeats (STRs).
- Linkage mapping can often locate a human disease gene to a chromosomal region that includes as many as 10 genes. To identify the gene of interest within this candidate region typically requires expression analysis and comparison of DNA sequences between wild-type and disease-affected individuals.
- Some inherited diseases can result from mutations in different genes in different individuals (genetic heterogeneity). The occurrence and severity of other diseases depend on the presence of mutant alleles of multiple genes in the same individual (polygenic traits). The genes associated with such diseases can be mapped by finding a statistical correlation between the disease and a particular chromosomal location in a genome-wide association study.

## 6.5 Inactivating the Function of Specific Genes in Eukaryotes

The elucidation of DNA and protein sequences in recent years has led to the identification of many genes, using sequence patterns in genomic DNA and the sequence similarity of the encoded proteins with proteins of known function. As discussed in Chapter 8, the general functions of proteins identified by sequence searches can be predicted by analogy with known proteins. However, the precise *in vivo* roles of such “new” proteins may be unclear in the absence of mutant forms of the corresponding genes. In this section, we describe several ways of disrupting the normal function of a specific gene in the genome of an organism. Analysis of the resulting mutant phenotype often helps reveal the *in vivo* function of the normal gene and its encoded protein.

Three basic approaches underlie these gene inactivation techniques: (1) replacing a normal gene with other sequences, (2) introducing an allele whose encoded protein inhibits the functioning of the expressed normal protein, and (3) promoting destruction of the mRNA transcribed from a gene. The normal endogenous gene is modified in techniques based on the first approach, but is not modified in the other approaches.

Often researchers desire to study the effect of a particular allele of a gene rather than observing the effect of complete inactivation of the gene. For example, testing the effect of a dominant allele of an oncogene on cell division might require replacing one of the normal copies of the gene with that dominant allele. Until recently, this type of precise genome editing was nearly impossible to achieve, but now a variation on a bacterial system for making sequence-specific cuts in phage DNA has been adapted to allow small deletions, or even specific sequence alterations, to be made in cells from a wide variety of organisms, including mammals, as we’ll see at the end of this section.

## Normal Yeast Genes Can Be Replaced with Mutant Alleles by Homologous Recombination

Modifying the genome of the yeast *S. cerevisiae* is particularly easy for two reasons: yeast cells readily take up exogenous DNA under certain conditions, and the introduced DNA is efficiently exchanged for the homologous chromosomal site in the recipient cell. This specific, targeted recombination of identical stretches of DNA allows any gene in yeast chromosomes to be replaced with a mutant allele. (As we saw in Section 6.1, recombination between homologous chromosomes also occurs naturally during meiosis.)

In one popular method for disrupting yeast genes in this fashion, PCR is used to generate a *disruption construct* containing a selectable marker, which is subsequently transfected into yeast cells. As shown in Figure 6-36a, the two primers for PCR amplification of the selectable marker are each designed to include about 20 nucleotides identical to sequences flanking the yeast gene to be replaced. The resulting amplified construct comprises the selectable marker (e.g., the *kanMX* gene, which, like *neo<sup>r</sup>*, confers resistance to G-418) flanked by about 20 bp at each end that match the ends of the target yeast gene. Transformed diploid yeast cells in which one of the two copies of the target endogenous gene has been replaced by the disruption construct can be identified by their resistance to G-418 or other selectable phenotype. These heterozygous diploid yeast cells generally grow normally regardless of the function of the target gene, but half the haploid spores derived from these cells will carry only the disrupted allele (Figure 6-36b). If a gene is essential for viability, then spores carrying a disrupted allele will not survive.

Disruption of genes by this method is proving particularly useful in assessing the roles of proteins identified by analysis of the entire genomic sequence of *S. cerevisiae* (see Chapter 8). Each of the approximately 6000 genes has been disrupted with the *kanMX* construct in diploids, and gene disruptions in haploid spores have also been produced. These analyses have shown that about 4500 of the 6000 yeast gene disruptions can reside in viable haploid spores, revealing an unexpectedly large number of apparently nonessential genes. In some cases, disruption of a particular gene may give rise to subtle defects that do not compromise the viability of yeast cells growing under laboratory conditions. Alternatively, cells carrying a disrupted gene may be viable because of the operation of backup or compensatory pathways. To investigate this possibility, yeast geneticists are currently testing all possible double-mutant combinations for synthetic lethal effects that might reveal nonessential genes with redundant functions (see Figure 6-9c).

## Genes Can Be Placed Under the Control of an Experimentally Regulated Promoter

Although disruption of an essential gene required for cell growth will yield nonviable spores, this method provides

**EXPERIMENTAL FIGURE 6-36 Homologous recombination with transfected disruption constructs can inactivate specific target genes in yeast.** (a) A suitable construct for disrupting a target gene can be prepared using PCR. The two primers designed for this purpose each contain a sequence of about 20 nucleotides (nt) that is homologous to one end of the target yeast gene as well as sequences needed to amplify a segment of DNA carrying a selectable marker gene such as *kanMX*, which confers resistance to G-418. (b) When recipient diploid *Saccharomyces* cells are transformed with the disruption construct, homologous recombination between the ends of the construct and the corresponding chromosomal sequences integrates the marker gene into the chromosome, replacing the target-gene sequence. The recombinant diploid cells will grow on a medium containing G-418, whereas untransformed cells will not. If the target gene is essential for viability, half the haploid spores that form after sporulation of recombinant diploid cells will be nonviable.

little information about what the encoded protein actually does in yeast cells. To learn more about how a specific gene contributes to cell growth and viability, investigators must be able to selectively inactivate the gene in a population of growing cells. One method for doing this employs a regulated promoter to selectively shut off transcription of an essential gene.

A useful promoter for this purpose is the yeast *GAL1* promoter, which is active in cells grown on galactose but completely inactive in cells grown on glucose. In this approach, the coding sequence of an essential gene (gene X) is ligated to the *GAL1* promoter and inserted into a yeast shuttle vector (see Figure 6-15a). The recombinant vector is then introduced into haploid yeast cells in which gene X has been disrupted. Haploid cells that are transformed will grow on galactose medium because the normal copy of gene X on the vector is expressed in the presence of galactose. When the cells are transferred to a glucose-containing medium, however, gene X no longer is transcribed; as the cells divide, the amount of the encoded protein X declines, eventually reaching a state of depletion that mimics a loss-of-function mutation. The observed changes in the phenotype of these cells after the shift to glucose medium may suggest which cellular processes depend on the protein encoded by the essential gene X.

In an early application of this method, researchers explored the function of *Hsp70* genes in yeast. Haploid cells with disruptions in all four redundant *Hsp70* genes were nonviable unless the cells carried a vector containing a copy of a *Hsp70* gene that could be expressed from the *GAL1* promoter on galactose medium. On transfer to glucose medium, the vector-carrying cells eventually stopped growing because of insufficient Hsp70 activity. Careful examination of these dying cells revealed that their secretory proteins could no longer enter the endoplasmic reticulum (ER). This study provided the first evidence for the unexpected role of Hsp70 proteins in translocation of secretory proteins into the ER, a process examined in detail in Chapter 13.

### Specific Genes Can Be Permanently Inactivated in the Germ Line of Mice

Many of the methods for disrupting genes in yeast can be applied to the genes of higher eukaryotes. These altered genes can be introduced into the germ line via homologous recombination to produce animals with a **gene knockout**, or simply “knockout.” Knockout mice in which a specific gene is disrupted are powerful experimental systems for studying mammalian development, behavior, and physiology. They are also useful for studying the molecular basis of certain human genetic diseases.

Knockout mice are generated by a two-stage procedure. In the first stage, a DNA construct containing a disrupted allele of a particular target gene is introduced into embryonic stem (ES) cells. These cells, which are derived from the blastocyst, can be grown in culture through many generations

(see Figure 21-7). In a small fraction of transfected cells, the introduced DNA undergoes homologous recombination with the target gene, although recombination at nonhomologous chromosomal sites occurs much more frequently. To enable selection for cells in which homologous recombination and gene-targeted insertion occurs, the recombinant DNA construct introduced into ES cells includes two selectable marker genes (Figure 6-37). One of these genes (*neo<sup>r</sup>*), which confers resistance to G-418, is inserted within the target gene (X), thereby disrupting it. The other selectable gene, the thymidine kinase gene from herpes simplex virus (*tk<sup>HSV</sup>*), is inserted into the construct outside the target-gene sequence. ES cells that undergo recombination between the recombinant DNA construct and the homologous site on the chromosome will contain *neo<sup>r</sup>* but will not incorporate *tk<sup>HSV</sup>*. Because *tk<sup>HSV</sup>* confers sensitivity to the cytotoxic nucleotide analog ganciclovir, the desired recombinant ES cells can be selected by their ability to survive in the presence of both G-418 and ganciclovir. In these cells, one allele of gene X will be disrupted.

In the second stage in the production of knockout mice, ES cells heterozygous for a knockout mutation in gene X are injected into a recipient wild-type mouse blastocyst, which subsequently is transferred into a pseudopregnant female mouse (Figure 6-38). The resulting progeny will be chimeras, containing tissues derived from both the transplanted ES cells and the host cells. If the ES cells are also homozygous for a visible marker trait (e.g., coat color), then chimeric progeny in which the ES cells have survived and proliferated can be identified easily. Chimeric mice are then mated with mice that are homozygous for another allele of the marker trait to determine if the knockout mutation has been incorporated into the germ line. Finally, mating of mice, each heterozygous for the knockout allele, will produce progeny homozygous for the knockout mutation.

The development of knockout mice that mimic certain human diseases can be illustrated by cystic fibrosis. By the methods discussed in Section 6.4, the recessive mutation that causes this disease was shown to be located in a gene known as *CFTR*, which encodes a chloride channel. Using the cloned wild-type human *CFTR* gene, researchers isolated the homologous mouse gene and subsequently introduced mutations in it. The gene-knockout technique was then used to produce homozygous mutant mice, which showed symptoms (i.e., a phenotype), including disturbances to the functioning of epithelial cells, similar to those of humans with cystic fibrosis. These knockout mice are currently being used as a model system for studying this genetic disease and developing effective therapies. ■

### Somatic Cell Recombination Can Inactivate Genes in Specific Tissues

Investigators are often interested in examining the effects of knockout mutations in a particular tissue of the mouse,

### (a) Formation of ES cells carrying a knockout mutation

### (b) Positive and negative selection of recombinant ES cells

at a specific stage in development, or both. However, mice carrying a germ-line knockout may have defects in numerous tissues or die before the developmental stage of interest. To address this problem, mouse geneticists have devised a clever technique to inactivate target genes in specific types of somatic cells or at particular times during development.

This technique employs site-specific DNA recombination sites (called *loxP sites*) and the enzyme Cre that catalyzes recombination between them. The *loxP-Cre recombination system* is derived from bacteriophage P1, but this site-specific

### EXPERIMENTAL FIGURE 6-37 Isolation of mouse ES cells with a gene-targeted disruption is the first stage in production of knockout mice.

(a) When a recombinant DNA construct is introduced into embryonic stem (ES) cells, random insertion via nonhomologous recombination occurs much more frequently than gene-targeted insertion via homologous recombination. Recombinant cells in which one allele of gene X (orange and white) is disrupted can be obtained by using a recombinant vector that carries gene X disrupted with *neo<sup>r</sup>* (green), which confers resistance to G-418, and, outside the region of homology, *tk<sup>HSV</sup>* (yellow), the thymidine kinase gene from herpes simplex virus. The viral thymidine kinase, unlike the endogenous mouse enzyme, can convert the nucleotide analog ganciclovir into the monophosphate form; this is then modified to the triphosphate form, which inhibits cellular DNA replication in ES cells. Thus ganciclovir is cytotoxic for recombinant ES cells carrying the *tk<sup>HSV</sup>* gene. Nonhomologous insertion includes the *tk<sup>HSV</sup>* gene, whereas homologous insertion does not; therefore, only cells with nonhomologous insertion are sensitive to ganciclovir. (b) Recombinant cells are selected by treatment with G-418, since cells that fail to pick up the construct or integrate it into their genome are sensitive to this cytotoxic compound. The surviving recombinant cells are treated with ganciclovir. Only cells with a targeted disruption in gene X, and therefore lacking the *tk<sup>HSV</sup>* gene and its accompanying cytotoxicity, will survive. See S. L. Mansour et al., 1988, *Nature* **336**:348.

recombination system also functions when placed in mouse cells. An essential feature of this technique is that expression of Cre is controlled by a cell-type-specific promoter. In *loxP-Cre* mice generated by the procedure depicted in Figure 6-39, inactivation of the gene of interest (X) occurs only in cells in which the promoter controlling the *cre* gene is active.

An early application of this technique provided strong evidence that a particular neurotransmitter receptor is important for learning and memory. Previous pharmacological and physiological studies had indicated that normal learning requires the NMDA class of glutamate receptors in the hippocampus, a region of the brain. But mice in which the gene encoding an NMDA receptor subunit was knocked out died neonatally, precluding analysis of the receptor's role in learning. Following the protocol in Figure 6-39, researchers generated mice in which the receptor subunit gene was inactivated in the hippocampus but expressed in other tissues. These mice survived to adulthood and showed learning and memory defects, confirming a role for these receptors in the ability of mice to encode their experiences into memory.

### Dominant-Negative Alleles Can Inhibit the Function of Some Genes

In diploid organisms, as noted in Section 6.1, the phenotypic effect of a recessive allele is expressed only in homozygous individuals, whereas dominant alleles are expressed in heterozygotes. Thus an individual must carry two copies of a recessive allele, but only one copy of a dominant allele, to exhibit the corresponding phenotypes.

We have seen how strains of mice that are homozygous for a given recessive knockout mutation can be produced by crossing individuals that are heterozygous for the same knockout mutation (see Figure 6-38). In experiments with cultured animal cells, however, it is usually difficult to disrupt both copies of a gene in order to produce a mutant phenotype. Moreover, the difficulty of producing strains with both copies of a gene mutated is often compounded by the presence of related genes of similar function that

**EXPERIMENTAL FIGURE 6-38 ES cells heterozygous for a disrupted gene are used to produce knockout mice.** Step **1**: Embryonic stem (ES) cells heterozygous for a knockout mutation in a gene of interest ( $X$ ) and homozygous for a dominant allele of a marker gene (here, brown coat color,  $A$ ) are transplanted into the blastocoel cavity of 4.5-day blastocysts that are homozygous for a recessive allele of the marker (here, black coat color,  $a$ ). Step **2**: The early embryos are then implanted into a pseudopregnant female. Those progeny containing ES-derived cells are chimeras, as indicated by their mixed black and brown coats. Step **3**: Chimeric mice are then backcrossed to black mice; brown progeny from this mating have ES-derived cells in their germ line. Steps **4–6**: Analysis of DNA isolated from a small amount of tail tissue can identify brown mice heterozygous for the knockout allele. Intercrossing of these mice produces some individuals homozygous for the disrupted allele—that is, knockout mice. See M. R. Capecchi, 1989, *Trends Genet.* **5**:70.

must also be inactivated in order to reveal an observable phenotype.

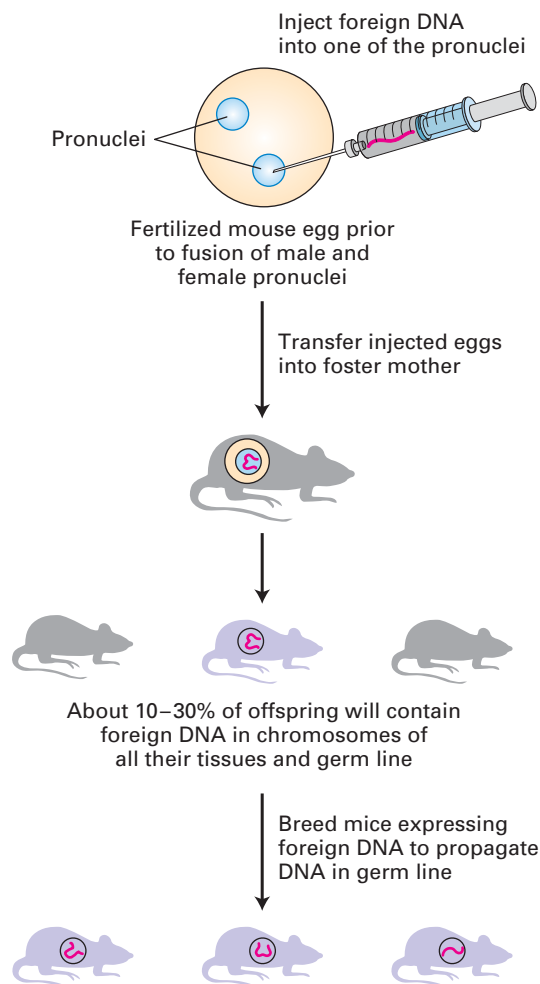

For certain genes, the difficulties of producing homozygous knockout mutants can be avoided by use of an allele carrying a dominant-negative mutation. These alleles are genetically dominant; that is, they produce a mutant phenotype even in cells carrying a wild-type copy of the gene. However, unlike other types of dominant alleles, dominant-negative alleles produce a phenotype equivalent to that of a loss-of-function mutation.

Useful dominant-negative alleles have been identified for a variety of genes and can be introduced into cultured cells by transfection or into the germ line of mice or other organisms. In both cases, the introduced gene is integrated into the genome by nonhomologous recombination. Such randomly inserted genes are called **transgenes**; the cells or organisms carrying them are referred to as transgenic. Transgenes carrying a dominant-negative allele are usually engineered so that the allele is controlled by a regulated promoter, which allows expression of the mutant protein in particular tissues or at particular times. As noted above, the random integration of exogenous DNA via nonhomologous recombination occurs at a much higher frequency than insertion via homologous recombination. Therefore, the production of transgenic mice is an efficient and straightforward process (Figure 6-40).

Among the genes that can be functionally inactivated by introduction of a dominant-negative allele are those encoding small (monomeric) GTP-binding proteins belonging to the GTPase superfamily. As we will see in several later chapters, these proteins (e.g., Ras, Rac, and Rab) act as intracellular switches. Conversion of these small GTPases from an inactive GDP-bound state to an active GTP-bound state depends on their interacting with a corresponding guanine nucleotide exchange factor (GEF). A mutant small GTPase that permanently binds to the GEF protein will block conversion of endogenous wild-type small GTPases to the active

**EXPERIMENTAL FIGURE 6-39** The *loxP*-Cre recombination system can knock out genes in specific cell types. A *loxP* site (purple) is inserted on each side of an essential exon (exon 2) of the target gene (gene X; blue) by homologous recombination, producing a *loxP* mouse. Since the *loxP* sites are in introns, they do not disrupt the function of X. A Cre mouse carries one gene X knockout allele and an introduced *cre* gene (orange) from bacteriophage P1 linked to a cell-type-specific promoter (yellow). The *cre* gene is incorporated into the mouse genome by nonhomologous recombination and does not affect the function of other genes. In the *loxP*-Cre mice that result from crossing these two types of mice, Cre protein is produced only in those cells in which the promoter is active. Thus these are the only cells in which recombination between the *loxP* sites catalyzed by Cre occurs, leading to deletion of exon 2. Since the other allele is a constitutive gene X knockout, deletion between the *loxP* sites results in complete loss of function of gene X in all cells expressing Cre. By using different promoters, researchers can study the effects of knocking out gene X in various types of cells.

GTP-bound state, thereby inhibiting them from performing their switching function (Figure 6-41).

## RNA Interference Causes Gene Inactivation by Destroying the Corresponding mRNA

The phenomenon known as RNA interference provides what may be the most straightforward method to inhibit the function of specific genes. This approach to disrupting genes is technically simpler than the methods described above. First observed in the roundworm *C. elegans*, **RNA interference (RNAi)** refers to the ability of double-stranded RNA to block expression of its corresponding single-stranded mRNA, but not that of mRNAs with a different sequence.

As described in Chapter 10, the phenomenon of RNAi rests on the general ability of eukaryotic cells to cleave double-stranded RNA into short (23-nt) double-stranded segments known as small inhibitory RNAs (siRNAs). The RNA endonuclease that catalyzes this reaction, known as Dicer, is found in all metazoans, but not in simpler

## EXPERIMENTAL FIGURE 6-40 Transgenic mice are produced by random integration of a foreign gene into the mouse germ line.

Foreign DNA injected into one of the two pronuclei (the male and female haploid nuclei contributed by the parents) has a good chance of being randomly integrated into the chromosomes of the diploid zygote. Because a transgene is integrated into the recipient genome by nonhomologous recombination, it does not disrupt endogenous genes. See R. L. Brinster et al., 1981, *Cell* 27:223.

**FIGURE 6-41 Inactivation of the function of a wild-type GTPase by the action of a dominant-negative mutant allele.** (a) Small (monomeric) GTPases (purple) are activated by their interaction with a guanine nucleotide exchange factor (GEF), which catalyzes the exchange of GDP for GTP. (b) Introduction of a dominant-negative allele of a small GTPase gene into cultured cells or transgenic animals leads to expression of a mutant GTPase that binds to and inactivates the GEF. As a result, endogenous wild-type copies of the same small GTPase are trapped in the inactive GDP-bound state. A single dominant-negative allele thus causes a loss-of-function phenotype in heterozygotes similar to that seen in homozygotes carrying two recessive loss-of-function alleles.

eukaryotes such as yeast. The siRNA molecules, in turn, can cause cleavage of mRNA molecules of matching sequence, in a reaction catalyzed by a protein complex known as *RISC*. *RISC* mediates recognition and hybridization between one strand of the siRNA and its complementary sequence on the target mRNA; subsequently, specific nucleases in the *RISC* complex cleave the mRNA-siRNA hybrid. This model accounts for the specificity of RNAi, since it depends on base pairing, and for its potency in silencing gene function, since the complementary mRNA is permanently destroyed by nucleolytic degradation. The normal function of both Dicer and *RISC* is to allow for gene regulation by small endogenous RNA molecules known as micro-RNAs, or miRNAs.

Researchers can exploit the micro-RNA pathway to intentionally silence a *C. elegans* gene of interest by using either of two general methods for generating siRNAs of defined sequence. In the first method, a double-stranded RNA corresponding to the target-gene sequence is produced by in vitro transcription of both sense and antisense copies of that sequence (Figure 6-42a). This dsRNA is then injected into the gonad of an adult worm, where it is converted to siRNA by Dicer in the developing embryos. In conjunction with the *RISC* complex, the siRNA molecules cause the corresponding mRNA molecules to be destroyed rapidly. The resulting worms display a phenotype similar to the one that would result from disruption of the target gene itself. In some cases, insertion of just a few molecules of a particular dsRNA into a cell is sufficient to inactivate many copies of the corresponding mRNA. Figure 6-42b illustrates the ability of an

**EXPERIMENTAL FIGURE 6-42 RNA interference (RNAi) can inhibit gene function in *C. elegans* and other organisms.** (a) In vitro production of double-stranded RNA (dsRNA) for interference with a specific target gene. The coding sequence of the gene, derived from either a cDNA clone or a segment of genomic DNA, is placed in two orientations in a plasmid vector adjacent to a strong promoter. Transcription of both constructs in vitro using RNA polymerase and ribonucleoside triphosphates yields many RNA copies in both the sense orientation (identical to the mRNA sequence) and the complementary antisense orientation. Under suitable conditions, these complementary RNA molecules hybridize to form dsRNA. When the dsRNA is injected into cells, it is cleaved by Dicer into siRNAs. (b) Inhibition of *mex3* RNA expression in *C. elegans* embryos by RNAi (see the text for the mechanism). Expression of *mex3* RNA in embryos was assayed by in situ hybridization to a probe specific for this mRNA, linked to an enzyme that produces a colored (purple) product. (Left) Wild-type embryo. (Right) Embryo derived from a worm injected with double-stranded *mex3* RNA. Each four-cell-stage embryo is ~50  $\mu$ m in length. (c) In vivo production of double-stranded RNA via an engineered plasmid introduced directly into cells. The synthetic gene construct is a tandem arrangement of both sense and antisense sequences of the target gene. When it is transcribed, double-stranded small hairpin RNA (shRNA) forms. The shRNA is cleaved by Dicer to form siRNA. [Part (b) reprinted by permission from Macmillan Publishers Ltd: from, Fire, A., "Potent and specific genetic interference by double-stranded RNA in *Caenorhabditis elegans*," *Nature*, 1998, **391**(6669):806-811; permission conveyed through Copyright Clearance Center, Inc.]

injected dsRNA to interfere with the production of the corresponding endogenous mRNA in *C. elegans* embryos. In this experiment, the mRNA levels in embryos were determined by in situ hybridization, as described earlier, using a fluorescently labeled probe.

The second method is to produce a specific double-stranded RNA in vivo. An efficient way to do this is to express a synthetic gene that is designed to contain tandem segments of both sense and antisense sequences corresponding to the target gene (Figure 6-42c). When this gene is transcribed, a double-stranded RNA “hairpin” structure forms, known as *small hairpin RNA*, or *shRNA*. The shRNA will then be cleaved by Dicer to form siRNA molecules. The lentiviral expression vectors are particularly useful for introducing synthetic genes for the expression of shRNA constructs into animal cells.

Both RNAi methods lend themselves to systematic studies in which researchers inactivate each of the known genes in an organism and observe what goes wrong. For example, in initial studies with *C. elegans*, RNA interference with 16,700 genes (about 86 percent of the genome) yielded 1722 visibly abnormal phenotypes. The genes whose functional inactivation causes particular abnormal phenotypes can be grouped into sets; each member of a set presumably controls the same signals or events. The regulatory relations between the genes in a set—for example, the genes that control muscle development—can then be worked out.

RNAi-mediated gene inactivation has been successful in many organisms, including *Drosophila*, many kinds of plants, zebrafish, the frog *Xenopus*, and mice, and these organisms are now the subjects of large-scale RNAi screens. For example, lentiviral vectors have been designed to inactivate by RNAi more than 10,000 different genes expressed in cultured mammalian cells. The functions of the inactivated genes can be inferred from defects in the growth or morphology of cell clones transfected with lentiviral vectors.

## Engineered CRISPR–Cas9 Systems Allow Precise Genome Editing

A recently developed technique allows precise alterations to be made in genomic DNA sequences by a process known as *genome editing*. This method is based on a natural mechanism that evolved to protect bacterial cells against foreign DNA such as phage DNA. This mechanism, called **CRISPR** (clustered regularly interspaced short palindromic repeats), is named after the curious arrays of tandem repeated sequences found in about half of the bacterial genomes that have been sequenced. The arrays of repeated sequences are flanked by a conserved set of genes, known as *Cas* (CRISPR-associated) genes, that show similarity to genes encoding nucleases.

The breakthrough in understanding the function of CRISPR sequences came from the observation that one set of repeated sequence elements in the array often matched short segments in phage genomes. It was subsequently shown that the CRISPR element and associated *Cas* genes confer on bacterial cells the ability to cleave phage DNA at precisely the

site that corresponds to repeated sequences in the CRISPR array. The acquisition of immunity to a phage by means of CRISPR takes place in two stages. In the first stage, a phage-infected bacterium carrying a CRISPR system cleaves the phage DNA into short segments and adds those segments to the CRISPR array so that they are interspersed with highly conserved repeats. In the second stage, transcription of the CRISPR array and processing of the resulting RNA yields mature bipartite RNA molecules that carry both the conserved repeat sequences and a phage-derived spacer sequence. The repeat sequence assembles with a second RNA molecule called *tracrRNA* that provides a scaffold for binding to *Cas* proteins to form an interference complex, and the phage-derived sequence guides the complex to a specific target sequence through base pairing. Once targeted to a specific DNA sequence, nucleases in the *Cas* proteins cleave both strands of the target DNA molecule at a site adjacent to the region base-paired with the guide sequence.

Although CRISPR elements have been found only in prokaryotic organisms, researchers proposed that the guide RNA and *Cas* proteins should be able to perform their functions if expressed in eukaryotic cells. To adapt CRISPR to function in virtually any cell type, minimal systems consisting of the nuclease *Cas9* and an engineered guide RNA have been developed (Figure 6-43a). *Cas9* contains all the enzymatic activities necessary for genome editing, including two separate endonuclease activities—one for each strand of DNA. The guide RNA is composed of two regions: the first is made up of two complementary sequences that form a double-stranded hairpin structure designed to bind to *Cas9*, and the second region of about 20 nt provides the targeting activity and is designed to perfectly match a specific site in genomic DNA. When both *Cas9* and the guide RNA are expressed in a recipient cell, *Cas9* will cleave both DNA strands at the chromosomal site specified by the guide RNA sequence (Figure 6-43b,c). Transfection with expression plasmids for *Cas9* and a specific guide RNA has been shown to give rise to specific DNA cleavages in cells derived from a variety of organisms, including *Drosophila*, *C. elegans*, zebrafish, mouse, rat, and human. A particularly efficient way to modify the germ line of an organism begins with microinjecting *Cas9* mRNA and a guide RNA into a mouse zygote. The resulting double-strand break in the specific target sequence is typically repaired by a set of enzymes that ligate the free DNA ends back together in a process known as nonhomologous end joining (Figure 6-43d). Typically, a few base pairs are deleted at the site of cleavage because nucleases can remove bases from the free DNA ends before the end joining reaction is completed. If the cleavage site is within a gene coding sequence, the deletion of several bases will usually cause a frameshift mutation, thus inactivating the targeted gene.

An important refinement of this method of genome editing is the addition of a segment of DNA, typically about 100 nt long, that matches the sequences flanking the cleavage site. When homologous DNA is present, the free ends can be repaired by homologous recombination using the added

**FIGURE 6-43 Single-nucleotide mutations can be introduced into the genome using an engineered CRISPR-Cas9 system.** (a) The genome of a target cell can be modified by expression of the double-stranded DNA endonuclease Cas9 and a guide RNA. Expression of these components can be achieved by transfection with plasmids carrying genes for Cas9 and the guide RNA or by direct injection of Cas9 mRNA and guide RNA. The guide RNA is composed of two parts: a sequence that folds into a hairpin scaffold structure that binds to Cas9, and a sequence of approximately 20 nt corresponding to the targeted site in the genome. Expression of these components can be achieved by transfection with plasmids carrying genes for Cas9 and the guide RNA or by direct injection of Cas9 mRNA and guide RNA. (b) A complex of guide RNA bound to Cas9 is targeted to the genome by base pairing of the guide RNA with the complementary genomic DNA sequence. This structure allows the two distinct nuclease active sites of Cas9 to cleave both strands of the target DNA adjacent to the heteroduplex formed with the guide RNA. (c) By this mechanism, the expression of both Cas9 and a bipartite guide RNA designed to target a specific gene sequence leads to a double-strand cleavage of the target gene. (d) Cleaved DNA can be repaired via a nonhomologous end joining (NHEJ) process, which usually removes a small number of bases at the cleavage site. If the cleavage occurs in a coding sequence, NHEJ will usually inactivate gene function by producing a frameshift mutation. If a ~100-nt single-stranded DNA segment that spans the sequences flanking the cleavage site is injected along with Cas9 mRNA and the guide RNA, the cleaved DNA can be repaired by homologous recombination (homology-directed repair, HDR). By this mechanism, single base changes can be introduced into the repaired genomic DNA.

[Part (b) data from C. Anders et al., 2014, *Nature* **513**:569-573, PDB ID 4un3.]

DNA segment (see Figure 6-43d). By appropriate design of the guide RNA to specify the cleavage site, and by introduction of appropriate sequence alterations in the added homologous DNA segment, exact single-base changes in the target DNA can be produced. In a dramatic demonstration of this genome editing method, a single-base mutation in *Crygc*, a gene for gamma-crystallin, that leads to the formation of cataracts was corrected back to the wild-type form by injection of a mutant mouse zygote with Cas9 mRNA, a guide RNA that directs cleavage at the site of the mutation, and a 90-nt DNA segment spanning the cleavage site and containing the wild-type *Crygc* sequence (see the chapter-opening photo). This experiment also illustrates the remarkable selectivity of CRISPR-Cas9 targeting, since correction of the mutant allele requires that the guide RNA discriminate between the mutant and wild-type alleles, which differ by only one base pair.

In Section 6.4, we saw that human genetic mapping and association studies have identified a large number of genetic variants, many representing single-nucleotide polymorphisms that predispose people to one or another inherited diseases. The ability to use CRISPR-Cas9 systems to produce specific single-base changes in the mammalian germ line now opens the possibility of creating the equivalent alleles in a well-controlled experimental organism such as the mouse.

## KEY CONCEPTS OF SECTION 6.5

### Inactivating the Function of Specific Genes in Eukaryotes

- Once a gene has been cloned, important clues about its normal function in vivo can be deduced from the observed phenotypic effects of mutating the gene.
- Genes can be disrupted in yeast by inserting a selectable marker gene into one copy of a wild-type gene via homologous recombination, producing a heterozygous mutant. When such a heterozygote forms spores, two nonviable haploid spores will be produced (see Figure 6-36).
- A yeast gene can be inactivated in a controlled manner by using the *GAL1* promoter to shut off transcription of a gene when cells are transferred to glucose medium.
- In mice, modified genes can be incorporated into the germ line at their original genomic location by homologous recombination, producing knockouts (see Figures 6-38 and 6-39). Knockout mice can provide models for human genetic diseases such as cystic fibrosis.
- The *loxP*-Cre recombination system permits production of mice in which a gene is knocked out in a specific tissue.
- In the production of transgenic cells or organisms, exogenous DNA is integrated into the host genome by nonhomologous recombination (see Figure 6-40). Introduction of a dominant-negative allele in this way can functionally inactivate a gene without altering its sequence.

- In many organisms, including the roundworm *C. elegans*, double-stranded RNA triggers destruction of all the mRNA molecules with the same sequence (see Figure 6-42). This phenomenon, known as RNAi (RNA interference), provides a specific and potent means of functionally inactivating genes without altering their structure.
- A bacterial system that evolved to precisely target and cleave foreign DNA, known as CRISPR, has been adapted for use in many organisms to enable specific changes to be introduced into genomic DNA. Cleavage of chromosomal DNA at a specific site by CRISPR-Cas9 usually results in a short deletion at the cleavage site. If an appropriately designed DNA segment is provided by transfection, specific DNA changes such as point mutations can be introduced at the cleavage site (see Figure 6-43).

## Review the Concepts

1. Genetic mutations can provide insights into the mechanisms of complex cellular or developmental processes. How might your analysis of a genetic mutation be different depending on whether a particular mutation is recessive or dominant?
2. What is a temperature-sensitive mutation? Why are temperature-sensitive mutations useful for uncovering the function of a gene?
3. Describe how complementation analysis can be used to reveal whether two mutations are in the same or in different genes. Explain why complementation analysis will not work with dominant mutations.
4. Jane has isolated a mutant strain of yeast that forms red colonies instead of the normal white when grown on a plate. To determine the mutant gene, she decides to use functional complementation with a DNA library containing a lysine selection marker. In addition to the unknown gene mutation, the yeast are lacking the gene required to synthesize the amino acids leucine and lysine. What media will Jane grow her yeast on to ensure that they have acquired the library plasmids? How will she know when a library plasmid has complemented her yeast mutation?
5. Restriction enzymes and DNA ligase play essential roles in DNA cloning. How is it that a bacterium that produces a restriction enzyme does not cut its own DNA? Describe some general features of restriction sites. What are the three types of DNA ends that can be generated after cutting DNA with restriction enzymes? What reaction is catalyzed by DNA ligase?
6. Bacterial plasmids often serve as cloning vectors. Describe the essential features of a plasmid vector. What are the advantages and applications of plasmids as cloning vectors?
7. A DNA library is a collection of clones, each containing a different fragment of DNA, inserted into a cloning vector. What is the difference between a cDNA library and a genomic DNA library? Suppose you would like to clone gene X, a gene expressed only in neurons, into a vector using a library as the source of the insert. You have the following libraries at your disposal: a genomic library from skin cells, a cDNA library from skin cells, a genomic library from neurons, and a cDNA library from neurons. Which could you use, and why?
8. In 1993, Kary Mullis won the Nobel Prize in Chemistry for his invention of the PCR process. Describe the three steps in each cycle of a PCR reaction. Why was the discovery of a thermostable DNA polymerase so important for the development of PCR?
9. Southern and Northern blotting are powerful molecular biological tools based on hybridization of nucleic acids. How are these techniques the same? How do they differ? Give some specific applications for each blotting technique.
10. A number of foreign proteins have been expressed in bacterial and mammalian cells. Describe the essential features of a recombinant plasmid that are required for

expression of a foreign gene. How can the foreign protein be modified to facilitate its purification? What is the advantage of expressing a protein in mammalian cells versus bacteria?

11. Northern blotting, RT-PCR, and microarrays can be used to analyze gene expression. A lab studies yeast cells, comparing their growth in two different sugars, glucose and galactose. One student is comparing expression of the gene *HMG2* under these two conditions. Which technique(s) could he use and why? Another student wants to compare expression of all the genes on chromosome 4, of which there are approximately 800. What technique(s) could she use and why?
12. In determining the identity of the protein that corresponds to a newly discovered gene, it often helps to know the pattern of tissue expression for that gene. For example, researchers have found that a gene called *SERPINA6* is expressed in the liver, kidney, and pancreas but not in other tissues. What techniques might researchers use to find out which tissues express a particular gene?
13. DNA polymorphisms can be used as DNA markers. Describe the differences between SNPs and STR polymorphisms. How can these markers be used for DNA-mapping studies?
14. How can linkage-disequilibrium mapping sometimes provide a much higher resolution of gene location than classical linkage mapping?
15. Genetic linkage studies can usually locate the chromosomal position of a disease gene only roughly. How can expression analysis and DNA sequence analysis help locate a disease gene within the region identified by linkage mapping?
16. The ability to selectively modify the genome in the mouse has revolutionized mouse genetics. Outline the procedure for generating a knockout mouse at a specific genetic locus. How can the *loxP*-Cre system be used to conditionally knock out a gene? What is an important medical application of knockout mice?
17. Two methods for functionally inactivating a gene without altering the gene sequence involve dominant-negative alleles and RNA interference (RNAi). Describe how each method can inhibit expression of a gene.

Molecular model of a lipid bilayer with embedded membrane proteins. Integral membrane proteins have distinct exoplasmic, cytosolic, and membrane-spanning domains. Shown here are portions of the insulin receptor, which regulates cell metabolism. [Ramon Andrade 3Dcienia/Science Photo Library/Science Source.]

**Membranes participate** in many aspects of cell structure and function. The **plasma membrane** defines the cell and separates the inside from the outside. In eukaryotes, membranes also define intracellular organelles such as the nucleus, mitochondrion, and lysosome. These biomembranes all have the same basic architecture: a phospholipid bilayer in which proteins are embedded (Figure 7-1). By preventing the unassisted movement of most water-soluble substances across the membrane, the phospholipid bilayer serves as a permeability barrier, helping to maintain the characteristic differences between the inside and the outside of the cell or organelle; in turn, the embedded proteins endow the membrane with specific functions, such as regulated transport of substances from one side to the other. Each cellular membrane has its own set of proteins that allow it to carry out many different functions.

Prokaryotes, the simplest and smallest cells, are about 1–2  $\mu\text{m}$  in length and are surrounded by a single plasma membrane; in most cases, they contain no internal membrane-limited subcompartments (see Figure 1-11). However, this single plasma membrane contains hundreds of different types of proteins that are integral to the function of the cell.

# Biomembrane Structure

Some of these proteins catalyze ATP synthesis and initiation of DNA replication, for instance. Others include the many types of **membrane transport proteins** that enable specific ions, sugars, amino acids, and vitamins to cross the otherwise impermeable phospholipid bilayer to enter the cell and that allow specific metabolic products to exit. **Receptor proteins** in the plasma membrane are proteins that allow the cell to recognize chemical signals present in its environment and adjust its metabolism or pattern of gene expression in response.

Eukaryotes also have a plasma membrane studded with many different proteins that perform a variety of functions, including membrane transport, cell signaling, and connecting cells into tissues. In addition, eukaryotic cells—which are generally much larger than prokaryotes—have a variety of internal membrane-bounded organelles (see Figure 1-12). Each type of organelle membrane has a unique complement of proteins that enable it to carry out its characteristic cellular functions, such as ATP generation (in mitochondria) and DNA synthesis (in the nucleus). Many plasma-membrane proteins also bind components of the **cytoskeleton**, a dense network of protein filaments that crisscrosses the cytosol to

## OUTLINE

**7.1** The Lipid Bilayer: Composition and Structural Organization

**7.2** Membrane Proteins: Structure and Basic Functions

**7.3** Phospholipids, Sphingolipids, and Cholesterol: Synthesis and Intracellular Movement

**FIGURE 7-1 Fluid mosaic model of biomembranes.** A bilayer of phospholipids about 3 nm thick provides the basic architecture of all cellular membranes; membrane proteins give each cellular membrane its unique set of functions. Individual phospholipids can move laterally and spin within the plane of the membrane, giving the membrane a fluidlike consistency similar to that of olive oil. Noncovalent interactions between phospholipids, and between phospholipids and proteins, lend strength and resilience to the membrane, while the hydrophobic core of the bilayer prevents the

unassisted movement of water-soluble substances from one side to the other. Integral membrane proteins (transmembrane proteins) span the bilayer and often form dimers and higher-order oligomers. Lipid-anchored proteins are tethered to one leaflet by a covalently attached hydrocarbon chain. Peripheral proteins associate with the membrane primarily by specific noncovalent interactions with integral membrane proteins or membrane lipids. Proteins in the plasma membrane also make extensive contact with the cytoskeleton. See D. Engelman, 2005, *Nature* **438**:578–580.

provide mechanical support for cellular membranes. These interactions are essential for the cell to assume its specific shape and for many types of cell movements.

Despite playing a structural role in cells, membranes are not rigid structures. They can bend and flex in three dimensions while still maintaining their integrity, in part because of the abundant noncovalent interactions that hold the lipids and proteins together. Moreover, there is considerable mobility of individual lipids and proteins within the plane of the membrane. According to the *fluid mosaic model* of biomembranes, first proposed by researchers in the 1970s, the phospholipid bilayer behaves in some respects like a two-dimensional fluid, with individual lipid molecules able to move past one another as well as spin in place. Such fluidity and flexibility not only allows organelles to assume their typical shapes, but also confers on the membrane the dynamic property that enables membrane budding and fusion, as occurs when viruses are released from an infected cell (Figure 7-2a) or when the internal cellular membranes of the

**FIGURE 7-2 Eukaryotic cellular membranes are dynamic structures.** (a) An electron micrograph of the plasma membrane of an HIV-infected cell, showing HIV particles budding into the culture medium. As the virus core buds from the cell, it becomes enveloped by a membrane, derived from the cell's plasma membrane, that contains specific viral proteins. (b) Stacked membranes of the Golgi complex with budding vesicles. Note the irregular shape and curvature of these membranes. [Part (a) from W. Sundquist and U. von Schwedler, University of Utah; part (b) Biology Pics/Science Source.]

Golgi complex bud into vesicles in the cytosol (Figure 7-2b) and then fuse with other membranes to transport their contents from one organelle to another (see Chapter 14).

We begin our examination of biomembranes by considering their lipid components. These molecules not only affect membrane shape and function, but also help anchor proteins to the membrane, modify membrane protein activities, and transduce signals to the cytoplasm. We then consider the structure of membrane proteins. Many of these proteins have large segments that are embedded in the hydrocarbon core of the phospholipid bilayer, and we focus on the principal classes of such transmembrane proteins. Finally, we consider how lipids such as phospholipids and cholesterol are synthesized in cells and distributed to their many membranes and organelles.

## 7.1 The Lipid Bilayer: Composition and Structural Organization

In Chapter 2, we learned that phospholipids are the principal building blocks of biomembranes. The most common phospholipids in membranes are the phosphoglycerides (see Figure 2-20), but as we will see in this chapter, there are multiple types of phospholipids. All phospholipids are **amphipathic** molecules that consist of two segments with very different chemical properties: a fatty acid-based (fatty acyl) hydrocarbon “tail” that is **hydrophobic** (“water fearing”) and partitions away from water, and a polar “head group” that is strongly **hydrophilic** (“water loving”) and tends to interact with water molecules. The interactions of phospholipids with one another and with water largely determine the structure of biomembranes.

Besides phospholipids, biomembranes contain smaller amounts of other amphipathic lipids, such as glycolipids and cholesterol, which contribute to membrane function in important ways. We first consider the structure and properties of pure phospholipid bilayers and then discuss the composition and behavior of natural cellular membranes. Then we consider how the precise lipid composition of a given membrane influences its physical properties.

**FIGURE 7-3 The bilayer structure of biomembranes.** (a) Electron micrograph of a thin section through an erythrocyte membrane stained with osmium tetroxide. The characteristic “railroad track” appearance of the membrane indicates the presence of two polar layers, consistent with the bilayer structure of phospholipid membranes. (b) Schematic interpretation of the phospholipid bilayer, in which polar groups face outward to shield the hydrophobic fatty acyl tails from water. The hydrophobic effect and van der Waals interactions between the fatty acyl tails drive the assembly of the bilayer (see Chapter 2). (c) Cross-sectional views of two other structures formed by dispersal of phospholipids in water. A spherical micelle has a hydrophobic interior composed entirely of fatty acyl chains; a spherical liposome consists of a phospholipid bilayer surrounding an aqueous center. (d) Under certain circumstances, lipids can assume yet other forms of organization. Shown here is the cubic phase of lipids, a highly regular recurring structure that has helped the formation of crystals of membrane proteins that were otherwise difficult to crystallize. [Part (a) Warren Rosenberg/Fundamental Photographs.]

## Phospholipids Spontaneously Form Bilayers

The amphipathic nature of phospholipids, which governs their interactions, is critical to the structure of biomembranes. When a suspension of phospholipids is mechanically dispersed in an aqueous solution, the phospholipids aggregate into one of three structures: spherical **micelles** or **liposomes** or sheet-like **phospholipid bilayers** that are two molecules thick (Figure 7-3). The type of structure formed

by pure phospholipids or a mixture of phospholipids in the absence of added proteins depends on several factors, including the length of the fatty acyl chains in the hydrophobic tails, their degree of saturation (i.e., the number of C—C and C=C bonds), and temperature. In all three structures, the hydrophobic effect (see Chapter 2) causes the fatty acyl chains to aggregate and exclude water molecules from the “core” of the structure. Micelles are rarely formed from natural phospholipids, whose fatty acyl chains are generally too bulky to fit into the interior of a micelle. Micelles are formed, however, if one of the two fatty acyl chains that make up the tail of a phospholipid is removed by hydrolysis to form a lysophospholipid, as occurs upon treatment with the enzyme phospholipase. In aqueous solutions, common detergents and soaps form micelles that behave like the balls in tiny ball bearings, thus giving soap solutions their slippery feel and lubricating properties.

Phospholipid mixtures of the composition present in cells spontaneously form a symmetric phospholipid bilayer. Each phospholipid layer in this lamellar structure is called a *leaflet*. The hydrophobic fatty acyl chains in each leaflet minimize their contact with water by aligning themselves tightly together in the center of the bilayer, forming a hydrophobic core that is about 3–4 nm thick (see Figure 7-3b). The close packing of these nonpolar tails is stabilized by van der Waals interactions between the hydrocarbon chains. Ionic and hydrogen bonds stabilize the interactions of the polar head groups with one another and with water. Electron microscopy of thin sections of cells stained with osmium tetroxide, which binds strongly to the polar head groups of phospholipids, shows the bilayer structure (see Figure 7-3a). A cross section of a single membrane stained with osmium tetroxide looks like a railroad track: two thin dark lines (the stained head group complexes) with a uniform light space of about 2 nm between them (the hydrophobic tails).

A phospholipid bilayer can be of almost unlimited size—from micrometers ( $\mu\text{m}$ ) to millimeters (mm) in length or width—and can contain tens of millions of phospholipid molecules. The phospholipid bilayer is the basic structural unit of nearly all biological membranes. Its hydrophobic core prevents most water-soluble substances from crossing from one side of the membrane to the other. Although biomembranes contain other molecules (e.g., cholesterol, glycolipids, proteins), it is the phospholipid bilayer that separates two

aqueous solutions and acts as a permeability barrier. The lipid bilayer thus defines cellular compartments and allows a separation of the cell’s interior from the outside world.

The three structures mentioned above are not the only forms that lipids can assume in an aqueous environment. Unusual configurations of lipids have been instrumental in enforcing order on otherwise difficult-to-crystallize membrane proteins, including G protein–coupled receptors, enabling crystallographic analysis of membrane proteins in a true lipid environment (Figure 7-3d).

## Phospholipid Bilayers Form a Sealed Compartment Surrounding an Internal Aqueous Space

Phospholipid bilayers can be generated in the laboratory by simple means, using either chemically pure phospholipids or lipid mixtures of the composition found in cellular membranes (Figure 7-4). Such synthetic bilayers possess three important properties. First, they are virtually impermeable

**EXPERIMENTAL FIGURE 7-4 Formation and study of pure phospholipid bilayers.** (Top) A preparation of biological membranes is treated with an organic solvent, such as a mixture of chloroform and methanol (3:1), which selectively solubilizes the phospholipids and cholesterol. Proteins and carbohydrates remain in an insoluble residue. The solvent is removed by evaporation. (Bottom left) If the extracted materials are mechanically dispersed in water, they spontaneously form a liposome, shown in cross section, with an internal aqueous compartment. (Bottom right) A planar bilayer, also shown in cross section, can form over a small hole in a partition separating two aqueous phases; such a system can be used to study the physical properties of bilayers, such as their permeability to solutes.

**FIGURE 7-5 The faces of cellular membranes.** The plasma membrane, a single bilayer, encloses the cell. In this highly schematic representation, internal cytosol (tan) and external environment (white) define the cytosolic (red) and exoplasmic (gray) faces of the bilayer. Vesicles and some organelles have a single membrane, and their internal aqueous space (white) is topologically equivalent to the outside of the cell. Three organelles—the nucleus, mitochondrion, and chloroplast (which is not shown)—are enclosed by two membranes separated by a small intermembrane space. The exoplasmic faces of the inner and outer membranes around these organelles border the intermembrane space between them. For simplicity, the hydrophobic membrane interior is not indicated in this diagram.

to water-soluble (hydrophilic) solutes, which do not readily diffuse across the bilayer. These solutes include salts, sugars, and most other small hydrophilic molecules—including water itself. The second property of a bilayer is its stability. The hydrophobic and van der Waals interactions between the fatty acyl chains maintain the integrity of the interior of the bilayer structure. Even though the exterior aqueous environment may vary widely in ionic strength and pH, the bilayer has the strength to retain its characteristic architecture. Third, all synthetic phospholipid bilayers can spontaneously form sealed closed compartments in which the aqueous space on the inside is separated from the exterior environment. An “edge” of a phospholipid bilayer, as depicted in Figure 7-3b, with the hydrocarbon core of the bilayer exposed to an aqueous solution, would be unstable; the exposed fatty acyl chains would be in an energetically much more stable state if they were not adjacent to water molecules but rather surrounded by other fatty acyl chains. Thus, in an aqueous solution, sheets of phospholipid bilayers spontaneously seal their edges, forming a spherical bilayer that encloses an aqueous central compartment. The liposome depicted in Figure 7-3c is an example of such a structure viewed in cross section.

This physical chemical property of a phospholipid bilayer has important implications for cellular membranes: no membrane in a cell can have an “edge” with exposed hydrocarbon fatty acyl chains. All membranes form closed compartments, similar in basic architecture to liposomes. Because all cellular membranes enclose an entire cell or an internal compartment, they have an *internal face* (the surface

oriented toward the interior of the compartment) and an *external face* (the surface presented to the environment). More commonly, we designate the two surfaces of a cellular membrane as the **cytosolic face** and the **exoplasmic face**. This nomenclature is useful in highlighting the topological equivalence of the faces in different membranes, as diagrammed in Figures 7-5 and 7-6. For example, the exoplasmic face of the plasma membrane is directed away from the cytosol, toward the extracellular space or external environment, and defines the outer limit of the cell. The cytosolic face of the plasma membrane faces the cytosol. Similarly for organelles and vesicles surrounded by a single membrane, the cytosolic face faces the cytosol. The exoplasmic face is always directed away from the cytosol, and in this case it is on the inside of the organelle, in contact with the internal aqueous space, or *lumen*. The lumen of a vesicle is topologically equivalent to the extracellular space, a concept most easily understood for vesicles that arise by invagination (endocytosis) of the plasma membrane. The external face of the plasma membrane becomes the internal face of the vesicle membrane, while in the vesicle the cytosolic face of the plasma membrane still faces the cytosol (see Figure 7-6).

Three organelles—the nucleus, mitochondrion, and chloroplast—are surrounded not by a single membrane, but by two. The exoplasmic surface of each membrane faces the space between the two membranes (the intermembrane space). This relationship can perhaps best be understood by reference to the *endosymbiont hypothesis*, discussed in Chapter 12, which posits that mitochondria and chloroplasts arose early in the evolution of eukaryotic cells by the

**FIGURE 7-6 The faces of cellular membranes are conserved during membrane budding and fusion.** Red membrane surfaces are cytosolic faces; gray membrane surfaces are exoplasmic faces. During endocytosis, a segment of the plasma membrane buds inward toward the cytosol and eventually pinches off a separate vesicle. During this process, the cytosolic face of the plasma membrane remains facing the cytosol, and the exoplasmic face of the new vesicle membrane faces the vesicle lumen. During exocytosis, an intracellular vesicle fuses with the plasma membrane, and the lumen of the vesicle (exoplasmic face) connects with the extracellular medium. Proteins that span the membrane retain their asymmetric orientation during vesicle budding and fusion; in particular, the same segment always faces the cytosol.

engulfment of bacteria capable of oxidative phosphorylation or photosynthesis, respectively (see Figure 12-7).

Natural membranes from different cell types exhibit a variety of shapes, which complement a cell's function. The smooth, flexible surface of the erythrocyte plasma membrane allows the cell to squeeze through narrow blood capillaries (Figure 7-7a). Some cells have a long, slender extension of the plasma membrane, called a **cilium** or **flagellum**, which beats in a whiplike manner (Figure 7-7b). This motion causes fluid to flow across the surface of a sheet of cells, or a sperm cell to swim toward an egg. The differing shapes and properties of biomembranes raise a key question in cell biology, namely, how the composition of biological membranes is regulated to establish and maintain the identity of the different membrane structures and membrane-delimited compartments. We return to this question in Section 7.3 and in Chapter 14.

## Biomembranes Contain Three Principal Classes of Lipids

The term *phospholipid* is a somewhat generic term. It refers to any amphipathic lipid with a phosphate-based head group and a two-chain hydrophobic tail. A typical biomembrane is not composed of phospholipids alone, but actually contains three classes of amphipathic lipids: phosphoglycerides, sphingolipids, and sterols, which differ in their chemical structures, abundance, and functions in the membrane

**FIGURE 7-7 Variation in biomembranes in different cell types.** (a) A smooth, flexible membrane covers the surface of the discoid erythrocyte cell, as seen in this scanning electron micrograph. (b) Tufts of cilia project from the ependymal cells that line the brain ventricles. [Part (a) Omikron/Science Source. Part (b) iophoto Associates/Science Source.]

(Figure 7-8). While all phosphoglycerides are phospholipids, only certain sphingolipids are, and no sterols are.

**Phosphoglycerides**, the most abundant class of phospholipids in most membranes, are derivatives of glycerol 3-phosphate (see Figure 7-8a). A typical phosphoglyceride molecule consists of a hydrophobic tail composed of two fatty acid-based (acyl) chains esterified to the two hydroxyl groups in glycerol phosphate and a polar head group attached to the phosphate group. The structure comprising the glycerol moiety and the two fatty acyl chains is referred to as a diacylglycerol. The two fatty acyl chains may differ in the number of carbons that they contain (commonly 16 or 18) and their degree of saturation (0, 1, or 2 double bonds). A phosphoglyceride is classified according to the nature of its head group. In phosphatidylcholines, the most abundant phospholipids in the plasma membrane, the head group consists of choline, a positively charged alcohol,

**FIGURE 7-8 Three classes of membrane lipids.** (a) Most phosphoglycerides are derivatives of glycerol 3-phosphate (red), which contains two esterified fatty acyl chains that constitute the hydrophobic “tail” and a polar “head group” esterified to the phosphate. The fatty acids can vary in length and be saturated (no double bonds) or unsaturated (one, two, or three double bonds). In phosphatidylcholine (PC), the head group is choline. Also shown are the molecules attached to the phosphate group in three other common phosphoglycerides: phosphatidylethanolamine (PE), phosphatidylserine (PS), and phosphatidylinositol (PI). Plasmalogens contain one fatty acyl chain attached to glycerol by an ester linkage and one attached by an ether linkage; they contain the same head groups as other phosphoglycerides. (b) Sphingolipids are derivatives of sphingosine (red), an amino alcohol with a long hydrocarbon

chain. Various fatty acyl chains are connected to sphingosine by an amide bond. The sphingomyelins (SM), which contain a phosphocholine head group, are phospholipids. Other sphingolipids are glycolipids in which a single sugar residue or branched oligosaccharide is attached to the sphingosine backbone. For instance, the simple glycolipid glucosylcerebroside (GlcCer) has a glucose head group. (c) The major sterols in animals (cholesterol), fungi (ergosterol), and plants (stigmasterol) differ slightly in structure, but all serve as key components of cellular membranes. The basic structure of sterols is a four-ring hydrocarbon (yellow). Like other membrane lipids, sterols are amphipathic. The single hydroxyl group is equivalent to the polar head group in other lipids; the conjugated ring and short hydrocarbon chain form the hydrophobic tail. See H. Sprong et al., 2001, *Nature Rev. Mol. Cell Biol.* **2**:504.

esterified to the negatively charged phosphate. In other phosphoglycerides, an OH-containing molecule such as ethanolamine, serine, or the sugar derivative inositol is linked to the phosphate group. In the case of the inositol head group, the hydroxyl groups may be further modified with phosphates, yielding a class of phospholipids called phosphoinositides. The phosphoinositides fulfill an important function in signal transduction. The negatively charged phosphate group and the positively charged groups or hydroxyl groups on the head group interact strongly with water. At neutral pH, some phosphoglycerides (e.g., phosphatidylcholine and phosphatidylethanolamine) carry no net electric charge, whereas others (e.g., phosphatidylinositol and phosphatidylserine) carry a single net negative charge. Nonetheless, the polar head groups in all these phospholipids can pack together into the characteristic bilayer structure. When phospholipases act on phosphoglycerides, they produce lysophospholipids, which lack one of the two acyl chains. Lysophospholipids are not only important signaling molecules, released from cells and recognized by specific receptors; their presence can also affect the physical properties of the membranes in which they reside.

The *plasmalogens* are a group of phosphoglycerides that contain one fatty acyl chain attached to carbon 2 of glycerol by an ester linkage and one long hydrocarbon chain attached to carbon 1 of glycerol by an ether (C—O—C) rather than an ester linkage. Plasmalogens are particularly abundant in human brain and heart tissue. The greater chemical stability of the ether linkage in plasmalogens compared with the ester linkage, and the subtle differences in three-dimensional structure between plasmalogens and other phosphoglycerides, may have as yet unrecognized physiological significance.

A second class of membrane lipids is the **sphingolipids**. All these compounds are derived from sphingosine, an amino alcohol with a long hydrocarbon chain, and contain a long-chain fatty acid attached in amide linkage to the sphingosine amino group (see Figure 7-8b). Like phosphoglycerides, some sphingolipids have a phosphate-based polar head group. In sphingomyelin, the most abundant sphingolipid, phosphocholine is attached to the terminal hydroxyl group of sphingosine (see Figure 7-8b, SM). Thus sphingomyelin is a phospholipid, and its overall structure is quite similar to that of phosphatidylcholine. Sphingomyelins are similar in shape to phosphoglycerides and can form mixed bilayers with them. Other sphingolipids are amphipathic **glycolipids** whose polar head groups are sugars that are not linked to the tails via a phosphate group (so they are technically not phospholipids). Glucosylcerebroside, the simplest glycosphingolipid, contains a single glucose unit attached to sphingosine. In the complex glycosphingolipids called *gangliosides*, one or two branched sugar chains (oligosaccharides) containing sialic acid groups are attached to sphingosine. Glycolipids constitute 2–10 percent of the total lipid content of plasma membranes; they are most abundant in nervous tissue.

**Cholesterol** and its analogs constitute the third important class of membrane lipids, the *sterols*. The basic structure of sterols is a four-ring isoprenoid-based hydrocarbon. The structures of the principal yeast sterol (ergosterol) and

plant phytosterols (e.g., stigmasterol) differ slightly from that of cholesterol, the major animal sterol (see Figure 7-8c). The small differences in the biosynthetic pathways and structures of fungal and animal sterols are the basis of most antifungal drugs currently in use. Cholesterol, like the two other sterols, has a hydroxyl substituent on one ring. Although cholesterol is almost entirely hydrocarbon in composition, it is amphipathic because its hydroxyl group can interact with water. Because it lacks a phosphate-based head group, it is not a phospholipid. Cholesterol is especially abundant in the plasma membranes of mammalian cells but is absent from most prokaryotic and all plant cells. As much as 30–50 percent of the lipids in plant plasma membranes consist of certain steroids unique to plants. Between 50 and 90 percent of the cholesterol in most mammalian cells is present in the plasma membrane and associated vesicles. Cholesterol and other sterols are too hydrophobic to form a bilayer structure on their own. Instead, at the concentrations found in natural membranes, these sterols must intercalate between phospholipid molecules to be incorporated into biomembranes. When so intercalated, sterols provide structural support to membranes, preventing too close a packing of the phospholipids' acyl chains to maintain a significant measure of membrane fluidity, and at the same time conferring the necessary rigidity required for mechanical support. Some of these effects can be highly local, as in the case of lipid rafts, discussed below.

In addition to its structural role in membranes, cholesterol is the precursor for several important bioactive molecules. They include *bile acids*, which are made in the liver and help emulsify dietary fats for digestion and absorption in the intestines; steroid hormones produced by endocrine cells (e.g., adrenal gland, ovary, testes); and vitamin D produced in the skin and kidneys. Another critical function of cholesterol is its covalent addition to Hedgehog protein, a key signaling molecule in embryonic development (see Chapter 16).

## Most Lipids and Many Proteins Are Laterally Mobile in Biomembranes

In the two-dimensional plane of a bilayer, thermal motion permits lipid molecules to rotate freely around their long axes and to diffuse laterally within each leaflet. Because such movements are lateral or rotational, the fatty acyl chains remain in the hydrophobic interior of the bilayer. In both natural and artificial membranes, a typical lipid molecule exchanges places with its neighbors in a leaflet about  $10^7$  times per second and diffuses several micrometers per second at 37 °C. These diffusion rates indicate that the bilayer is 100 times more viscous than water—about the same as the viscosity of olive oil. Even though lipids diffuse more slowly in the bilayer than in an aqueous solvent, a membrane lipid could diffuse the length of a typical bacterial cell (1  $\mu\text{m}$ ) in only 1 second and the length of an animal cell in about 20 seconds. When artificial pure phospholipid membranes are cooled below 37 °C, the lipids can undergo a *phase transition* from a liquid-like (fluid) state to a gel-like (semisolid) state, analogous to the liquid-solid transition when liquid water freezes (Figure 7-9). Below the

**FIGURE 7-9 Gel-like and fluidlike forms of the phospholipid bilayer.** (Top) Depiction of gel-to-fluid transition. Phospholipids with long saturated fatty acyl chains tend to assemble into a highly ordered, gel-like bilayer in which there is little overlap of the nonpolar tails in the two leaflets. Heat disorders the nonpolar tails and induces a transition from a gel to a fluid within a temperature range of only a few degrees. As the chains become disordered, the bilayer also decreases in thickness. (Bottom) Molecular models of phospholipid monolayers in gel-like and fluidlike states, as determined by molecular dynamics calculations. [Data from H. Heller et al., 1993, *J. Phys. Chem.* **97**:8343.]

phase-transition temperature, the rate of diffusion of the lipids drops precipitously. At usual physiological temperatures, the hydrophobic interior of natural membranes generally has a low viscosity and a fluidlike consistency, in contrast to the gel-like consistency observed at lower temperatures.

In pure lipid bilayers (i.e., in the absence of protein), phospholipids and sphingolipids rotate and move laterally, but they do not spontaneously migrate, or flip-flop, from one leaflet to the other. The energetic barrier is too high; migration would require moving the polar head group from its aqueous environment through the hydrocarbon core of the bilayer to the aqueous solution on the other side. Special membrane proteins discussed in Chapter 11 are required to flip membrane lipids and other polar molecules from one leaflet to the other.

The lateral movements of specific plasma-membrane proteins and lipids can be quantified by a technique called *fluorescence recovery after photobleaching (FRAP)*. Phospholipids containing a fluorescent substituent are used to monitor lipid movement. For proteins, a fragment of a monoclonal antibody that is specific for the exoplasmic domain of the desired protein and that has only a single antigen-binding site is tagged with a fluorescent dye. With this method, described in Figure 7-10, the rate at which membrane molecules move—the diffusion coefficient—can be determined, as well as the proportion of the molecules that are laterally mobile.

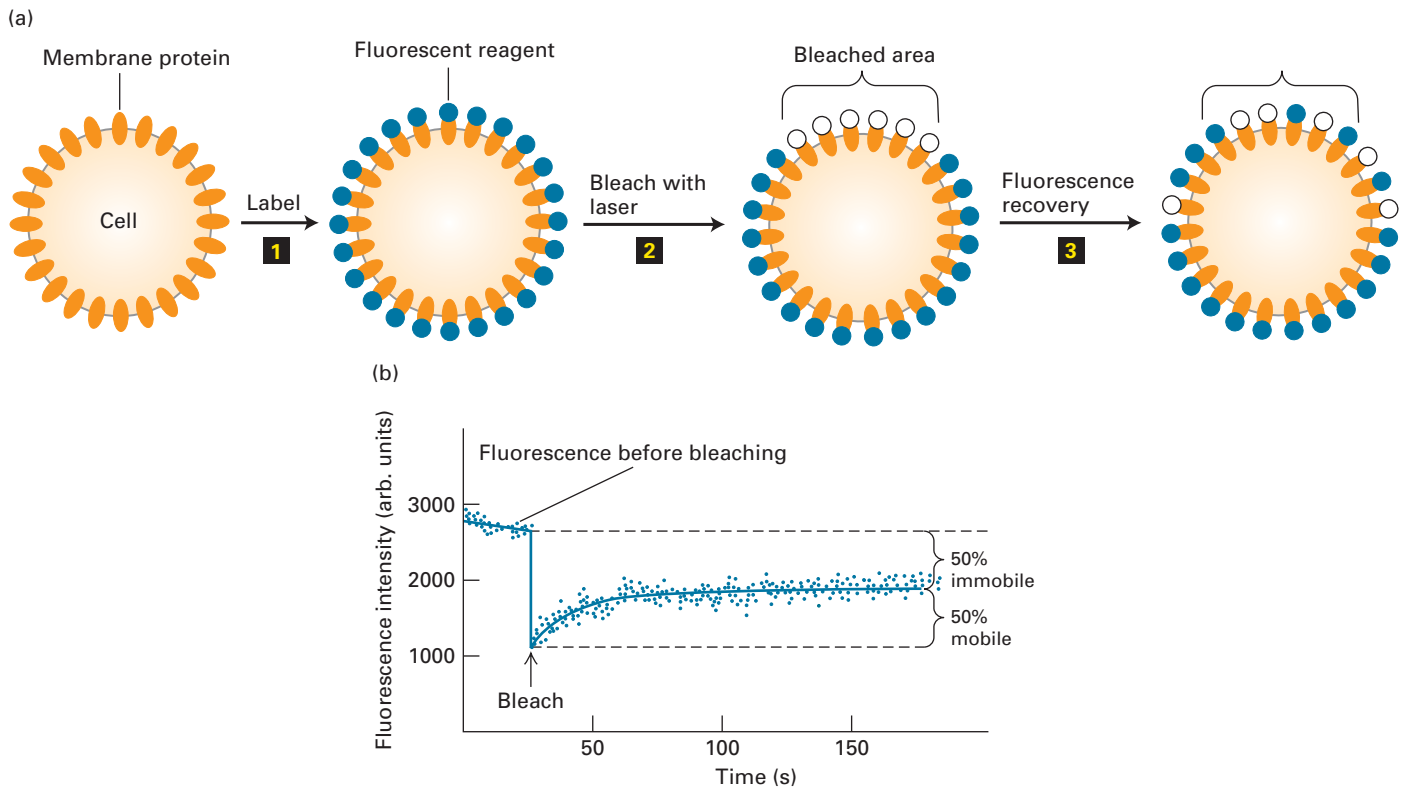

The results of FRAP studies with fluorescence-labeled phospholipids have shown that in fibroblast plasma membranes, all the phospholipids are freely mobile over distances

of about 0.5  $\mu\text{m}$ , but most cannot diffuse over much longer distances. These findings suggest that protein-rich regions of the plasma membrane about 1  $\mu\text{m}$  in diameter separate lipid-rich regions containing the bulk of the membrane phospholipids. Phospholipids are free to diffuse within such regions, but not from one lipid-rich region to an adjacent one. Furthermore, the rate of lateral diffusion of lipids in the plasma membrane is nearly an order of magnitude slower than in pure phospholipid bilayers: diffusion constants of  $10^{-8} \text{ cm}^2$  per second and  $10^{-7} \text{ cm}^2$  per second are characteristic of the plasma membrane and a pure phospholipid bilayer, respectively. This difference suggests that lipids may be tightly but not irreversibly bound to certain integral proteins in some membranes, as indeed has recently been demonstrated (see the discussion of annular phospholipids below).

## Lipid Composition Influences the Physical Properties of Membranes

A typical cell contains many different types of membranes, each with unique properties derived from its particular mix of lipids and proteins. The data in Table 7-1 illustrate the variation in lipid composition in different biomembranes. Several phenomena contribute to these differences. For instance, the relative abundances of phosphoglycerides and sphingolipids differ between membranes in the endoplasmic reticulum (ER), where phospholipids are synthesized, and the Golgi complex, where sphingolipids are synthesized. The proportion of sphingomyelin as a percentage of total membrane lipid phosphorus is about six times as high in Golgi membranes as it is in ER membranes. In other cases, the movement of membranes from one cellular compartment to another can selectively enrich certain membranes in lipids such as cholesterol. In responding to differing environments throughout an organism, different types of cells generate membranes with differing lipid compositions. In the cells that line the intestinal tract, for example, the membranes that face the harsh environment in which dietary nutrients are digested have a sphingolipid-to-phosphoglyceride-to-cholesterol ratio of 1:1:1, rather than the 0.5:1.5:1 ratio found in cells subject to less stress. The relatively high concentration of sphingolipids in these intestinal membranes may increase their stability because of extensive hydrogen bonding by the free  $-\text{OH}$  group in the sphingosine moiety (see Figure 7-8).

The degree of bilayer fluidity depends on lipid composition, the structure of the phospholipid hydrophobic tails, and temperature. As already noted, van der Waals interactions and the hydrophobic effect cause the nonpolar tails of phospholipids to aggregate. Long, saturated fatty acyl chains have the greatest tendency to aggregate, packing tightly together into a gel-like state. Phospholipids with short fatty acyl chains, which have less surface area and therefore fewer van der Waals interactions, form more fluid bilayers. Likewise, the kinks in *cis*-unsaturated fatty acyl chains (see Chapter 2) result in their forming less stable van der Waals interactions with other lipids, and hence more fluid bilayers,

**EXPERIMENTAL FIGURE 7-10 Fluorescence recovery after photobleaching (FRAP) experiments can quantify the lateral movement of proteins and lipids within the plasma membrane.**

(a) Experimental protocol. Step **1**: Cells are first labeled with a fluorescent reagent that binds uniformly to a specific membrane lipid or protein. Step **2**: A laser light is then focused on a small area of the cell surface, irreversibly bleaching the bound reagent and thus reducing the fluorescence in the illuminated area. Step **3**: In time, the fluorescence of the bleached patch increases as unbleached fluorescent surface molecules diffuse into it and bleached ones diffuse outward. The extent of recovery of fluorescence in the bleached

patch is proportional to the fraction of labeled molecules that are mobile in the membrane. (b) Results of a FRAP experiment with human hepatoma cells treated with a fluorescent antibody specific for the asialoglycoprotein receptor protein. The finding that 50 percent of the fluorescence returned to the bleached area indicates that 50 percent of the receptor molecules in the illuminated membrane patch were mobile and 50 percent were immobile. Because the rate of fluorescence recovery is proportional to the rate at which labeled molecules move into the bleached region, the diffusion coefficient of a protein or lipid in the membrane can be calculated from such data. See Y. I. Henis et al., 1990, *J. Cell Biol.* **111**:1409.

than do straight saturated chains, which can pack more tightly together.

Cholesterol is important in maintaining the appropriate fluidity of natural membranes, a property that appears to be essential for normal cell growth and reproduction. Cholesterol restricts the random movement of phospholipid head groups at the outer surfaces of the leaflets, but its effect on the movement of long phospholipid tails depends on its concentration. At the cholesterol concentrations normally present in the plasma membrane, the interaction of the steroid ring with the long hydrophobic tails of phospholipids tends to immobilize those lipids and thus decreases biomembrane fluidity. It is this property that can help organize the plasma membrane into discrete subdomains of unique lipid and protein composition. At lower cholesterol concentrations, however, the steroid ring separates and disperses phospholipid tails, causing the inner regions of the membrane to become slightly more fluid.

The lipid composition of a bilayer also influences its thickness, which in turn may influence the distribution of

other membrane components, such as proteins, in a particular membrane. It has been argued that relatively short transmembrane segments of certain Golgi-resident enzymes (glycosyltransferases) are an adaptation to the lipid composition of the Golgi membrane and contribute to the retention of these enzymes in the Golgi apparatus. The results of biophysical studies on artificial membranes demonstrate that sphingomyelin associates into a more gel-like and thicker bilayer than phosphoglycerides do (Figure 7-11a). Cholesterol and other molecules that decrease membrane fluidity also increase membrane bilayer thickness. Because sphingomyelin tails are already optimally stabilized, the addition of cholesterol has no effect on the thickness of a sphingomyelin bilayer.

Another property dependent on the lipid composition of a bilayer is its curvature, which depends on the relative sizes of the polar head groups and nonpolar tails of its constituent phospholipids. Lipids with long tails and large head groups are cylindrical in shape; those with small head groups are cone-shaped (Figure 7-11b). As a result, bilayers composed

of cylindrical lipids are relatively flat, whereas those containing large numbers of cone-shaped lipids form curved bilayers (Figure 7-11c). This effect of lipid composition on bilayer curvature may play a role in the formation of highly curved membranes, such as sites of viral budding (see Figure 7-2)

and of formation of internal vesicles from the plasma membrane (see Figure 7-6), and in specialized stable membrane structures such as microvilli. Several proteins bind to the surface of a phospholipid bilayer and cause the membrane to curve; such proteins are important in formation of transport vesicles that bud from a donor membrane (see Chapter 14).

### Lipid Composition Is Different in the Exoplasmic and Cytosolic Leaflets

A characteristic of all biomembranes is an asymmetry in lipid composition across the bilayer. Although most phospholipids are present in both membrane leaflets, some are commonly more abundant in one or the other leaflet. For instance, in plasma membranes from human erythrocytes and Madin-Darby canine kidney (MDCK) cells grown in culture, almost all the sphingomyelin and phosphatidylcholine, both of which form less fluid bilayers, are found in the exoplasmic leaflet. In contrast, phosphatidylethanolamine, phosphatidylserine,

**FIGURE 7-11 Effect of lipid composition on bilayer thickness and curvature.** (a) A pure sphingomyelin (SM) bilayer is thicker than one formed from a phosphoglyceride such as phosphatidylcholine (PC). Cholesterol has a lipid-ordering effect on phosphoglyceride bilayers that increases their thickness, but it does not affect the thickness of the more ordered SM bilayer. (b) Phospholipids such as PC have a cylindrical shape and form essentially flat monolayers, whereas those with smaller head groups, such as phosphatidylethanolamine (PE), have a conical shape. (c) A bilayer enriched with PC in the exoplasmic leaflet and with PE in the cytosolic face, as in many plasma membranes, would have a natural curvature. See H. Sprong et al., 2001, *Nature Rev. Mol. Cell Biol.* 2:504.

and phosphatidylinositol, which form more fluid bilayers, are preferentially located in the cytosolic leaflet. Because phosphatidylserine and phosphatidylinositol carry a net negative charge, the stretch of amino acids on the cytosolic face of a membrane protein with a single transmembrane segment, is often enriched in positively charged (Lys, Arg) residues in close proximity to the transmembrane segment (this distribution of charged amino acids is referred to as the “inside positive” rule). This segregation of lipids across the bilayer may influence membrane curvature (see Figure 7-11c). Unlike particular phospholipids, cholesterol is relatively evenly distributed in both leaflets of cellular membranes.

The relative abundances of a particular phospholipid in the two leaflets of a plasma membrane can be determined experimentally on the basis of the susceptibility of phospholipids to hydrolysis by **phospholipases**, enzymes that cleave the ester bonds via which acyl chains and head groups are connected to the lipid molecule (Figure 7-12). When added to the external medium, phospholipases cannot cross the membrane, and thus they cleave off the head groups of only those lipids present in the exoplasmic face; phospholipids in the cytosolic leaflet are resistant to hydrolysis because the enzymes cannot penetrate to the cytosolic face of the plasma membrane.

How the asymmetric distribution of phospholipids in membrane leaflets arises is still unclear. As noted, in pure bilayers, phospholipids do not spontaneously migrate, or flip-flop, from one leaflet to the other. In part, the asymmetry in phospholipid distribution may reflect where these lipids are synthesized in the endoplasmic reticulum and Golgi. Sphingomyelin is synthesized on the luminal (exoplasmic) face of the Golgi, which becomes the exoplasmic face of the plasma membrane. In contrast, phosphoglycerides are synthesized on the cytosolic face of the

ER membrane, which is topologically equivalent to the cytosolic face of the plasma membrane (see Figure 7-5). Clearly, however, this explanation does not account for the preferential location of phosphatidylcholine (a phosphoglyceride) in the exoplasmic leaflet. Movement of this phosphoglyceride, and perhaps others, from one leaflet to the other in some natural membranes is most likely catalyzed by ATP-powered transport proteins called **flippases**, which are discussed in Chapter 11.

The preferential location of lipids on one face of the bilayer is necessary for a variety of membrane-based functions. For example, the head groups of all phosphorylated forms of phosphatidylinositol (PI; see Figure 7-8), an important source of second messengers, face the cytosol. Stimulation of many cell-surface receptors by their corresponding ligands results in activation of the cytosolic enzyme phospholipase C, which can then hydrolyze the bond within PI connecting the phosphoinositols to the diacylglycerol. As we will see in Chapter 15, both water-soluble phosphoinositols and membrane-embedded diacylglycerol participate in intracellular signaling pathways that affect many aspects of cellular metabolism. Phosphatidylserine too is normally most abundant in the cytosolic leaflet of the plasma membrane. In the initial stages of platelet stimulation by serum, phosphatidylserine is briefly translocated to the exoplasmic face, presumably by a flippase enzyme, where it activates enzymes participating in blood clotting. When cells die, lipid asymmetry is no longer maintained, and phosphatidylserine, normally enriched in the cytosolic leaflet, is increasingly found in the exoplasmic one. This increased exposure is detected experimentally by use of a labeled version of annexin V, a protein that specifically binds to phosphatidylserine, to measure the onset of programmed cell death (apoptosis). The increased exposure of phosphatidylserine on dying or dead cells is recognized by phagocytic cells, which initiate engulfment of such apoptotic bodies and thus ensure timely and safe disposal of cell remnants.

**FIGURE 7-12 Specificity of phospholipases.** Each type of phospholipase cleaves one of the susceptible bonds shown in red. The glycerol carbon atoms are indicated by small numbers. In intact cells, only phospholipids in the exoplasmic leaflet of the plasma membrane are cleaved by phospholipases in the surrounding medium. Phospholipase C, a cytosolic enzyme, cleaves certain phospholipids in the cytosolic leaflet of the plasma membrane.

## Cholesterol and Sphingolipids Cluster with Specific Proteins in Membrane Microdomains

Membrane lipids are not randomly distributed (evenly mixed) in each leaflet of a bilayer. One hint that lipids may be organized within the leaflets was the discovery that the lipids remaining after the extraction (solubilization) of plasma membranes with non-ionic detergents such as Triton X-100 predominantly contain two species: cholesterol and sphingomyelin. Because these two lipids are found in more ordered, less fluid bilayers, researchers hypothesized that they form microdomains, termed **lipid rafts**, surrounded by other, more fluid phospholipids that are more readily extracted by non-ionic detergents. (We discuss more fully the role of ionic and non-ionic detergents in extracting membrane proteins in Section 7.2.)

Some biochemical and microscopic evidence supports the existence of lipid rafts, which in natural membranes

are typically 50 nm in diameter. Rafts can be disrupted by methyl- $\beta$ -cyclodextrin, which specifically extracts cholesterol from membranes, or by antibiotics such as filipin that sequester cholesterol into aggregates within the membrane. Such findings indicate the importance of cholesterol in maintaining the integrity of lipid rafts. These raft fractions, defined by their insolubility in non-ionic detergents, contain a subset of plasma-membrane proteins, many of which are implicated in sensing extracellular signals and transmitting them into the cytosol. Because raft fractions are enriched in glycolipids, an important tool for microscopic visualization of raft-type structures in intact cells is the use of fluorescently labeled cholera toxin, a protein that specifically binds to certain gangliosides. By bringing many key proteins into close proximity and stabilizing their interactions, lipid rafts may facilitate signaling by cell-surface receptors and the subsequent activation of cytosolic events. However, much remains to be learned about the structure and biological function of lipid rafts. The unique properties of some of the raft-associated lipids, such as glycolipids, may permit interactions of their tails across the hydrophobic core and help organize lipids of the cytosolic leaflet in the formation of signaling platforms.

**FIGURE 7-13 Lipid droplets form by budding and scission from the ER membrane.** Lipid droplet formation begins with the accumulation of cholesterol esters and triglycerides (yellow) within the hydrophobic core of the lipid bilayer. The resulting delamination of the two lipid monolayers causes a “lens” to form, the further growth of which creates a spherical droplet that is then released by scission at the neck. The newly formed droplet is surrounded by a lipid monolayer, derived from the cytosolic leaflet of the ER membrane.

## Cells Store Excess Lipids in Lipid Droplets

*Lipid droplets* are vesicular structures, composed of triglycerides and cholesterol esters, that originate from the ER and serve a lipid-storage function. When a cell’s supply of lipids exceeds the immediate need for membrane construction, excess lipids are relegated to these lipid droplets, readily visualized in live cells by staining with a lipophilic dye such as Congo red. Feeding cells with oleic acid, a type of fatty acid, enhances lipid droplet formation. Lipid droplets are not only storage compartments for triglycerides and cholesterol esters, but may also serve as platforms for storage of proteins targeted for degradation. The biogenesis of lipid droplets starts with delamination of the lipid bilayer of the ER through insertion of triglycerides and cholesterol esters (Figure 7-13). The lipid “lens” continues to grow by insertion of more lipid, until finally a lipid droplet is hatched by scission from the ER. The resulting cytoplasmic droplet is thereby surrounded by a phospholipid monolayer. The details of lipid droplet biogenesis, as well as its functions, remain to be defined more clearly.

### KEY CONCEPTS OF SECTION 7.1

#### The Lipid Bilayer: Composition and Structural Organization

- Membranes are crucial to cell structure and function. The eukaryotic cell is demarcated from the external environment by the plasma membrane and organized into membrane-limited internal compartments (organelles and vesicles).
- The phospholipid bilayer, the basic structural unit of all biomembranes, is a two-layered lipid sheet with hydrophilic faces and a hydrophobic core, which is impermeable to water-soluble molecules and ions. Proteins embedded in the bilayer endow the membrane with specific functions (see Figure 7-1).
- Phospholipids spontaneously form bilayers and sealed compartments surrounding an aqueous space (see Figure 7-3).
- As bilayers, all biological membranes have an internal (cytosolic) face and an external (exoplasmic) face (see Figure 7-5). Some organelles are surrounded by two, rather than one, membrane bilayer.
- The primary lipid components of biomembranes are phosphoglycerides, sphingolipids, and sterols such as cholesterol. The term “phospholipid” applies to any amphipathic lipid molecule with a fatty acyl hydrocarbon tail and a phosphate-based polar head group (see Figure 7-8).
- Biomembranes can undergo phase transitions from fluid-like to gel-like states depending on the temperature and the composition of the membrane (see Figure 7-9).
- Most lipids and many proteins are laterally mobile in biomembranes (see Figure 7-10).

- Different cellular membranes vary in lipid composition (see Table 7-1). Phospholipids and sphingolipids are asymmetrically distributed in the two leaflets of the bilayer, whereas cholesterol is fairly evenly distributed in both leaflets.
- Natural biomembranes generally have a viscous consistency with fluidlike properties. In general, membrane fluidity is decreased by sphingolipids and cholesterol and increased by phosphoglycerides. The lipid composition of a membrane also influences its thickness and curvature (see Figure 7-11).
- Lipid rafts are microdomains containing cholesterol, sphingolipids, and certain membrane proteins that form in the plane of the bilayer. These lipid-protein aggregates might facilitate signaling by certain plasma-membrane receptors.
- Lipid droplets are storage vesicles for lipids, originating in the ER (see Figure 7-13).

## 7.2 Membrane Proteins: Structure and Basic Functions

Membrane proteins are defined by their location within or at the surface of a phospholipid bilayer. Although every biological membrane has the same basic bilayer structure, the proteins associated with a particular membrane are responsible for its distinctive activities. The kinds and amounts of proteins associated with biomembranes vary depending on cell type and subcellular location. For example, the inner mitochondrial membrane is 76 percent protein; the myelin membrane that surrounds nerve axons, only 18 percent. The high phospholipid content of myelin allows it to electrically insulate the nerve from its environment, as we discuss in Chapter 22. The importance of membrane proteins is evident from the finding that approximately a third of all yeast genes encode a membrane protein. The relative abundance of genes for membrane proteins is even greater in multicellular organisms, in which membrane proteins have additional functions in cell adhesion and in communication between different cell types (cell-cell interactions).

The lipid bilayer presents a distinctive two-dimensional hydrophobic environment for membrane proteins. Some proteins contain segments that are embedded within the hydrophobic core of the phospholipid bilayer; other proteins are associated with the exoplasmic or cytosolic leaflet of the bilayer. Protein domains on the extracellular surface of the plasma membrane generally bind to extracellular molecules, including external signaling proteins, ions, and small metabolites (e.g., glucose, fatty acids), as well as proteins on other cells or in the external environment. Segments of proteins within the plasma membrane perform multiple functions, such as forming the channels and pores through which molecules and ions move into and out of cells. These intramembrane segments also serve to organize multiple membrane proteins into larger assemblies within the plane of the membrane. Domains lying along the cytosolic face of the plasma membrane have a wide range of

functions, from anchoring cytoskeletal proteins to the membrane to triggering intracellular signaling pathways.

In many cases, the function of a membrane protein and the topology of its polypeptide chain in the membrane can be predicted on the basis of its similarity with other well-characterized proteins. In this section, we examine the characteristic structural features of membrane proteins and some of their basic functions. We describe the structures of several proteins to help you get a feel for the way membrane proteins interact with membranes. More complete characterizations of the properties of various types of membrane proteins are presented in later chapters that focus on their structures and activities in the context of their cellular functions.

### Proteins Interact with Membranes in Three Different Ways

Membrane proteins can be classified into three categories—integral, lipid-anchored, and peripheral—on the basis of their position with respect to the membrane (see Figure 7-1). **Integral membrane proteins**, also called *transmembrane proteins*, span a phospholipid bilayer and comprise three domains. The cytosolic and exoplasmic domains have hydrophilic exterior surfaces that interact with the aqueous environment on the cytosolic and exoplasmic faces of the membrane. These domains resemble segments of other water-soluble proteins in their amino acid composition and structure. In contrast, the membrane-spanning segments usually contain many hydrophobic amino acids whose side chains protrude outward and interact with the hydrophobic hydrocarbon core of the phospholipid bilayer. In all transmembrane proteins examined to date, the membrane-spanning domains consist of one or more  $\alpha$  helices or of multiple  $\beta$  strands. We discuss the ribosomal synthesis and post-translational processing of soluble cytosolic proteins in Chapters 5 and 10; the process by which integral membrane proteins are inserted into membranes as part of their synthesis is discussed in Chapter 13.

**Lipid-anchored membrane proteins** are bound covalently to one or more lipid molecules. The hydrophobic tail of the attached lipid is embedded in one leaflet of the membrane and anchors the protein to the membrane. The polypeptide chain itself does not enter the phospholipid bilayer.

**Peripheral membrane proteins** do not directly contact the hydrophobic core of the phospholipid bilayer. Instead, they are bound to the membrane either indirectly by interactions with integral or lipid-anchored membrane proteins or directly by interactions with lipid head groups. Peripheral proteins can be bound to either the cytosolic or the exoplasmic face of the plasma membrane. In addition to these proteins, which are closely associated with the bilayer, cytoskeletal filaments can be more loosely associated with the cytosolic face, usually through one or more peripheral adapter proteins. Such associations with the cytoskeleton provide support for various cellular membranes, helping to determine the cell's shape and mechanical properties, and play a role in the two-way communication between the cell interior and the exterior, as we learn in Chapter 17. Finally, peripheral proteins on the outer surface of the plasma membrane and

the exoplasmic domains of integral membrane proteins are often attached to components of the extracellular matrix or to the cell walls surrounding bacterial and plant cells, providing a crucial interface between the cell and its environment.

## Most Transmembrane Proteins Have Membrane-Spanning $\alpha$ Helices

Soluble proteins exhibit hundreds of distinct localized folded structures, or motifs (see Figure 3-10). In comparison, the repertoire of folded structures in the transmembrane domains of integral membrane proteins is quite limited, with the hydrophobic  $\alpha$  helix predominating. Proteins containing membrane-spanning  $\alpha$ -helical domains are stably embedded in membranes because of energetically favorable hydrophobic and van der Waals interactions of the hydrophobic side chains in the domain with specific lipids and probably also because of ionic interactions with the polar head groups of the phospholipids.

A single  $\alpha$ -helical domain is sufficient to incorporate an integral membrane protein into a membrane. However, many such proteins have more than one transmembrane  $\alpha$  helix. Typically, a membrane-embedded  $\alpha$  helix is composed of a continuous segment of 20–25 hydrophobic (uncharged)

amino acids (see Figure 2-14). The predicted length of such an  $\alpha$  helix (3.75 nm) is just sufficient to span the hydrocarbon core of a phospholipid bilayer. In many membrane proteins, these helices are perpendicular to the plane of the membrane, whereas in others, the helices traverse the membrane at an oblique angle. The hydrophobic side chains protrude outward from the helix and form van der Waals interactions with the fatty acyl chains in the bilayer. In contrast, the hydrophilic amide peptide bonds are in the interior of the  $\alpha$  helix (see Figure 3-4); each carbonyl (C=O) group forms a hydrogen bond with the amide hydrogen atom of the amino acid four residues toward the C-terminus of the helix. These polar groups are shielded from the hydrophobic interior of the membrane.

To help you get a better sense of the structures of proteins with  $\alpha$ -helical domains, we will briefly discuss four different kinds of such proteins: glycophorin A, G protein-coupled receptors, aquaporins (water/glycerol channels), and the T cell receptor for antigen.

Glycophorin A, the major protein in the erythrocyte plasma membrane, is a representative *single-pass* transmembrane protein, which contains only one membrane-spanning  $\alpha$  helix (Figure 7-14a). The 23-residue membrane-spanning

**FIGURE 7-14 Structure of glycophorin A, a typical single-pass transmembrane protein.** (a) Diagram of dimeric glycophorin, showing its major sequence features and its relation to the membrane. The single 23-residue membrane-spanning  $\alpha$  helix in each monomer is composed of amino acids with hydrophobic (uncharged) side chains (red and green spheres). By binding negatively charged phospholipid head groups, the positively charged arginine and lysine residues (blue spheres) near the cytosolic side of the helix help anchor glycophorin in the membrane. Both the extracellular and the cytosolic domains are rich in charged residues and polar uncharged residues; the extracellular domain is heavily

glycosylated, with carbohydrate chains (green diamonds) attached to specific serine, threonine, and asparagine residues. (b) Molecular model of the transmembrane domain of dimeric glycophorin A corresponding to residues 73–96. The hydrophobic side chains of the  $\alpha$  helix in one monomer are shown in pink; those of the other monomer, in green. Residues depicted as space-filling structures participate in van der Waals interactions that stabilize the coiled-coil dimer. Note how the hydrophobic side chains project outward from the helix, toward what would be the surrounding fatty acyl chains. [Part (b) data from K. R. MacKenzie et al., 1997, *Science* **276**:131, PDB ID 1afo.]

$\alpha$  helix is composed of amino acids with hydrophobic (uncharged) side chains, which interact with the fatty acyl chains in the surrounding bilayer. In cells, glycophorin A typically forms dimers: the transmembrane helix of one glycophorin A polypeptide associates with the corresponding transmembrane helix in a second glycophorin A to form a coiled-coil structure (Figure 7-14b). Such interactions of membrane-spanning  $\alpha$  helices are a common mechanism for creating dimeric membrane proteins, and many membrane proteins form oligomers (two or more polypeptides bound together noncovalently) by interactions between their membrane-spanning helices.

A large and important group of integral membrane proteins is defined by the presence of seven membrane-spanning  $\alpha$  helices. This group includes the large family of G protein-coupled cell-surface receptors discussed in Chapter 15, many of which have been crystallized. One such *multipass* transmembrane protein of known structure is bacteriorhodopsin, a protein found in the membranes of certain photosynthetic bacteria; it illustrates the general structure of all these proteins (Figure 7-15a). Absorption of light by the retinal group covalently attached to this protein causes a conformational change in the protein that results in the pumping of protons from the cytosol across the bacterial membrane to the extracellular space. The proton concentration gradient thus generated across the membrane is used to synthesize ATP during photosynthesis (see Chapter 12). In the high-resolution structure of bacteriorhodopsin, the positions of all the individual amino acids, the retinal group, and the surrounding

lipids are clearly defined. As might be expected, virtually all the amino acids on the exterior of the membrane-spanning segments of bacteriorhodopsin are hydrophobic, permitting energetically favorable interactions with the hydrocarbon core of the surrounding lipid bilayer.

The **aquaporins** are a large family of highly conserved proteins that transport water, glycerol, and other hydrophilic molecules across biomembranes. They illustrate several aspects of the structure of multipass transmembrane proteins. Aquaporins are tetramers of four identical subunits. Each of the four subunits has six membrane-spanning  $\alpha$  helices, some of which traverse the membrane at oblique angles rather than perpendicularly. Because all aquaporins have similar structures, we will focus on one, the glycerol channel Glpf, whose structure has been especially well defined by x-ray diffraction studies (Figure 7-15b). This aquaporin has one long transmembrane helix with a bend in the middle, and more strikingly, there are two  $\alpha$  helices that penetrate only *halfway* through the membrane. The N-termini of these helices face each other (yellow Ns in the figure), and together they span the membrane at an oblique angle. Thus some membrane-embedded helices—and other, nonhelical, structures we will encounter later—do not traverse the entire bilayer. As we will see in Chapter 11, these short helices in aquaporins form part of the glycerol/water-selective pore in the middle of each subunit. This structure highlights the considerable diversity in the ways membrane-spanning  $\alpha$  helices interact with the lipid bilayer and with other segments of the protein.

**FIGURE 7-15 Structural models of two multipass membrane proteins.** (a) Bacteriorhodopsin, a photoreceptor in certain bacteria. The seven hydrophobic  $\alpha$  helices in bacteriorhodopsin traverse the lipid bilayer roughly perpendicular to the plane of the membrane. A retinal molecule (black) covalently attached to one helix absorbs light. The large class of G protein-coupled receptors in eukaryotic cells also has seven membrane-spanning  $\alpha$  helices; their three-dimensional structure is thought to be similar to that of bacteriorhodopsin. (b) Two views of the glycerol channel Glpf, rotated  $180^\circ$  with respect to each other along an axis perpendicular to the plane of the membrane. Note the

several membrane-spanning  $\alpha$  helices that are at oblique angles, the two helices that penetrate only halfway through the membrane (purple with yellow arrows), and the one long membrane-spanning helix with a “break” or distortion in the middle (purple with yellow line). The glycerol molecule in the hydrophilic “core” is colored red. The protein structure was approximately positioned in the hydrocarbon core of the membrane by finding the most hydrophobic  $3\text{-}\mu\text{m}$  slab of the protein perpendicular to the membrane plane. [Part (a) data from H. Luecke et al., 1999, *J. Mol. Biol.* **291**:899. Part (b) data from J. Bowie, 2005, *Nature* **438**:581–589, PDB ID 1c3w and D. Fu et al., 2000, *Science* **290**:481–486, PDB ID 1fx8.]

The specificity of phospholipid-protein interactions is evident from the structure of a different aquaporin, aquaporin 0 (Figure 7-16). Aquaporin 0 is the most abundant protein in the plasma membrane of the fiber cells that make up the bulk of the lens of the mammalian eye. Like other aquaporins, it is a tetramer of identical subunits. The protein's surface is not covered by a set of uniform binding sites for phospholipid molecules. Instead, fatty acyl chains pack tightly against the irregular hydrophobic outer surface of the protein. The lipids involved in this interaction are referred to as *annular phospholipids* because they form a tight ring (annulus) of lipids around the protein that are not easily exchanged with bulk phospholipids in the bilayer. Some of the fatty acyl chains are straight, in the trans conformation (see Chapter 2), whereas others are kinked in order to interact with bulky hydrophilic side chains on the surface of the protein. Some of the lipid head groups are parallel to the surface of the membrane, as is the case in pure phospholipid bilayers. Others, however, are oriented almost at right angles to the plane of the membrane. Thus there can be specific interactions between phospholipids and membrane-spanning proteins, and the function of many membrane proteins can be affected by the specific types of phospholipids present in the bilayer.

In addition to the predominantly hydrophobic (uncharged) residues that serve to embed integral membrane

**FIGURE 7-16 Annular phospholipids.** Side view of the three-dimensional structure of one subunit of the lens-specific aquaporin 0 homotetramer, crystallized in the presence of the phospholipid dimyristoylphosphatidylcholine, a phospholipid with 14 carbon-saturated fatty acyl chains. Note the lipid molecules forming a bilayer shell around the protein. The protein is shown as a surface plot (the lighter background molecule). The lipid molecules are shown in space-filling format; the polar lipid head groups (gray and red) and the lipid fatty acyl chains (the extended black and gray structures) form a bilayer with almost uniform thickness around the protein. Presumably, in the membrane, lipid fatty acyl chains cover the whole of the hydrophobic surface of the protein; only the most ordered of the lipid molecules would be resolved in the crystallographic structure. [Data from A. Lee, 2005, *Nature* **438**:569–570, and T. Gonen et al., 2005, *Nature* **438**:633–688, PDB ID 2b6o.]

proteins in the bilayer, many  $\alpha$ -helical transmembrane segments contain polar or charged residues. Their amino acid side chains can be used to guide the assembly and stabilization of multimeric membrane proteins. The T cell receptor for antigen is a case in point: it is composed of four separate dimers, the interactions of which are driven by charge-charge interactions between  $\alpha$  helices at the appropriate “depth” in the hydrocarbon core of the lipid bilayer (Figure 7-17). The electrostatic attraction of positive and negative charges on each dimer helps the dimers to “find each other.” Thus charged residues in otherwise hydrophobic transmembrane segments can help guide assembly of multimeric membrane proteins.

**FIGURE 7-17 Charged residues can orchestrate the assembly of multimeric membrane proteins.** The T cell receptor (TCR) for antigen is composed of four separate dimers: an  $\alpha\beta$  pair directly responsible for antigen recognition, and accessory subunits collectively referred to as the CD3 complex. These accessory subunits include the  $\gamma$ ,  $\delta$ ,  $\epsilon$ , and  $\zeta$  subunits. The  $\zeta$  subunits form a disulfide-linked homodimer. The  $\gamma$  and  $\delta$  subunits occur in complex with an  $\epsilon$  subunit, to generate a  $\gamma\epsilon$  and a  $\delta\epsilon$  pair. The transmembrane segments of the TCR  $\alpha$  and  $\beta$  chains each contain positively charged residues (blue). These residues allow recruitment of corresponding  $\delta\epsilon$  and  $\gamma\epsilon$  heterodimers, which carry negative charges (red) at the appropriate depth in the hydrophobic core of the bilayer. The  $\zeta$  homodimer docks onto the charges in the TCR  $\alpha$  chain (dark green), while the  $\gamma\epsilon$  and  $\delta\epsilon$  subunit pairs find their corresponding partners deeper down in the hydrophobic core on both the TCR  $\alpha$  and TCR  $\beta$  chain (light green). Charged residues in otherwise nonpolar transmembrane segments can thus guide assembly of higher-order structures. [Data from K. W. Wucherpfennig et al., 2010, *Cold Spring Harb. Perspect. Biol.*, **2**:a005140, PDB ID 1xmw; M. E. Call et al., 2006, *Cell*, **127**:355, PDB ID 2hac; and L. Kjer-Nielsen et al., 2003, *Immunity*, **18**:53, PDB ID 1mi5.]

## Multiple $\beta$ Strands in Porins Form Membrane-Spanning “Barrels”

The **porins** are a class of transmembrane proteins whose structure differs radically from that of other integral membrane proteins based on  $\alpha$ -helical transmembrane domains. Several types of porins are found in the outer membranes of gram-negative bacteria such as *E. coli* and in the outer membranes of mitochondria and chloroplasts. The outer membrane protects an intestinal bacterium from harmful agents (e.g., antibiotics, bile salts, and proteases), but permits the uptake and disposal of small hydrophilic molecules, including nutrients and waste products. Different types of porins in the outer membrane of an *E. coli* cell provide channels for the passage of specific types of disaccharides or other small molecules as well as for ions such as phosphate. The amino acid sequences of porins contain none of the long, continuous hydrophobic segments typical of integral membrane proteins with  $\alpha$ -helical membrane-spanning domains. Rather, it is the entire outer surface of the fully folded porin that displays its hydrophobic character to the hydrocarbon core of the lipid bilayer. X-ray crystallography shows that porins are trimers of identical subunits. In each subunit, 16  $\beta$  strands form a sheet that twists into a barrel-shaped structure with a pore in the center (Figure 7-18). Unlike a typical water-soluble

**FIGURE 7-18 Structural model of one subunit of OmpX, a porin found in the outer membrane of *E. coli*.** All porins are trimeric transmembrane proteins. Each subunit is barrel shaped, with  $\beta$  strands forming the wall and a transmembrane pore in the center. A band of aliphatic (hydrophobic and noncyclic) side chains (yellow) and a border of aromatic (ring-containing) side chains (red) position the protein in the bilayer. See G. E. Schulz, 2000, *Curr. Opin. Struct. Biol.* **10**:443. [Data from J. Vogt and G. E. Schulz, 1999, *Structure* **7**:1301, PDB ID 1qj8.]

globular protein, a porin has a hydrophilic interior and a hydrophobic exterior; in this sense, porins are inside out. In a porin monomer, the outward-facing side chains on each of the  $\beta$  strands are hydrophobic and form a nonpolar ribbonlike band that encircles the outside of the barrel. This hydrophobic band interacts with the fatty acyl groups of the membrane lipids or with other porin monomers. The side chains facing the inside of a porin monomer are predominantly hydrophilic; they line the pore through which small water-soluble molecules cross the membrane. (Note that the aquaporins discussed above, despite their name, are not porins and contain multiple transmembrane  $\alpha$  helices.)

## Covalently Attached Lipids Anchor Some Proteins to Membranes

In eukaryotic cells, covalently attached lipids anchor some otherwise typically water-soluble proteins to one or the other leaflet of the membrane. In such lipid-anchored proteins, the hydrocarbon chains of the lipid anchor are embedded in the bilayer, but the protein itself does not enter the bilayer. The lipid anchors used to anchor proteins to the cytosolic face are not used for the exoplasmic face, and vice versa.

One group of cytosolic proteins is anchored to the cytosolic face of a membrane by a fatty acyl group (e.g., myristate or palmitate) covalently attached to an N-terminal glycine residue, a modification called *acylation* (Figure 7-19a). Retention of such proteins at the membrane by the N-terminal acyl anchor may play an important role in a membrane-associated function. For example, v-Src, a mutant form of a cellular tyrosine kinase, induces abnormal cellular growth that can lead to cancer, but does so only when it has a myristylated N-terminus.

A second group of cytosolic proteins are anchored to membranes by a hydrocarbon chain attached to a cysteine residue at or near the C-terminus, a modification called *prenylation* (Figure 7-19b). Prenyl anchors are built from 5-carbon isoprene units, which, as detailed in the following section, are also used in the synthesis of cholesterol. In prenylation, a 15-carbon farnesyl or 20-carbon geranylgeranyl group is bound by a thioether bond to the  $-SH$  group of a C-terminal cysteine residue of the protein, usually part of a C-terminal Cys-Ala-Ala-X (X = any of a number of amino acids) or CAAX box. Once prenylation has occurred, the C-terminal Ala-Ala-X motif may be removed by proteolysis. In some cases, a second geranylgeranyl group or a fatty acyl palmitate group is linked to a nearby cysteine residue. The additional hydrocarbon anchor is thought to reinforce the attachment of the protein to the membrane. For example, Ras, a GTPase superfamily protein that functions in intracellular signaling (see Chapter 15), is recruited to the cytosolic face of the plasma membrane by such a double anchor. Rab proteins, which also belong to the GTPase superfamily, are similarly bound to the cytosolic surface of intracellular vesicles by prenyl anchors; these proteins are required for the fusion of vesicles with their target

**FIGURE 7-19 Anchoring of plasma-membrane proteins to the phospholipid bilayer by covalently linked hydrocarbon groups.** (a) Cytosolic proteins such as v-Src are associated with the plasma membrane through a single fatty acyl chain attached to the N-terminal glycine (Gly) residue of the polypeptide. Myristate (C14) and palmitate (C16) are common acyl anchors. (b) Other cytosolic proteins (e.g., Ras and Rab proteins) are anchored to the membrane by prenylation of one or two cysteine (Cys) residues at or near the C-terminus. The anchors are farnesyl (C15) and geranylgeranyl (C20) groups, both of which are unsaturated. (c) The lipid anchor on the exoplasmic surface of the plasma membrane is glycosylphosphatidylinositol (GPI). The phosphatidylinositol part (red) of this anchor contains two fatty acyl chains that extend into the bilayer. The phosphoethanolamine unit (purple) in the anchor links it to the protein. The two green hexagons represent sugar units, which vary in number, nature, and arrangement in different GPI anchors. The complete structure of a yeast GPI anchor is shown in Figure 13-15. See H. Sprong et al., 2001, *Nature Rev. Mol. Cell Biol.* **2**:504.

membranes (see Chapter 14). Yet other proteins are palmitoylated on membrane-proximal cysteine residues in the absence of other lipid modifications.

Some cell-surface proteins, and some specialized proteins with distinctive covalently attached polysaccharides called proteoglycans (see Chapter 20), are bound to the exoplasmic face of the plasma membrane by a third anchor group, glycosylphosphatidylinositol (GPI) anchors. The exact structures of *GPI anchors* vary greatly among different cell types, but they always contain phosphatidylinositol, whose two fatty acyl chains extend into the lipid bilayer just like those of typical membrane phospholipids; phosphoethanolamine, which covalently links the anchor to the C-terminus of a protein; and several sugar residues (Figure 7-19c). Therefore, GPI anchors are glycolipids. The GPI anchor is both necessary and sufficient for binding proteins to the membrane. For instance, treatment of cells with phospholipase C, which cleaves the phosphate-glycerol bond in phospholipids

and in GPI anchors (see Figure 7-12), releases GPI-anchored proteins such as Thy-1 and placental alkaline phosphatase (PLAP) from the cell surface.

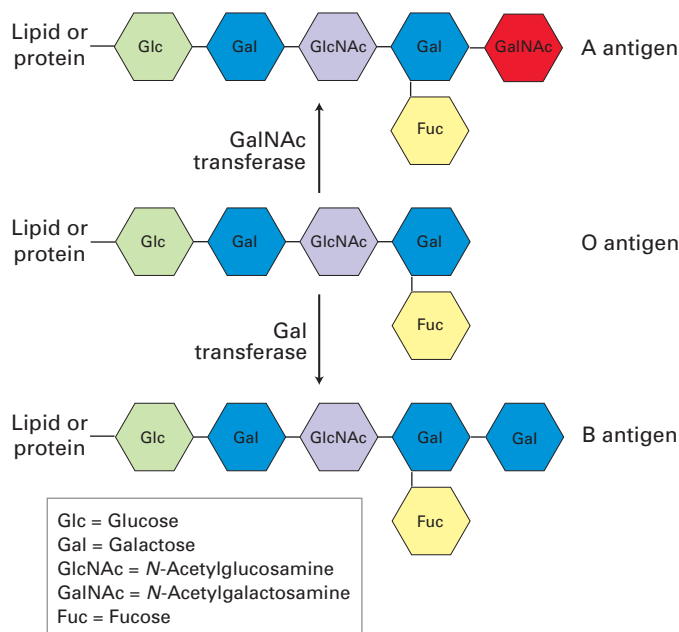

## All Transmembrane Proteins and Glycolipids Are Asymmetrically Oriented in the Bilayer

Every type of transmembrane protein has a specific orientation, known as its *topology*, with respect to the membrane faces. Its cytosolic segments always face the cytosol, and its exoplasmic segments always face the opposite side of the membrane. This asymmetry in protein orientation gives the two membrane faces their different properties. The orientations of different types of transmembrane proteins are established during their synthesis, as we will see in Chapter 13. Membrane proteins have never been observed to flip-flop across a membrane; such movement, requiring a transient movement of hydrophilic amino acid residues through the hydrophobic interior of the membrane, would be energetically unfavorable. Accordingly, the asymmetric topology of a transmembrane protein is maintained throughout the protein's lifetime. As Figure 7-6 shows, membrane proteins retain their asymmetric orientation during membrane budding and fusion events; the same segment always faces the cytosol and the same segment is always exposed to the exoplasmic face. In multipass membrane proteins, the orientation of individual transmembrane segments can be affected by changes in the membrane's phospholipid composition.

Many transmembrane proteins contain carbohydrate chains covalently linked to serine, threonine, or asparagine side chains of the polypeptide. Such transmembrane **glycoproteins** are always oriented so that all the carbohydrate chains are in the exoplasmic domain (see Figure 7-14 for the example of glycophorin A). Likewise, glycolipids, in which a carbohydrate chain is attached to the glycerol or sphingosine backbone of a membrane lipid, are always located in the exoplasmic leaflet, with the carbohydrate chain protruding from the membrane surface. The biosynthetic basis for the asymmetric glycosylation of proteins is described in Chapter 14. Both glycoproteins and glycolipids are especially abundant in the plasma membranes of eukaryotic cells and in the membranes of the intracellular compartments that establish the secretory and endocytic pathways; they are absent from the inner mitochondrial membrane, chloroplast lamellae, and several other intracellular membranes. Because the carbohydrate chains of glycoproteins and glycolipids in the plasma membrane extend into the extracellular space, they are available to interact with components of the extracellular matrix as well as with **lectins** (proteins that bind specific sugars), growth factors, and antibodies.

One important consequence of interactions involving membrane glycoproteins and glycolipids is illustrated by the ABO blood-group antigens. These three structurally related oligosaccharide components of certain glycoproteins and glycolipids are expressed on the surfaces of human red

**FIGURE 7-20 Human ABO blood group antigens.** These antigens are oligosaccharide chains covalently attached to glycolipids or glycoproteins in the plasma membrane. The terminal oligosaccharide sugars distinguish the three antigens. The presence or absence of the glycosyltransferases that add galactose (Gal) or *N*-acetylgalactosamine (GalNAc) to O antigen determine a person's blood type.

blood cells and many other cell types (Figure 7-20). All humans have the enzymes for synthesizing O antigen. Persons with type A blood also have a glycosyltransferase enzyme that adds an extra modified monosaccharide called *N*-acetylgalactosamine to O antigen to form A antigen. Those with type B blood have a different transferase that adds an extra galactose to O antigen to form B antigen. People with both transferases produce both A and B antigen (AB blood type); those who lack these transferases produce O antigen only (O blood type).

People whose erythrocytes lack the A antigen, the B antigen, or both on their surface normally have antibodies against the missing antigen(s) in their serum. Thus if a type A or O person receives a transfusion of type B blood, antibodies against the B antigen will bind to the introduced red cells and trigger their destruction. To prevent such harmful

reactions, blood group typing and appropriate matching of blood donors and recipients are required in all transfusions (Table 7-2). ■

## Lipid-Binding Motifs Help Target Peripheral Proteins to the Membrane

Many water-soluble enzymes whose substrates are phospholipids must bind to membrane surfaces. Phospholipases, for example, hydrolyze various bonds in the head groups of phospholipids (see Figure 7-12) and thereby play a variety of roles in cells—helping to degrade damaged or aged cellular membranes, generating precursors to signaling molecules, and even serving as the active components in many snake venoms. Many peripheral proteins, including phospholipases, initially bind to the polar head groups of membrane phospholipids to carry out their catalytic functions. The mechanism of action of phospholipase  $A_2$  illustrates how such enzymes can reversibly interact with membranes and catalyze reactions at the interface of an aqueous solution and a lipid surface. When this enzyme is in aqueous solution, its  $Ca^{2+}$ -containing active site is buried in a channel lined with hydrophobic amino acids. The enzyme binds with greatest affinity to bilayers composed of negatively charged phospholipids (e.g., phosphatidylserine). This observation suggests that the rim of positively charged lysine and arginine residues around the entrance to the catalytic channel is particularly important in binding (Figure 7-21a) and constitutes a lipid binding motif. Binding induces a conformational change in phospholipase  $A_2$  that strengthens its binding to the phospholipid heads and opens the hydrophobic channel. As a phospholipid molecule moves from the bilayer into the channel, the enzyme-bound  $Ca^{2+}$  binds to the phosphate in the head group, thereby positioning the ester bond to be cleaved in the catalytic site (Figure 7-21b), releasing the acyl chain.

## Proteins Can Be Removed from Membranes by Detergents or High-Salt Solutions

Membrane proteins are often difficult to purify and study, mostly because of their tight association with membrane lipids and other membrane proteins. *Detergents*, which are amphipathic molecules that disrupt membranes by

**TABLE 7-2 ABO Blood Groups**

Blood Group	Antigens on RBCs*	Serum Antibodies	Can Receive Blood Types
A	A	Anti-B	A and O
B	B	Anti-A	B and O
AB	A and B	None	All
O	O	Anti-A and anti-B	O

\*See Figure 7-20 for antigen structures.

**FIGURE 7-21 Lipid-binding surface and mechanism of action of phospholipase A<sub>2</sub>.** (a) A structural model of the enzyme, showing the surface that interacts with a membrane. This lipid-binding surface contains a rim of positively charged arginine and lysine residues, shown in blue surrounding the cavity of the catalytic active site, in which a substrate lipid (red ball-and-stick structure) is bound. (b) Diagram of catalysis by phospholipase A<sub>2</sub>. When docked on a lipid membrane, positively charged residues of the binding site bind to negatively charged polar groups at the membrane surface. This binding triggers a small conformational change, opening a channel lined with hydrophobic amino acids that leads from the bilayer to the catalytic site. As a phospholipid moves into the channel, an enzyme-bound Ca<sup>2+</sup> ion (green) binds to the head group, positioning the ester bond to be cleaved (red) next to the catalytic site. See D. Blow, 1991, *Nature* **351**:444, and M. H. Gelb et al., 1999, *Curr. Opin. Struct. Biol.* **9**:428. [Part (a) data from D. L. Scott et al., 1990, *Science* **250**:1563, PDB ID 1poc.]

intercalating into phospholipid bilayers, can be used to solubilize lipids and many membrane proteins. The hydrophobic part of a detergent molecule is attracted to the phospholipid hydrocarbons and mingles with them readily; the hydrophilic part is strongly attracted to water. Some detergents, such as bile salts, are natural products, but most are synthetic molecules developed for cleaning and for dispersing mixtures of oil and water in the food industry (e.g., creamy peanut butter) (Figure 7-22). Ionic detergents, such as sodium deoxycholate (a bile salt) and sodium dodecylsulfate (SDS), contain a charged group; non-ionic detergents, such as Triton X-100 and octylglucoside, lack a charged group. At very low concentrations, detergents dissolve in pure water as isolated molecules. As the concentration increases, the molecules begin to form micelles—small spherical aggregates in which the hydrophilic parts of the molecules face outward and the hydrophobic parts cluster in the center (see Figure 7-3c). The *critical micelle concentration* (CMC) at which micelles form is characteristic of each detergent and is a function of the structures of its hydrophobic and hydrophilic parts.

Ionic and non-ionic detergents interact differently with proteins and have different uses in the lab. Ionic detergents bind to the exposed hydrophobic regions of membrane proteins as well as to the hydrophobic cores of water-soluble proteins. Because of their charge, these detergents can disrupt ionic and hydrogen bonds. At high concentrations, sodium dodecylsulfate, for example, completely denatures proteins by binding to every side chain, a property that is exploited in SDS gel electrophoresis (see Figure 3-38). Non-ionic detergents generally do not denature proteins and are thus useful in extracting proteins in their folded and active form from membranes before the proteins are purified. Protein-protein interactions, especially the weaker ones, can be sensitive to both ionic and non-ionic detergents.

At high concentrations (above the CMC), non-ionic detergents solubilize biological membranes by forming

**FIGURE 7-22 Structures of four common detergents.** The hydrophobic part of each molecule is shown in yellow; the hydrophilic part, in blue. The bile salt sodium deoxycholate is a natural product; the others are synthetic. Although ionic detergents commonly cause denaturation of proteins, non-ionic detergents do not and are thus useful in solubilizing integral membrane proteins.

**FIGURE 7-23 Solubilization of integral membrane proteins by non-ionic detergents.**

At a concentration higher than its critical micelle concentration (CMC), a detergent solubilizes lipids and integral membrane proteins, forming mixed micelles containing detergent, protein, and lipid molecules. At concentrations below the CMC, non-ionic detergents (e.g., octylglucoside, Triton X-100) can dissolve membrane proteins without forming micelles by coating the membrane-spanning regions.

mixed micelles of detergent, phospholipids, and integral membrane proteins, bulky hydrophobic structures that do not dissolve in water (Figure 7-23, *top*). At low concentrations (below the CMC), these detergents bind to the hydrophobic regions of most integral membrane proteins, but without forming micelles, allowing the proteins to remain soluble (Figure 7-23, *bottom*). Creating such an aqueous solution of integral membrane proteins is a necessary first step in protein purification.

Treatment of cultured cells with a buffered salt solution containing a non-ionic detergent such as Triton X-100 extracts water-soluble proteins as well as integral membrane proteins from cellular membranes. As noted earlier, the exoplasmic and cytosolic domains of integral membrane proteins are generally hydrophilic and soluble in water. The membrane-spanning domains, however, are rich in hydrophobic and uncharged residues (see Figure 7-14). When separated from membranes, these exposed hydrophobic segments tend to interact with one another, causing the protein molecules to aggregate and precipitate from aqueous solutions. The hydrophobic parts of non-ionic detergent molecules preferentially bind to the hydrophobic segments of transmembrane proteins, preventing protein aggregation and allowing the proteins to remain in aqueous solution. Detergent-solubilized transmembrane proteins can then be purified by affinity chromatography and other techniques used in purifying water-soluble proteins (see Chapter 3).

As discussed previously, most peripheral membrane proteins are bound to specific transmembrane proteins or membrane phospholipids by ionic or other weak noncovalent interactions. Generally, peripheral proteins can be removed from the membrane by solutions of high ionic strength (high salt concentrations), which disrupt ionic bonds, or by chemicals that bind divalent cations such as  $Mg^{2+}$ . Unlike integral membrane proteins, most peripheral proteins are soluble in water and need not be solubilized by non-ionic detergents.

## KEY CONCEPTS OF SECTION 7.2

### Membrane Proteins: Structure and Basic Functions

- Biological membranes usually contain integral (transmembrane) proteins as well as lipid-anchored proteins and peripheral membrane proteins, which do not enter the hydrophobic core of the bilayer (see Figure 7-1).
- Most integral membrane proteins contain one or more membrane-spanning hydrophobic  $\alpha$  helices bracketed by hydrophilic domains that extend into the aqueous environment surrounding the cytosolic and exoplasmic faces of the membrane (see Figures 7-14, 7-15, and 7-17).
- Fatty acyl side chains as well as the polar head groups of membrane lipids pack tightly and irregularly around the hydrophobic segments of integral membrane proteins (see Figure 7-16).
- The porins, unlike other integral membrane proteins, contain membrane-spanning  $\beta$  sheets that form a barrel-like channel through the bilayer (see Figure 7-18).
- Lipids attached to certain amino acids anchor some proteins to one or the other membrane leaflet (see Figure 7-19).
- All transmembrane proteins and glycolipids are asymmetrically oriented in the bilayer. Invariably, carbohydrate chains are present only on the exoplasmic surface of a glycoprotein or glycolipid.
- Many water-soluble enzymes (e.g., phospholipases) whose substrates are phospholipids must bind to the membrane surface to carry out their function. Such binding is often due to the attraction between positive charges on lysine and arginine residues in the protein and negative charges on phospholipid head groups in the bilayer.
- Transmembrane proteins can be selectively extracted from membranes with the use of non-ionic detergents.

## 7.3 Phospholipids, Sphingolipids, and Cholesterol: Synthesis and Intracellular Movement

In this section, we consider some of the special challenges that a cell faces in synthesizing and transporting lipids, which are poorly soluble in the aqueous interior of a cell. The focus of our discussion will be the biosynthesis and movement of the major lipids found in cellular membranes—phospholipids, sphingolipids, and cholesterol—and their precursors. In lipid biosynthesis, water-soluble precursors are assembled into membrane-associated intermediates that are then converted into membrane lipid products. The movement of these lipids, especially membrane components, between different organelles is critical for maintaining the proper composition and properties of membranes and overall cell structure.

A fundamental principle of membrane biosynthesis is that cells synthesize new membranes only by the expansion of existing membranes. [The one exception may be autophagy, in which new membrane is formed first through the formation of an autophagic crescent, the construction of which involves modification of phosphatidylethanolamine with the ubiquitin-like modifier Atg8 (see Figure 14-35).] Although some early steps in the synthesis of membrane lipids take place in the cytosol, the final steps are catalyzed by enzymes bound to preexisting cellular membranes, and the products are incorporated into the membranes as they are generated. Evidence for this process is seen when cells are briefly exposed to radioactively labeled precursors (e.g., phosphates or fatty acids): all the phospholipids and sphingolipids incorporating these labeled precursors are associated with intracellular membranes; as expected from the hydrophobicity of the fatty acyl chains, none are found free in the cytosol.

After they are formed, membrane lipids must be distributed appropriately both between the leaflets of a given membrane and among the independent membranes of different organelles in eukaryotic cells, as well as the plasma membrane. Here we consider how this precise lipid distribution is accomplished; in Chapters 13 and 14, we discuss how membrane proteins are inserted into cellular membranes and trafficked to their appropriate location within the cell.

### Fatty Acids Are Assembled from Two-Carbon Building Blocks by Several Important Enzymes

Fatty acids (see Chapter 2) play a number of important roles in cells. In addition to being a cellular fuel source

(see the discussion of aerobic oxidation in Chapter 12), fatty acids are key components of both the phospholipids and the sphingolipids that make up cellular membranes; they also anchor some proteins to cellular membranes (see Figure 7-19). Thus the regulation of fatty acid synthesis plays a key role in the regulation of membrane synthesis as a whole. The major fatty acids in phospholipids contain 14, 16, 18, or 20 carbon atoms and include both saturated and unsaturated chains. The fatty acyl chains found on sphingolipids can be longer than those in the phosphoglycerides, containing up to 26 carbon atoms, and may bear other chemical modifications (e.g., hydroxylation) as well.

Fatty acids are synthesized from the two-carbon building block acetate ( $\text{CH}_3\text{COO}^-$ ). In cells, both acetate and the intermediates in fatty acid biosynthesis are esterified to a large water-soluble molecule called coenzyme A (CoA), as exemplified by the structure of **acetyl CoA** (below).

Acetyl CoA is an important intermediate in the metabolism of glucose, fatty acids, and many amino acids, as detailed in Chapter 12. It also contributes acetyl groups in many biosynthetic pathways. **Saturated** fatty acids (with no carbon-carbon double bonds) containing 14 or 16 carbon atoms are made from acetyl CoA by two enzymes, *acetyl-CoA carboxylase* and *fatty acid synthase*. In animal cells, these enzymes are found in the cytosol; in plants, they are found in chloroplasts. Palmitoyl CoA (a 16-carbon fatty acyl group linked to CoA) can be elongated to 18–24 carbons by the sequential addition of two-carbon units in the endoplasmic reticulum (ER) or sometimes in the mitochondrion. Desaturase enzymes, also located in the ER, introduce double bonds at specific positions in some fatty acids, yielding **unsaturated** fatty acids. Oleyl CoA (oleate linked to CoA; see Table 2-4), for example, is formed by removal of two H atoms from stearyl CoA. In contrast to free fatty acids, fatty acyl CoA derivatives are soluble in aqueous solutions because of the hydrophilicity of the CoA segment.

### Small Cytosolic Proteins Facilitate Movement of Fatty Acids

In order to be transported through the cell cytosol, free, or unesterified, fatty acids (those unlinked to CoA) are commonly bound by *fatty acid-binding proteins* (FABPs), which belong to a group of small cytosolic proteins that act as chaperones to facilitate the intracellular movement of many lipids. These proteins contain a hydrophobic pocket lined by  $\beta$  sheets (Figure 7-24). A long-chain fatty acid can fit into this pocket and interact noncovalently with the surrounding protein.

**FIGURE 7-24 Binding of a fatty acid to the hydrophobic pocket of a fatty acid-binding protein (FABP).** The crystal structure of adipocyte FABP (ribbon diagram) reveals that the hydrophobic binding pocket is generated from two  $\beta$  sheets that are nearly at right angles to each other, forming a clam shell-like structure. A fatty acid (carbons yellow; oxygens red) interacts noncovalently with hydrophobic amino acid residues within this pocket. See A. Reese-Wagoner et al., 1999, *Biochim. Biophys. Acta* **23**:1441(2–3):106–116. [Data from Z. Xu, D. A. Bernlohr, and L. J. Banaszak, 1993, *J. Biol. Chem.* **268**:7874, PDB ID 1lid.]

The expression of cellular FABPs is regulated coordinately with cellular requirements for the uptake and release of fatty acids. Thus FABP levels are high in active muscles that are using fatty acids for generation of ATP, and in adipocytes (fat-storing cells) when they are either taking up

fatty acids to be stored as triglycerides or releasing fatty acids for use by other cells. The importance of FABPs in fatty acid metabolism is highlighted by the observations that they can compose as much as 5 percent of all cytosolic proteins in the liver, and that genetic inactivation of cardiac muscle FABP converts the heart from a muscle that primarily burns fatty acids for energy into one that primarily burns glucose.

## Fatty Acids Are Incorporated into Phospholipids Primarily on the ER Membrane

Fatty acids are not directly incorporated into phospholipids; rather, in eukaryotic cells, they are first converted into CoA esters. The subsequent synthesis of phospholipids such as the phosphoglycerides is carried out by enzymes associated with the cytosolic face of the ER membrane, usually the smooth ER, in animal cells; through a series of steps, fatty acyl CoAs, glycerol 3-phosphate, and polar head group precursors are linked together and then inserted into the ER membrane (Figure 7-25). The fact that the enzymes involved in this process are located on the cytosolic side of the membrane means that there is an inherent asymmetry in membrane biogenesis: new membranes are initially synthesized only on one leaflet—a fact with important consequences for the asymmetric distribution of lipids in membrane leaflets. Once synthesized on the ER, phospholipids are transported to other organelles and to the plasma membrane. Mitochondria synthesize some of their own membrane lipids and import others.

**FIGURE 7-25 Phospholipid synthesis in the ER membrane.** Because phospholipids are amphipathic molecules, the last steps of their multistep synthesis take place at the interface between a membrane and the cytosol and are catalyzed by membrane-associated enzymes. Step **1**: Two fatty acids from fatty acyl CoA are esterified to the phosphorylated glycerol backbone, forming phosphatidic acid, whose two long hydrocarbon

chains anchor the molecule to the membrane. Step **2**: A phosphatase converts phosphatidic acid into diacylglycerol. Step **3**: A polar head group (e.g., phosphorylcholine) is transferred from cytosine diphosphocholine (CDP-choline) to the exposed hydroxyl group. Step **4**: Flippase proteins catalyze the movement of phospholipids from the cytosolic leaflet in which they are initially formed to the exoplasmic leaflet.

Sphingolipids are also synthesized indirectly from multiple precursors. Sphingosine, the building block of these lipids, is made in the ER, beginning with the coupling of a palmitoyl group from palmitoyl CoA to serine; the subsequent addition of a second fatty acyl group to form *N*-acyl sphingosine (ceramide) also takes place in the ER. Later, in the Golgi, a polar head group is added to ceramide, yielding *sphingomyelin*, whose head group is phosphorylcholine, and various *glycosphingolipids*, in which the head group may be a monosaccharide or a more complex oligosaccharide (see Figure 7-8b). Some sphingolipid synthesis can also take place in mitochondria. In addition to serving as the backbone for sphingolipids, ceramide and its metabolic products are important signaling molecules that can influence cell growth, proliferation, endocytosis, resistance to stress, and programmed cell death (apoptosis).

After their synthesis is completed in the Golgi, sphingolipids are transported to other cellular compartments through vesicle-mediated mechanisms similar to those for the transport of proteins, discussed in Chapter 14. Any type of vesicular transport results in movement not only of the protein payload, but also of the lipids that compose the vesicular membrane. Phospholipids such as phosphoglycerides, as well as cholesterol, can move between organelles by additional mechanisms, described below.

## Flippases Move Phospholipids from One Membrane Leaflet to the Opposite Leaflet

Even though phospholipids are initially incorporated into the cytosolic leaflet of the ER membrane, various phospholipids are asymmetrically distributed in the two leaflets of the ER membrane and of other cellular membranes. As noted above, phospholipids do not readily flip-flop from one leaflet to the other. For the ER membrane to expand by growth of both leaflets and to have asymmetrically distributed phospholipids, its phospholipid components must be able to move from one leaflet to the other. Although the mechanisms employed to generate and maintain membrane phospholipid asymmetry are not well understood, it is clear that flippases play a key role. As described in Chapter 11, these integral membrane proteins use the energy of ATP hydrolysis to facilitate the movement of phospholipid molecules from one leaflet to the other (see Figure 11-16).

## Cholesterol Is Synthesized by Enzymes in the Cytosol and ER Membrane

Next we focus on cholesterol, the principal sterol in animal cells. Cholesterol is synthesized mainly in the liver. The first steps of cholesterol synthesis (Figure 7-26)—conversion of

**FIGURE 7-26 Cholesterol biosynthetic pathway.** The regulated rate-controlling step in cholesterol biosynthesis is the conversion of  $\beta$ -hydroxy- $\beta$ -methylglutaryl CoA (HMG-CoA) into mevalonate by HMG-CoA reductase, an ER-membrane protein. Mevalonate is then converted into isopentenyl pyrophosphate (IPP), which has the basic

five-carbon isoprenoid structure. IPP can be converted into cholesterol and into many other lipids, often through the polyisoprenoid intermediates shown here. Some of the numerous compounds derived from isoprenoid intermediates and cholesterol itself are indicated.

three acetyl groups linked to CoA (acetyl CoA) forming the six-carbon molecule  $\beta$ -hydroxy- $\beta$ -methylglutaryl linked to CoA (HMG-CoA)—take place in the cytosol. The conversion of HMG-CoA into mevalonate, the key rate-controlling step in cholesterol biosynthesis, is catalyzed by *HMG-CoA reductase*, an ER integral membrane protein, even though both its substrate and its product are water soluble. The water-soluble catalytic domain of HMG-CoA reductase extends into the cytosol, but its eight transmembrane  $\alpha$  helices firmly embed the enzyme in the ER membrane. Five of the transmembrane  $\alpha$  helices compose the so-called *sterol-sensing domain* and regulate enzyme stability. When levels of cholesterol in the ER membrane are high, binding of cholesterol to this domain causes the enzyme to bind to two other integral ER membrane proteins, Insig-1 and Insig-2. This binding, in turn, induces ubiquitinylation (see Figure 3-31) of HMG-CoA reductase and its degradation by the proteasome pathway, reducing the production of mevalonate, the key intermediate in cholesterol biosynthesis.

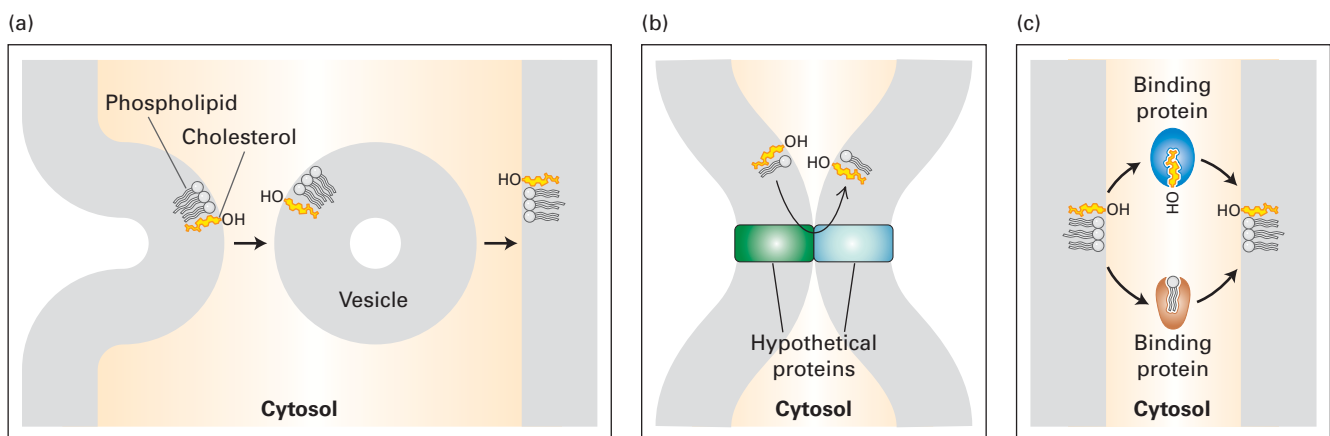

**Atherosclerosis**, frequently called cholesterol-dependent clogging of the arteries, is characterized by the progressive deposition of cholesterol and other lipids, cells, and extracellular matrix material in the inner layer of the wall of an artery. The resulting distortion of the artery's wall can lead, either alone or in combination with a blood clot, to major blockage of blood flow. Atherosclerosis accounts for 75 percent of deaths due to cardiovascular disease in the United States.

Perhaps the most successful anti-atherosclerosis medications are the *statins*. These drugs bind to HMG-CoA reductase and directly inhibit its activity, thereby lowering cholesterol biosynthesis. As a consequence, the concentration of low-density lipoproteins (see Figure 14-27)—the small, membrane-enveloped particles containing cholesterol esterified to fatty acids that often and rightly are called “bad cholesterol”—drops in the blood, reducing the formation of atherosclerotic plaques. ■

Mevalonate, the six-carbon product formed by HMG-CoA reductase, is converted in several steps into the five-carbon isoprenoid compound isopentenyl pyrophosphate (IPP) and its stereoisomer, dimethylallyl pyrophosphate (DMPP) (see Figure 7-26). These reactions are catalyzed by cytosolic enzymes, as are the subsequent reactions in the cholesterol synthesis pathway, in which six IPP units condense to yield squalene, a branched-chain 30-carbon intermediate. Enzymes bound to the ER membrane catalyze the multiple reactions that convert squalene into cholesterol in mammals or into related sterols in other species. One of the intermediates in this pathway, farnesyl pyrophosphate, is the precursor of the prenyl lipid that anchors Ras and related proteins to the cytosolic surface of the plasma membrane (see Figure 7-19) as well as other important biomolecules (see Figure 7-26).

### Cholesterol and Phospholipids Are Transported Between Organelles by Several Mechanisms

As already noted, the final steps in the synthesis of cholesterol and phospholipids take place primarily in the ER. Thus the plasma membrane and the membranes bounding other organelles must obtain these lipids by means of one or more intracellular transport processes. Membrane lipids can and do accompany both soluble and membrane proteins along the secretory pathway described in Chapter 14: membrane vesicles bud from the ER and fuse with membranes in the Golgi complex, and other membrane vesicles bud from the Golgi complex and fuse with the plasma membrane (Figure 7-27a). However, several lines of evidence suggest that there is substantial inter-organelle movement of cholesterol and phospholipids through other mechanisms. For example, chemical inhibitors of the classic secretory pathway and mutations that impede vesicular traffic along this pathway do not prevent cholesterol or phospholipid transport between membranes.

**FIGURE 7-27 Proposed mechanisms of transport of cholesterol and phospholipids between membranes.** In mechanism (a), vesicles transfer lipids between membranes. In mechanism (b), lipid transfer is a consequence of direct contact between membranes that is

mediated by membrane-embedded proteins. In mechanism (c), transfer is mediated by small, soluble lipid-transfer proteins. See F. R. Maxfield and D. Wustner, 2002, *J. Clin. Invest.* **110**:891.

A second proposed mechanism of lipid movement entails direct protein-mediated contact of ER or ER-derived membranes with the membranes of other organelles (Figure 7-27b). In a third proposed mechanism, small lipid-transfer proteins facilitate the exchange of phospholipids or cholesterol between different membranes (Figure 7-27c). Although such lipid-transfer proteins have been identified in assays *in vitro*, their role in the intracellular movements of most phospholipids is not well defined. For instance, mice with a knockout mutation in the gene encoding the phosphatidylcholine-transfer protein appear to be normal in most respects, indicating that this protein is not essential for cellular phospholipid metabolism.

As noted earlier, the lipid compositions of different organelle membranes vary considerably (see Table 7-1). Some of these differences are due to different sites of synthesis. For example, a phospholipid called cardiolipin, which is localized to the mitochondrial membrane, is made only in mitochondria, and little of it is transferred to other organelles. Differential transport of lipids also plays a role in determining the lipid compositions of different cellular membranes. For instance, even though cholesterol is made in the ER, the cholesterol concentration (cholesterol-to-phospholipid molar ratio) is 1.5–13-fold higher in the plasma membrane than in other organelles (ER, Golgi, mitochondrion, lysosome). Although the mechanisms responsible for establishing and maintaining these differences are not well understood, we have seen that the distinctive lipid composition of each membrane has a major influence on its physical and biological properties.

- Most membrane phospholipids are preferentially distributed in either the exoplasmic or the cytosolic leaflet. This asymmetry results in part from the action of flippases, which flip phospholipids from one leaflet to the other.
- The initial steps in cholesterol biosynthesis take place in the cytosol, whereas the last steps are catalyzed by enzymes associated with the ER membrane.
- The rate-controlling step in cholesterol biosynthesis is catalyzed by HMG-CoA reductase, whose transmembrane segments are embedded in the ER membrane and contain a sterol-sensing domain.
- Considerable evidence indicates that vesicular transport, direct protein-mediated contacts between different membranes, soluble lipid-transfer proteins, or all three may account for some inter-organelle transport of cholesterol and phospholipids (see Figure 7-27).

## KEY CONCEPTS OF SECTION 7.3

### Phospholipids, Sphingolipids, and Cholesterol: Synthesis and Intracellular Movement

- Saturated and unsaturated fatty acids of various chain lengths are components of phospholipids and sphingolipids.
- Fatty acids are synthesized from acetyl CoA by water-soluble enzymes and modified by elongation and desaturation in the endoplasmic reticulum (ER).
- Free fatty acids are transported within cells by fatty acid-binding proteins (FABPs).
- Fatty acids are incorporated into phospholipids through a multistep process. The final steps in the synthesis of phosphoglycerides and sphingolipids are catalyzed by membrane-associated enzymes primarily on the cytosolic face of the ER (see Figure 7-25).
- Each type of newly synthesized lipid is incorporated into the preexisting membranes on which it is made; thus, membranes are themselves the platform for the synthesis of new membrane material.

## Key Terms

amphipathic 273	lipid raft 282
aquaporin 286	liposome 273
atherosclerosis 296	lumen 275
cholesterol 278	membrane transport protein 271

## Review the Concepts

1. When viewed by electron microscopy, the lipid bilayer is often described as looking like a railroad track. Explain how the structure of the bilayer creates this image.
2. Explain the following statement: The structure of all biomembranes depends on the chemical properties of phospholipids, whereas the function of each specific biomembrane depends on the specific proteins associated with that membrane.
3. Biomembranes contain many different types of lipid molecules. What are the three main types of lipid molecules found in biomembranes? How are the three types similar, and how are they different?
4. Lipid bilayers are said to behave like two-dimensional fluids. What does this mean? What drives the movement of lipid molecules and proteins within the bilayer? How can such movement be measured? What factors affect the degree of membrane fluidity?
5. Why are water-soluble substances unable to freely cross the lipid bilayer of the plasma membrane? How does the cell overcome this permeability barrier?
6. Name the three groups into which membrane-associated proteins may be classified. Explain the mechanism by which each group associates with a biomembrane.
7. Identify the following membrane-associated proteins based on their structure: (a) tetramers of identical subunits, each with six membrane-spanning  $\alpha$  helices; (b) trimers of identical subunits, each with 16  $\beta$  sheets forming a barrel-like structure.
8. Proteins may be bound to the exoplasmic or cytosolic face of the plasma membrane by way of covalently attached lipids. What are the three types of lipid anchors responsible for tethering proteins to the plasma-membrane bilayer? Which type is used by cell-surface proteins that face the external medium? By glycosylated proteoglycans?
9. Although both faces of a biomembrane are composed of the same general types of macromolecules, principally lipids and proteins, the two faces of the bilayer are not identical. What accounts for the asymmetry between the two faces?
10. What are detergents? How do ionic and non-ionic detergents differ in their ability to disrupt biomembrane structure?
11. What is the likely identity of these membrane-associated proteins: (a) a protein that is released from a membrane treated with a high-salt solution, which causes disruption of ionic linkages; (b) a protein that is not released from the membrane upon its exposure to a high-salt solution alone, but is released when the membrane is incubated with an enzyme that cleaves phosphate-glycerol bonds and covalent linkages are disrupted; (c) a protein that is not released from the membrane upon exposure to a high-salt solution, but is released after the addition of the detergent sodium dodecyl-sulfate (SDS). Will the activity of the protein released in part (c) be preserved following its release?

12. Following the production of membrane extracts using the non-ionic detergent Triton X-100, you analyze the membrane lysates via mass spectrometry and note a high content of cholesterol and sphingolipids. Furthermore, biochemical analysis of the lysates reveals potential kinase activity. What have you probably isolated?
13. Phospholipid biosynthesis at the interface between the endoplasmic reticulum (ER) and the cytosol presents a number of challenges that must be solved by the cell. Explain how each of the following is handled.
  - a. The substrates for phospholipid biosynthesis are all water soluble, yet the end products are not.
  - b. The immediate site of incorporation of all newly synthesized phospholipids is the cytosolic leaflet of the ER membrane, yet phospholipids must be incorporated into both leaflets.
  - c. Many membrane systems in the cell, such as the plasma membrane, are unable to synthesize their own phospholipids, yet these membranes must also expand if the cell is to grow and divide.
14. What are the common fatty acid chains in phosphoglycerides, and why do these fatty acid chains differ in their number of carbon atoms by multiples of 2?
15. Fatty acids must associate with lipid chaperones in order to move within the cell. Why are these chaperones needed, and what is the name given to a group of proteins that are responsible for this intracellular trafficking of fatty acids? What is the key distinguishing feature of these proteins that allows fatty acids to move within the cell?
16. The biosynthesis of cholesterol is a highly regulated process. What is the key regulated enzyme in cholesterol biosynthesis? This enzyme is subject to feedback inhibition. What is feedback inhibition? How does this enzyme sense cholesterol levels in a cell?
17. Phospholipids and cholesterol must be transported from their site of synthesis to various membrane systems within cells. One way of doing this is through vesicular transport, as is the case for many proteins in the classic secretory pathway (see Chapter 14). However, phospholipid and cholesterol membrane-to-membrane transport in cells does not occur solely by vesicular transport. What is the evidence for this statement? What appear to be the major mechanisms for phospholipid and cholesterol transport?
18. Explain the mechanism by which statins lower “bad” cholesterol.

These brightly colored FISH-painted chromosomes are not only beautiful, but also useful in revealing chromosome anomalies and in comparing karyotypes of different species. [L. Willatt/Science Source.]

# Genes, Genomics, and Chromosomes

**In previous chapters**, we learned how the structure and composition of proteins allow them to perform a wide variety of cellular functions. We also examined another vital component of cells, the nucleic acids, and the process by which information encoded in the sequence of DNA is translated into protein. In this chapter, our focus again is on DNA and proteins as we consider the characteristics of eukaryotic nuclear genomes: the features of genes and the other DNA sequences that constitute the genome, and how this DNA is structured and organized by proteins within the cell.

By the beginning of the twenty-first century, molecular biologists had completed the sequencing of the entire genomes of hundreds of viruses, scores of bacteria, and one unicellular eukaryote, the budding yeast *S. cerevisiae*. By now, the vast majority of the genomic sequence is also known for the fission yeast *S. pombe*, the simple plant *A. thaliana*, rice, and multiple multicellular animals (metazoans), including the roundworm *C. elegans*, the fruit fly *D. melanogaster*, mice, humans, and at least one representative each of the 35 or so metazoan phyla. Detailed analysis of these sequencing data has revealed insights into evolution, genome organization,

and gene function. It has also allowed researchers to identify previously unknown genes and to estimate the total number of protein-coding genes in each genome. Comparisons between gene sequences often provide insight into possible functions of newly identified genes. Comparisons of genomic sequence and organization between species also help us understand the evolution of organisms.

Surprisingly, DNA sequencing revealed that large portions of the genomes of metazoans and plants do not encode mRNAs or any other RNAs required by the organism. Remarkably, such noncoding DNA constitutes about 98.5 percent of human chromosomal DNA! The noncoding DNA in multicellular organisms contains many regions that are similar, but not identical, to one another. Variations within some stretches of this *repetitious* DNA between individuals are so great that every person can be distinguished by a DNA “fingerprint” based on these sequence variations. Moreover, some repetitious DNA sequences are not found in the same positions in the genomes of different individuals of the same species. At one time, all noncoding DNA was collectively termed “junk DNA” and was considered to serve

### 8.5 Structural Organization of Eukaryotic Chromosomes

### 8.6 Morphology and Functional Elements of Eukaryotic Chromosomes

no purpose. We now understand the evolutionary basis of all this extra DNA, and of the variation in location of certain sequences between individuals. Cellular genomes harbor transposable (mobile) DNA elements that can copy themselves and move throughout the genome. Although transposable DNA elements seem to have little function in the life cycle of an individual organism, over evolutionary time they have shaped our genomes and contributed to the rapid evolution of multicellular organisms. Moreover, we now understand that much of the DNA that does not encode proteins or stable RNAs functions as binding sites for protein complexes that regulate gene transcription.

The sheer length of cellular DNA is a significant problem with which cells must contend. The DNA in a single human cell, which measures about 2 m in total length, must be contained within nuclei with diameters of less than 10  $\mu\text{m}$ , a compaction ratio of greater than  $10^5$  to 1. In relative terms, if a cell were 1 cm in diameter (about the size of a pea), the length of DNA packed into its nucleus would be about 2 km (1.2 miles)! Specialized eukaryotic proteins associated with nuclear DNA exquisitely fold and organize the DNA so that it fits into nuclei. And yet, at the same time, any given portion of this highly compacted DNA can be accessed readily for transcription, replication, and repair of damage without the long DNA molecules becoming tangled or broken. Furthermore, the integrity of DNA must be maintained during the process of cell division when it is partitioned into daughter cells. In eukaryotes, the complex of DNA and the

proteins that organize it, called chromatin, can be visualized as individual chromosomes during mitosis. As we will see in this and the following chapter, the organization of DNA into chromatin allows a mechanism for regulation of gene expression that is not available in bacteria.

In the first four sections of this chapter, we provide an overview of the landscape of eukaryotic genes and genomes. First we discuss the structure of eukaryotic genes and the complexities that arise in higher organisms from the processing of mRNA precursors into alternatively spliced mRNAs. Next we discuss the main classes of eukaryotic DNA, including the special properties of transposable DNA elements and how they have shaped contemporary genomes. This background prepares us to discuss **genomics**, computer-based methods for analyzing and interpreting vast amounts of sequence data. The final two sections of the chapter address how DNA is physically organized in eukaryotic cells. We consider the packaging of DNA and histone proteins into the compact complexes called nucleosomes that are the fundamental building blocks of chromatin, the large-scale structure of chromosomes, and the functional elements required for chromosome duplication and segregation. Figure 8-1 provides an overview of these interrelated subjects. The understanding of genes, genomics, and chromosomes gained in this chapter will prepare us to explore current knowledge about how the synthesis and concentration of each protein and functional RNA in a cell is regulated in the following two chapters.

**FIGURE 8-1 Overview of the structure of genes and chromosomes.**

DNA of higher eukaryotes consists of both unique and repeated sequences. Only about 1.5 percent of human DNA encodes proteins and functional RNAs. The remainder includes regulatory sequences that control gene expression, which are scattered through intergenic DNA between genes and in introns within genes. Much of this intergenic DNA, about 45 percent in humans, is derived from mobile DNA elements, genetic symbionts that have contributed to the evolution of contemporary genomes. Each chromosome consists of a single long molecule of DNA (as long as 280 Mb in humans), organized into increasing levels of condensation by the histone and nonhistone proteins with which it is intricately complexed. Each chromosome occupies its own "territory" in the nucleus.

## 8.1 Eukaryotic Gene Structure

In molecular terms, a *gene* is commonly defined as *the entire nucleic acid sequence that is necessary for the synthesis of a functional gene product (polypeptide or RNA)*. According to this definition, a gene includes more than the nucleotides encoding an amino acid sequence or a functional RNA, referred to as the *coding region*. A gene also includes all the DNA sequences required for synthesis of a particular RNA transcript, no matter where those sequences are located in relation to the coding region. For example, in eukaryotic genes, transcription-control regions known as **enhancers** can lie 50 kb or more from the coding region. As we learned in Chapter 5, other critical noncoding regions in eukaryotic genes include not only the promoter, but also sequences that specify 3' cleavage and polyadenylation, known as *poly(A) sites*, and splicing of primary RNA transcripts, known as *splice sites* (see Figure 5-15). Mutations in these sequences, which control transcription initiation and RNA processing, affect the normal expression and function of RNAs, producing distinct phenotypes in mutant organisms. We examine these various control elements of genes in greater detail in Chapters 9 and 10.

Although most genes are transcribed into mRNAs, which encode proteins, some DNA sequences are transcribed into RNAs that do not encode proteins [e.g., tRNAs and rRNAs, described in Chapters 5 and 10; miRNAs and siRNAs that regulate mRNA translation and stability, discussed in Chapter 10; and long noncoding RNAs (lncRNAs) that regulate transcription, discussed in Chapter 9]. Because the DNA sequences that encode tRNAs, rRNAs, miRNAs, siRNAs, and lncRNAs can cause specific phenotypes when they are mutated, these DNA regions are generally referred to as tRNA, rRNA, miRNA, siRNA, and lncRNA *genes*, even though the final products of these genes are RNA molecules and not proteins.

In this section, we will examine the structure of genes in bacteria and eukaryotes and discuss how their respective gene structures influence their gene expression and evolution.

### Most Eukaryotic Genes Contain Introns and Produce mRNAs Encoding Single Proteins

As discussed in Chapter 5, many bacterial mRNAs (e.g., the mRNA encoded by the *trp* operon) include the coding region for several proteins that function together in a biological process. Such mRNAs are said to be *polycistronic*. (A *cistron* is a genetic unit encoding a single polypeptide.) In contrast, most eukaryotic mRNAs are *monocistronic*; that is, each mRNA molecule encodes a single protein. This difference between polycistronic and monocistronic mRNAs correlates with a fundamental difference in their translation.

Within a bacterial polycistronic mRNA, a ribosome-binding site is located near the start site for each of the protein-coding regions, or cistrons, in the mRNA. Translation initiation can begin at any of these multiple internal sites, producing multiple proteins (see Figure 5-13a). In most eukaryotic mRNAs, however, the 5' cap directs ribosome

binding, and translation begins at the closest AUG start codon (see Figure 5-13b). As a result, translation begins only at this site. In many cases, the primary transcripts of eukaryotic protein-coding genes are processed into a single type of mRNA, which is translated to give a single type of polypeptide (see Figure 5-15).

Unlike bacterial and yeast genes, which generally lack introns, most genes in multicellular animals and plants contain introns, which are removed during RNA processing in the nucleus before the fully processed mRNA is exported to the cytosol for translation. In many cases, the introns in a gene are considerably longer than the exons. The median intron length in human genes is 3.3 kb. Some, however, are much longer: the longest known human intron is 17,106 bp and lies within the *titin* gene, which encodes a structural protein in muscle cells. In comparison, most human exons contain only 50–200 bp. The typical human gene encoding an average-sized protein is about 50,000 bp long, but more than 95 percent of that sequence consists of introns and flanking noncoding 5' and 3' regions.

Many large proteins in higher organisms that have repeated domains are encoded by genes consisting of repeats of similar exons separated by introns of variable length. An example is fibronectin, a component of the extracellular matrix. The fibronectin gene contains multiple copies of five types of exons (see Figure 5-16). Such genes evolved by tandem duplication of the DNA encoding the repeated exon, probably by unequal crossing over during meiosis, as shown in Figure 8-2a.

### Simple and Complex Transcription Units Are Found in Eukaryotic Genomes

The cluster of genes that forms a bacterial operon constitutes a single **transcription unit**, which is transcribed from a specific promoter in the DNA sequence to a termination site, producing a single primary transcript. In other words, genes and transcription units are often distinguishable in prokaryotes, since a single transcription unit contains several genes when they are part of an operon. In contrast, most eukaryotic genes are expressed from separate transcription units, so that each mRNA is translated into a single protein.

Eukaryotic transcription units, however, are classified into two types, depending on the fate of the primary transcript. The primary transcript produced from a *simple* transcription unit, such as the one encoding  $\beta$ -globin (see Figure 5-15), is processed to yield a single type of mRNA, encoding a single protein. Mutations in exons, introns, and transcription-control regions may all influence expression of the protein encoded by a simple transcription unit (Figure 8-3a). In humans, simple transcription units such as the one encoding  $\beta$ -globin are rare. Approximately 90 percent of human transcription units are *complex*. In these cases, the primary RNA transcript can be processed in more than one way, leading to formation of mRNAs containing different exons. Each alternative mRNA, however, is monocistronic: it is translated into a single polypeptide, with translation usually initiating at the first AUG in the mRNA.

### (a) Exon duplication

### (b) Gene duplication

**FIGURE 8-2 Exon and gene duplication.** (a) Exon duplication results from unequal crossing over during meiosis. Each parental chromosome (*top*) contains one ancestral gene containing three exons (blue) and two introns (orange). Homologous noncoding sequences called L1 long interspersed elements lie 5' and 3' of the gene as well as in the intron between exons 2 and 3. As we will see later in the chapter, L1 elements have been repeatedly transposed to new sites in the genome over the course of human evolution, so that all chromosomes are peppered with them. The parental chromosomes are shown displaced relative to each other, so that the L1 elements are aligned. Homologous recombination between these L1 elements as shown

would generate one recombinant chromosome in which the gene now has four exons (two copies of exon 3) and one chromosome in which the gene is missing exon 3. (b) The same process can generate duplications of entire genes. Each parental chromosome (*top*) contains one ancestral  $\beta$ -globin gene. After unequal recombination between L1 elements, subsequent independent mutations in the resulting duplicated genes could lead to slight changes in sequence that might result in slightly different functional properties of the encoded proteins. Unequal crossing over can also result from rare recombinations between unrelated sequences. See D. H. A. Fitch et al., 1991, *Proc. Natl. Acad. Sci. USA* **88**:7396.

Multiple mRNAs can arise from a primary transcript in three ways, as shown in Figure 8-3b. Examples of all three types of alternative RNA processing occur in the genes that regulate sexual differentiation in *Drosophila* (see Figure 10-18). Commonly, one mRNA is produced from a complex transcription unit in some cell types, and a different mRNA is made in other cell types. For example, **alternative splicing** of the primary fibronectin transcript in fibroblasts and hepatocytes determines whether or not the secreted protein includes domains that adhere to cell surfaces (see Figure 5-16). The phenomenon of alternative splicing greatly expands the number of proteins encoded in the genomes of higher organisms. It is estimated that about 90 percent of human genes are contained within complex transcription units that give rise to alternatively spliced mRNAs encoding proteins with distinct functions, as for the fibroblast and hepatocyte forms of fibronectin.

The relationship between a mutation and a gene is not always straightforward when it comes to complex transcription units. A mutation in the control region or in an exon shared by alternatively spliced mRNAs will affect all the alternative proteins encoded by a given complex transcription unit. On the other hand, a mutation in an exon present in only one of the alternative mRNAs will affect only the protein encoded by that mRNA. As explained in Chapter 6, **genetic complementation** tests are commonly used to determine if two mutations are in the same or different genes (see Figure 6-7). However, in the complex transcription unit shown in Figure 8-3b (*middle*), mutations *d* and *e* would complement each other in a genetic complementation test, even though they occur in the same gene, because a chromosome with mutation *d* can express a normal protein encoded by mRNA<sub>2</sub> and a chromosome with mutation *e* can express a normal protein encoded by mRNA<sub>1</sub>. Both mRNAs

### (a) Simple transcription unit

### (b) Complex transcription units

produced from this gene would be present in a diploid cell carrying both mutations, generating both protein products and hence a wild-type phenotype. However, a chromosome with mutation *c* in an exon common to both mRNAs would not complement either mutation *d* or mutation *e*. In other words, mutation *c* would be in the same complementation groups as mutations *d* and *e*, even though *d* and *e* themselves would not be in the same complementation group! Given these complications with the genetic definition of a gene, the genomic definition outlined at the beginning of this section is commonly used. In the case of protein-coding genes, a gene is the DNA sequence transcribed into a pre-mRNA precursor, equivalent to a transcription unit, plus any other

### FIGURE 8-3 Simple and complex eukaryotic transcription units.

(a) A simple transcription unit includes a region that encodes one protein, extending from the 5' cap site to the 3' poly(A) site, and associated control regions. Introns lie between exons (light blue rectangles) and are removed during processing of the primary transcripts (dashed red lines); thus they do not occur in the functional monocistronic mRNA. Mutations in a transcription-control region (*a*, *b*) may reduce or prevent transcription, thus reducing or eliminating synthesis of the encoded protein. A mutation within an exon (*c*) may result in an abnormal protein with diminished activity. A mutation within an intron (*d*) that introduces a new splice site results in an abnormally spliced mRNA encoding a nonfunctional protein. (b) Complex transcription units produce primary transcripts that can be processed in alternative ways. (Top) If a primary transcript contains alternative splice sites, it can be processed into mRNAs with the same 5' and 3' exons but different internal exons. (Middle) If a primary transcript has two poly(A) sites, it can be processed into mRNAs with alternative 3' exons. (Bottom) If alternative promoters (*f* or *g*) are active in different cell types, mRNA<sub>1</sub>, produced in a cell type in which *f* is activated, has a different first exon (1A) than mRNA<sub>2</sub>, which is produced in a cell type in which *g* is activated (and in which exon 1B is used). Mutations in control regions (*a* and *b*) and in regions within exons shared by the alternative mRNAs (designated *c*) affect the proteins encoded by both alternatively processed mRNAs. In contrast, mutations (designated *d* and *e*) within exons unique to one of the alternatively processed mRNAs affect only the protein translated from that mRNA. For genes that are transcribed from different promoters in different cell types (bottom), mutations in different control regions (*f* and *g*) affect expression only in the cell type in which that control region is active.

regulatory elements required for synthesis of the primary transcript. The various proteins encoded by the alternatively spliced mRNAs expressed from one gene are called **isoforms**.

### Protein-Coding Genes May Be Solitary or Belong to a Gene Family

The nucleotide sequences within chromosomal DNA can be classified on the basis of their structure and function, as shown in Table 8-1. Here we examine the properties of each class, beginning with protein-coding genes, which comprise two groups.

In multicellular organisms, roughly 25–50 percent of the protein-coding genes are represented only once in the haploid genome and thus are termed *solitary* genes. A well-studied example of a solitary protein-coding gene is the chicken lysozyme gene. Lysozyme, an enzyme that cleaves the polysaccharides in bacterial cell walls, is an abundant component of chicken egg-white protein and is also found in human tears. Its activity helps to keep the egg and the surface of the eye sterile. The 15-kb DNA sequence encoding chicken lysozyme constitutes a simple transcription unit containing four exons and three introns. The flanking regions, extending about 20 kb upstream and downstream from the transcription unit, do not encode any detectable mRNAs, and are thus examples of intergenic regions.

*Duplicated* genes constitute the second group of protein-coding genes. These genes have close but nonidentical

**TABLE 8-1 Major Classes of Nuclear Eukaryotic DNA and Their Representation in the Human Genome**

Class	Length	Copy Number in Human Genome	Fraction of Human Genome (%)*
Protein-coding genes	0.5–2200 kb	~21,000	~40** (2.0†)
Long noncoding RNA genes	0.2–50 kb	~10,000	~15 (0.9†)
Tandemly repeated genes			
U2 snRNA	6.1 kb‡	~20	<0.0001
rRNAs	43 kb‡	~300	0.4
Repetitious DNA			
Simple-sequence DNA	1–500 bp	Variable	~6
Interspersed repeats (mobile DNA elements)			
DNA transposons	2–3 kb	300,000	3
LTR retrotransposons	6–11 kb	440,000	8
Non-LTR retrotransposons			
LINEs	6–8 kb	860,000	21
SINEs	100–400 bp	1,600,000	13
Processed pseudogenes	Variable	~12,500	~0.4
Intergenic regions	Variable	n.a.	~25

\*The sum of “Fraction of the Human Genome (%)” totals more than 100% because mobile DNA elements are counted twice: once to show the different classes of human mobile DNA elements; and second as part of the intergenic regions and protein coding genes where they are located in introns and 3' untranslated regions of terminal exons.

\*\*Complete transcription units including exons and introns.

† Total length of all exons. Protein-coding regions total 1.2 percent of the genome.

‡ Length of each repeat in a tandemly repeated sequence.

SOURCE: Data from International Human Genome Sequencing Consortium, 2001, *Nature* 409:860 and 2004, *Nature* 431:931.

sequences and are often located within 5–50 kb of one another. A set of duplicated genes that encodes proteins with similar but nonidentical amino acid sequences is called a **gene family**; the encoded, closely related, homologous proteins constitute a **protein family**. A few protein families, such as protein kinases, vertebrate immunoglobulins, and olfactory receptors, include hundreds of members. Most protein families, however, include from just a few to 30 or so members; common examples are cytoskeletal proteins, the myosin heavy chain, and the  $\alpha$ -likes and  $\beta$ -likeas globins in vertebrates.

The genes encoding the  $\beta$ -likeas globins are a good example of a gene family. As shown in Figure 8-4a, the  $\beta$ -likeas globin gene family contains five functional genes, designated *HBB* (encoding the most abundant adult  $\beta$ -globin), *HBD* (a minor adult  $\beta$ -globin), *HBG1* and *HBG2* (fetal  $\beta$ -globins), and *HBE1* (embryonic  $\beta$ -globin). Two identical  $\beta$ -likeas globin polypeptides combine with two identical  $\alpha$ -likes globin polypeptides (encoded by another gene family expressed during embryonic, fetal, and adult stages of development) and four heme prosthetic groups to form a hemoglobin molecule (see Figures 3-14 and 12-20). All the hemoglobins formed from the different  $\alpha$ -likes and  $\beta$ -likeas globins carry oxygen in the blood, but they exhibit somewhat different properties that are suited to their specific functions in human physiology.

For example, hemoglobins containing either the *HBG1*- or *HBG2*-encoded polypeptides are expressed only during fetal life. Because these fetal hemoglobins have a higher affinity for oxygen than adult hemoglobins, they can effectively extract oxygen from the maternal circulation in the placenta. The lower oxygen affinity of adult hemoglobins, which are expressed after birth, permits better release of oxygen to the tissues, especially muscles, which have a high demand for oxygen during exercise. The embryonic hemoglobin assembled from polypeptides encoded by the *HBE1* gene and the embryonic  $\alpha$ -likes globin gene *HBZ* has an even higher affinity for oxygen than the fetal and adult hemoglobins.

The different  $\beta$ -like globin genes arose by duplication of an ancestral gene, most likely as the result of unequal crossing over during meiotic recombination in a developing germ cell (egg or sperm) (see Figure 8-2b). Over evolutionary time, the two copies of the gene that resulted accumulated random mutations, resulting in *sequence drift*. Beneficial mutations that conferred some refinement in the basic oxygen-carrying function of hemoglobin were retained by natural selection. Repeated gene duplications and subsequent sequence drift and selection are thought to have generated the contemporary  $\beta$ -likeas globin genes observed in humans and other mammals today.

(a) Human  $\beta$ -globin gene cluster (chromosome 11)

(b) *S. cerevisiae* (chromosome III)

**FIGURE 8-4 Comparison of gene density in higher and lower eukaryotes.** (a) In this diagram of the  $\beta$ -globin gene cluster on human chromosome 11, the green boxes represent exons of  $\beta$ -globin-related genes. Exons spliced together to form one mRNA are connected by caret-like spikes. The human  $\beta$ -globin gene cluster contains two pseudogenes (white); these regions are related to the functional  $\beta$ -globin genes but are not transcribed. Each red arrow indicates the location of an *Alu* sequence, a roughly 300-bp noncoding repeated

sequence that is abundant in the human genome. See F. S. Collins and S. M. Weissman, 1984, *Prog. Nucl. Acid Res. Mol. Biol.* **31**:315. (b) In this diagram of yeast DNA from chromosome III, the green boxes indicate open reading frames. Most of these potential protein-coding sequences are functional genes without introns. Note the much higher proportion of noncoding to coding sequences in the human DNA than in the yeast DNA. See S. G. Oliver et al., 1992, *Nature* **357**:28.

Two regions in the human  $\beta$ -like globin gene cluster contain nonfunctional sequences, called **pseudogenes**, that are similar to the functional  $\beta$ -like globin genes (see Figure 8-4a). Sequence analysis shows that these pseudogenes have the same apparent exon–intron structure as the functional  $\beta$ -like globin genes, suggesting that they arose by duplication of the same ancestral gene. However, there was little selective pressure to maintain the function of these genes. Consequently, sequence drift during evolution generated sequences that either terminate translation or block mRNA processing, rendering these regions nonfunctional. Because such pseudogenes are not deleterious, they remain in the genome and mark the location of a gene duplication that occurred in one of our ancestors.

Duplications of segments of a chromosome (called *segmental duplication*) occurred fairly often during the evolution of multicellular plants and animals. As a result, a large fraction of the genes in these organisms today have been duplicated, allowing the process of sequence drift to generate gene families and pseudogenes. The extent of sequence divergence between duplicated copies of the genome and characterization of the homologous genomic sequences in related organisms allow us to estimate the time in evolutionary history when the duplication occurred. For example, the human fetal globin genes (HGB1 and HGB2) evolved following the duplication of a 5.5-kb region in the  $\beta$ -globin locus that included the single *HGB*-globin gene in the common ancestor of catarrhine primates (Old World monkeys, apes, and humans) and platyrrhine primates (New World monkeys) about 50 million years ago.

Although members of gene families that arose relatively recently in evolution, such as the genes of the human  $\beta$ -globin family, are often found near one another on the same chromosome, members of gene families may also be found on different chromosomes in the same organism. This is the case for the human  $\alpha$ -like globin genes, which were

separated from the  $\beta$ -globin genes by an ancient chromosomal translocation. Both the  $\alpha$ - and  $\beta$ -globin genes evolved from a single ancestral globin gene that was duplicated (see Figure 8-2b) to generate the predecessors of the contemporary  $\alpha$ - and  $\beta$ -globin genes in mammals. Both the primordial  $\alpha$ - and  $\beta$ -globin genes then underwent further duplications to generate the different genes of the  $\alpha$ - and  $\beta$ -globin gene clusters found in mammals today.

Several different gene families encode the various proteins that make up the cytoskeleton. These proteins are present in varying amounts in almost all cells. In vertebrates, the major cytoskeletal proteins are the actins, tubulins, and intermediate filament proteins such as the keratins, discussed in Chapters 17, 18, and 20. We examine the origin of one such family, the tubulin family, in Section 8.4. Although the physiological rationale for the cytoskeletal protein families is not as obvious as it is for the globins, the different members of a family probably have similar but subtly different functions suited to the particular type of cell in which they are expressed.

## Heavily Used Gene Products Are Encoded by Multiple Copies of Genes

In vertebrates and invertebrates, the genes encoding ribosomal RNAs and some other nonprotein-coding RNAs, such as those involved in RNA splicing, occur as *tandemly repeated arrays*. These multiple tandemly repeated genes are distinguished from the duplicated genes of gene families in that they encode identical, or nearly identical, proteins or functional RNAs. Most often, copies of these sequences appear one after the other, in a head-to-tail fashion, over a long stretch of DNA. Within a tandem array of rRNA genes, each copy is nearly exactly like all the others. Although the transcribed portions of the genes are the same, the nontranscribed regions between the transcribed regions can vary in length and sequence.

These tandemly repeated rRNA genes have evolved to meet the great cellular demand for their transcripts. To understand why, consider that a fixed maximal number of rRNA molecules can be produced from a single gene during one cell generation when the gene is fully loaded with RNA polymerase molecules. If more RNA is required than can be transcribed from one gene, multiple copies of the gene are necessary. For example, during early embryonic development in humans, many embryonic cells have a doubling time of about 24 hours and contain 5 million–10 million ribosomes. To produce enough rRNA to form this many ribosomes, an embryonic human cell needs at least 100 copies of genes encoding the large and small rRNA subunits, and most of these genes must be close to maximally active for the cell to divide every 24 hours; that is, multiple RNA polymerases must be transcribing each rRNA gene at the same time (see Figure 10-39). Indeed, all eukaryotes, including yeasts, contain 100 or more copies of the 5S rRNA gene and of the genes encoding the other rRNAs.

The genes encoding tRNA and the genes encoding the histone proteins are also present in multiple copies. As we will see later in this chapter, histones bind and organize nuclear DNA. Just as the cell requires multiple rRNA and tRNA genes to produce sufficient numbers of ribosomes and tRNAs, multiple copies of the histone genes are required to produce sufficient histone protein to bind the large amount of nuclear DNA produced in each round of cell replication. While tRNA

and histone genes often occur in clusters, they generally do not occur in tandem arrays in the human genome.

## Nonprotein-Coding Genes Encode Functional RNAs

In addition to rRNA and tRNA genes, there are thousands of additional genes that are transcribed into nonprotein-coding RNAs, some with various known functions and many whose functions are not yet known. For example, **small nuclear RNAs (snRNAs)** function in RNA splicing, and **small nucleolar RNAs (snoRNAs)** function in rRNA processing and base modification in the nucleolus. The RNase P RNA functions in tRNA processing, and a large family (~2000 in humans) of short **micro-RNAs (miRNAs)** regulates the translation and stability of specific mRNAs. The functions of these nonprotein-coding RNAs are discussed in Chapter 10. An RNA found in telomerase (see Figure 8-44 below) functions in maintaining the sequence at the ends of chromosomes, and the 7SL RNA functions in the transport of secreted proteins and most membrane proteins into the endoplasmic reticulum (see Chapter 13). These and other nonprotein-coding RNAs encoded in the human genome, and their functions when known, are listed in Table 8-2. Recent advances in DNA sequencing have led to the discovery of about 10,000 *long noncoding RNAs* (lncRNAs) in nuclei of mammalian cells. Some of these have been found

**TABLE 8-2** Known Nonprotein-Coding RNAs and Their Functions

RNA	Number of Genes in Human Genome	Function
rRNAs	~300	Protein synthesis
tRNAs	~500	Protein synthesis
snRNAs	~40	mRNA splicing
U7 snRNA	1	Histone mRNA 3' processing
snoRNAs	~85	Pre-rRNA processing and rRNA modification
miRNAs	~2000	Regulation of gene expression
Xist	1	X-chromosome inactivation
7SK	1	Transcription control
RNase P RNA	1	tRNA 5' processing
7SL RNA	3	Protein secretion (component of signal recognition particle, SRP)
RNase MRP RNA	1	rRNA processing, mtDNA* replication
Telomerase RNA	1	Template for addition of telomeres
Vault RNAs	3	Components of Vault ribonucleoproteins (RNPs), function unknown
hY1, hY3, hY4, hY5	~30	Components of ribonucleoproteins (RNPs), function unknown
H19	1	Unknown

\*Mitochondrial DNA

to function in regulating the expression of specific protein-coding genes. Pursuing the functions of lncRNAs is currently a highly active area of research.

## KEY CONCEPTS OF SECTION 8.1

### Eukaryotic Gene Structure

- In molecular terms, a gene is the entire DNA sequence required for synthesis of a functional protein or RNA molecule. In addition to the coding regions (exons), a gene includes control regions, and in multicellular animals and plants, most genes include introns.
- A simple eukaryotic transcription unit produces a single monocistronic mRNA, which is translated into a single protein.
- A complex eukaryotic transcription unit is transcribed into a primary transcript that can be processed into two or more different monocistronic mRNAs depending on the choice of splice sites or polyadenylation sites. A complex transcription unit with alternative promoters generates two or more different mRNAs in different cell types (see Figure 8-3b).
- Many complex transcription units (e.g., the fibronectin gene) express one mRNA in one cell type and an alternative mRNA in a different cell type.
- About half the protein-coding genes in vertebrate genomic DNA are solitary genes, each occurring only once in the haploid genome. The remainder are duplicated genes, which arose by duplication of an ancestral gene and subsequent independent mutations (see Figure 8-2b). The proteins encoded by a gene family have homologous but nonidentical amino acid sequences and exhibit similar but slightly different properties.
- In invertebrates and vertebrates, rRNAs are encoded by multiple copies of genes located in tandem arrays in genomic DNA. Multiple copies of tRNA, snRNA, and histone genes also occur, often in clusters, but not generally in tandem arrays.
- Many genes also encode functional RNAs that are not translated into proteins but nonetheless perform significant functions, such as rRNA, tRNA, and snRNA. Among these are micro-RNAs, whose biological significance in regulating gene expression has only recently been appreciated. Understanding the function of thousands of newly discovered nuclear long noncoding RNAs (lncRNAs) is currently an intense area of research.

## 8.2 Chromosomal Organization of Genes and Noncoding DNA

Having reviewed the relationship between transcription units and genes, we now consider the organization of genes on chromosomes and the relationship of noncoding DNA sequences to coding sequences.

## Genomes of Many Organisms Contain Nonfunctional DNA

Comparisons of the total chromosomal DNA per cell in various species first suggested that much of the DNA in certain organisms does not encode functional RNA or have any apparent regulatory function. For example, yeasts, fruit flies, chickens, and humans have successively more DNA in their haploid chromosome sets (12.5, 180, 1300, and 3300 Mb, respectively), in keeping with what we perceive to be the increasing complexity of these organisms. Yet the vertebrates with the greatest amount of DNA per cell are amphibians, which are surely less complex than humans in their structure and behavior. Even more surprising, the unicellular protozoan *Amoeba dubia* has 200 times more DNA per cell than humans. Many plant species also have considerably more DNA per cell than humans have; tulips, for example, have 10 times as much DNA per cell as humans. The DNA content per cell also varies considerably between closely related species. All insects or all amphibians would appear to be similarly complex, but the amount of haploid DNA in species within each of these phylogenetic classes varies by a factor of 100.

Sequencing and identification of exons in chromosomal DNA have provided direct evidence that the genomes of higher eukaryotes contain large amounts of noncoding DNA. For instance, only a small portion of the  $\beta$ -globin gene cluster of humans, which is about 80 kb long, encodes protein (see Figure 8-4a). In contrast, a typical 80-kb stretch of DNA from the yeast *S. cerevisiae*, a single-celled eukaryote, contains many closely spaced protein-coding sequences without introns and relatively much less noncoding DNA (see Figure 8-4b). Moreover, the introns in globin genes are considerably shorter than those in most human genes. Globin proteins comprise about 50 percent of the total protein in developing red blood cells (erythroid progenitors), and the globin genes are expressed at maximum rates (i.e., a new RNA polymerase initiates transcription as soon as the previous polymerase transcribes far enough from the promoter to allow it to do so). Consequently, there has been selective pressure on globin genes for small introns that are compatible with the required high rate of globin mRNA transcription and processing. However, the vast majority of human genes are expressed at much lower levels, which require production of one encoded mRNA on a time scale of only tens of minutes or hours. Consequently, there has been little selective pressure to reduce the sizes of introns in most human genes.

The density of genes varies among regions of human chromosomal DNA, from “gene-rich” regions, where a few hundred base pairs separate transcription units, to large gene-poor “gene deserts,” where intergenic regions are a few million base pairs long. Of the 96 percent of human genomic DNA that has been sequenced, only about 2.9 percent corresponds to exons, and only about 1.2 percent encodes proteins. (The fraction of the genome that corresponds to exons is much larger than the fraction that encodes proteins because many protein-coding genes include exons for long 3' untranslated regions and because there are many

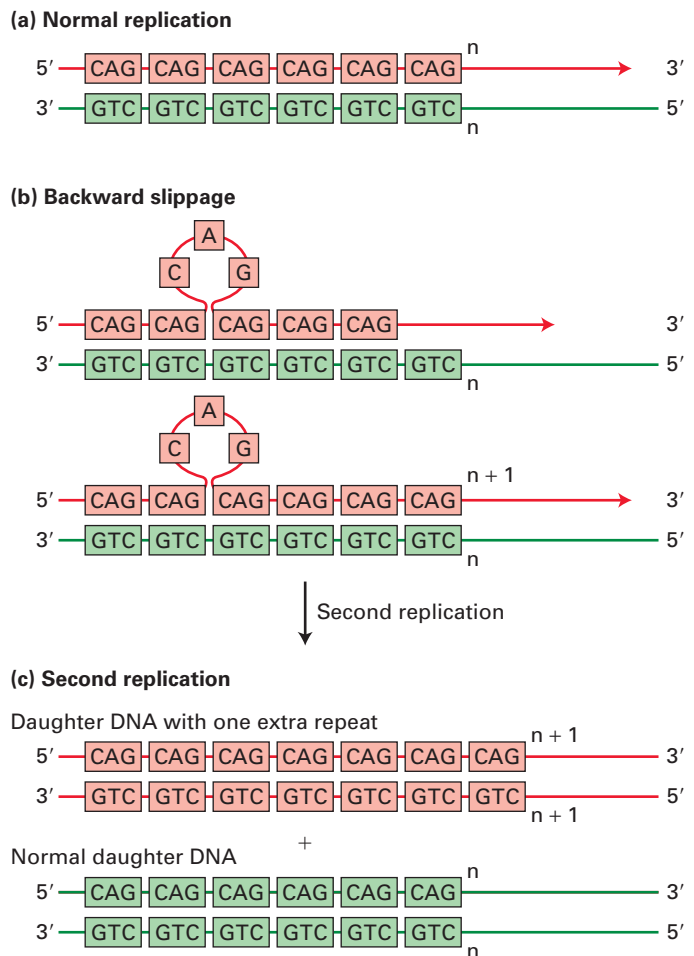

exons in nonprotein-coding lncRNAs; see Chapter 9.) We learned in the previous section that the intron sequences of most human genes are significantly longer than the exon sequences. Approximately 55 percent of human genomic DNA is thought to be transcribed into pre-mRNAs, pre-lncRNAs, or other nonprotein-coding RNAs in one cell or another, but some 95 percent of this sequence is intronic and is thus removed by RNA splicing. The remaining 45 percent of human DNA constitutes noncoding DNA between genes as well as the regions of repeated DNA sequences that make up the centromeres and telomeres of the human chromosomes. Consequently, about 97 percent of human DNA does not encode proteins, functional noncoding RNAs, or potentially functional lncRNAs.

Different selective pressures may account, at least in part, for the remarkable difference in the amount of nonfunctional DNA in different organisms. For example, many microorganisms must compete with other species of microorganisms in the same environment for limited amounts of available nutrients, and metabolic economy is thus a critical characteristic for these organisms. Because synthesis of nonfunctional (i.e., noncoding) DNA requires time, nutrients, and energy, presumably there was selective pressure to lose nonfunctional DNA during the evolution of rapidly growing microorganisms such as the yeast *S. cerevisiae*. On the other hand, natural selection in vertebrates depends largely on their behavior. The energy invested in DNA synthesis is trivial compared with the metabolic energy required for the movement of muscles and the function of the nervous system; thus there may have been little selective pressure on vertebrates to eliminate nonfunctional DNA. Furthermore, the replication time of cells in most vertebrates and plants is much longer than in rapidly growing microorganisms, so there may have been little selective pressure to eliminate nonfunctional DNA in order to permit rapid cellular replication.

## Most Simple-Sequence DNAs Are Concentrated in Specific Chromosomal Locations

Besides duplicated protein-coding genes and tandemly repeated genes, eukaryotic cells contain multiple copies of other DNA sequences, generally referred to as *repetitious DNA* (see Table 8-1). Of the two main types of repetitious DNA, the less prevalent is **simple-sequence DNA**, or **satellite DNA**. This type of DNA, which constitutes about 6 percent of the human genome, is composed of perfect or nearly perfect repeats of relatively short sequences. The second, more common type of repetitious DNA, collectively called **interspersed repeats**, is composed of much longer sequences. These sequences, consisting of several types of transposable elements, are discussed in Section 8.3.

The length of each repeat in simple-sequence DNA can range from 1 to 500 base pairs. DNA sequences in which the repeats each contain 1–13 bp are often called **microsatellites**. Most microsatellite DNA has a repeat length of 1–4 bp, and the repeats usually occur in tandem sequences of 150 repeats or fewer. Microsatellites are thought to have

**FIGURE 8-5 Generation of microsatellite repeats by backward slippage of the nascent daughter strand during DNA replication.**

If, during replication (a), the nascent daughter strand “slips” backward relative to the template strand by one repeat, one new copy of the repeat is added to the daughter strand when DNA replication continues (b). An extra copy of the repeat forms a single-stranded loop in the daughter strand of the daughter duplex DNA molecule. If this single-stranded loop is not removed by DNA repair proteins before the next round of DNA replication (c), the extra copy of the repeat is added to one of the double-stranded daughter DNA molecules.

originated by “backward slippage” of a daughter strand on its template strand during DNA replication so that the same short sequence was copied twice (Figure 8-5).

 Microsatellites occasionally occur within transcription units. Some individuals are born with a larger number of repeats in specific genes than are observed in the general population, presumably because of daughter-strand slippage during DNA replication in the germ cells from which they and their forebears developed. Such expanded microsatellites have been found to cause at least 14 different types of neuromuscular diseases, depending on the gene in which they occur. In some cases, expanded microsatellites behave like a recessive mutation because they interfere with just the function or expression of the gene in which they

occur. But in the more common types of diseases associated with expanded microsatellites, the expanded microsatellites behave like dominant mutations. In some of these diseases, such as *Huntington disease*, triplet repeats occur within a coding region, resulting in the formation of long polymers of a single amino acid that may aggregate over time in long-lived neuronal cells, eventually interfering with normal cellular function. For example, expansion of a CAG repeat in the first exon of the gene involved in Huntington disease leads to synthesis of long stretches of polyglutamine, which over several decades form toxic aggregates resulting in neuronal cell death in patients with the disease.

Pathogenic expanded repeats can also occur in the non-coding regions of some genes, where they are thought to function as dominant mutations because they interfere with the processing of a subset of mRNAs in the muscle cells and neurons where the affected genes are expressed. For example, in patients with *myotonic dystrophy type 1*, transcripts of the *DMPK* gene contain between 50 and 1500 repeats of the sequence CUG in the 3' untranslated region, compared with 5–34 repeats in unaffected individuals. The extended stretch of CUG repeats in affected individuals is thought to form a long RNA hairpin (see Figure 5-9), which binds and sequesters nuclear RNA-binding proteins that normally regulate alternative RNA splicing of a subset of pre-mRNAs essential for muscle and nerve cell function. ■

Most simple-sequence satellite DNA is composed of repeats of 14–500 bp in tandem arrays 20–100 kb long. In situ hybridization studies with metaphase chromosomes have localized this simple-sequence DNA to specific chromosomal regions. Much of this DNA lies near centromeres, the discrete chromosomal regions that attach to spindle microtubules during mitosis and meiosis (Figure 8-6). Experiments in the fission yeast *S. pombe* indicate that these sequences are required to form a specialized chromatin structure called *centromeric heterochromatin*, necessary for the proper segregation of chromosomes to daughter cells during mitosis. Simple-sequence DNA is also found in long tandem repeats at the ends of chromosomes, the telomeres, where it functions to maintain those chromosome ends and prevent their joining to the ends of other DNA molecules, as discussed further in the last section of this chapter.

### DNA Fingerprinting Depends on Differences in Length of Simple-Sequence DNAs

Within a species, the nucleotide sequences of the repeat units composing a simple-sequence DNA tandem array are highly conserved among individuals. In contrast, the *number* of repeats, and thus the length of simple-sequence tandem arrays containing the same repeat unit, is quite variable among individuals. These differences in length are thought to result from unequal crossing over within regions of simple-sequence DNA during meiosis. As a consequence of this unequal crossing over, the lengths of some tandem arrays are unique in each individual.

**EXPERIMENTAL FIGURE 8-6 Simple-sequence DNA is localized at the centromere in mouse chromosomes.** Purified simple-sequence DNA from mouse cells was copied in vitro using *E. coli* DNA polymerase I and fluorescently labeled dNTPs to generate a fluorescently labeled DNA “probe” for mouse simple-sequence DNA. Chromosomes from cultured mouse cells were fixed and denatured on a microscope slide, and the chromosomal DNA was then hybridized in situ to the labeled probe (light blue). The slide was also stained with DAPI, a DNA-binding dye, to visualize the full length of the chromosomes (dark blue). Fluorescence microscopy shows that the simple-sequence probe hybridizes primarily to one end of the telocentric mouse chromosomes (i.e., chromosomes in which the centromeres are located near one end). [Courtesy of Sabine Mal, Ph.D., Manitoba Institute of Cell Biology, Canada.]

In humans and other mammals, some simple-sequence DNA exists in relatively short 1–5-kb regions made up of 20–50 repeat units, each containing 14–100 bp. These regions are called *minisatellites*, in contrast to microsatellites made up of tandem repeats of 1–13 bp. Even slight differences in the total lengths of various minisatellites from different individuals can be detected by Southern blotting (see Figure 6-24). This technique was exploited in the first application of *DNA fingerprinting*, which was developed to detect DNA *polymorphisms* (i.e., differences in sequence between individuals of the same species) (Figure 8-7). Today the far more sensitive polymerase chain reaction (PCR) technique (see Figure 6-18) is generally used in forensic genetic testing. Microsatellites consisting of tandem repeats of four bases in 30–50 copies are usually analyzed today. The exact number of repeats at a specific location in the genome generally varies between the two homologous chromosomes of an individual (one inherited from the mother and one from the father) and between the Y chromosomes of different males. A mixture of pairs of PCR primers that hybridize to unique sequences flanking 13 of these short tandem repeats and a Y-chromosome short tandem repeat are used to amplify

**FIGURE 8-7 Distinguishing individuals by DNA fingerprinting.**

(a) In this analysis of paternity, several minisatellite repeat lengths were determined by Southern blot analysis of restriction enzyme–digested genomic DNA and hybridization with a probe for a sequence shared by several minisatellite sequences. This method generated hypervariable multiband patterns for each individual called “DNA fingerprints.” Lane M shows the pattern of restriction fragment bands using the mother’s DNA; C, using the child’s DNA; and F1 and F2 using DNA from two potential fathers. The child has minisatellite repeat lengths inherited from either the mother or F1, demonstrating that F1 is the father. Arrows indicate restriction fragments from F1, but not F2, found in the child’s DNA. (b) In these “DNA fingerprints” of a specimen isolated from a rape victim and three men suspected of the crime, it is clear that minisatellite repeat lengths in the specimen match those of suspect 1. The victim’s DNA was included in the analysis to ensure that the specimen DNA was not contaminated with DNA from the victim.

DNA in a sample from one individual. The resulting mixture of PCR product lengths is unique in the human population, except for identical twins. The use of PCR allows analysis of minute amounts of DNA, and individuals can be distinguished more precisely and reliably than by conventional fingerprinting.

### Unclassified Intergenic DNA Occupies a Significant Portion of the Genome

About 45 percent of human DNA lies between transcription units. Much of this sequence is not repeated anywhere else in the genome. Enhancers on the order of 50–200 bp in length that help to regulate transcription at distant promoters occur in these long stretches of intergenic DNA, as well as in introns. These enhancers (discussed in Chapter 9) are often conserved during evolution, while the neighboring intergenic sequences are not conserved. Other conserved

intergenic regions may perform significant functions that are not yet understood. For example, they may contribute to the structures of chromosomes discussed in Section 8.6.

## KEY CONCEPTS OF SECTION 8.2

### Chromosomal Organization of Genes and Noncoding DNA

- In the genomes of prokaryotes and most lower eukaryotes, which contain few nonfunctional sequences, coding regions are densely arrayed along the genomic DNA.
- In contrast, genomes of multicellular animals and plants contain many sequences that do not apparently code for functional RNAs or have any regulatory function. Much of this nonfunctional DNA is composed of repeated sequences. In humans, only about 2.9 percent of total DNA (the exons) actually encodes proteins or functional RNAs.
- Variation in the amount of nonfunctional DNA in the genomes of different species is largely responsible for the lack of a consistent relationship between the amount of DNA in the haploid chromosomes of an animal or plant and its phylogenetic complexity.
- Simple-sequence DNA, consisting of short sequences repeated in long tandem arrays, is preferentially located in centromeres and telomeres.
- The length of a particular simple-sequence tandem array is quite variable between individuals in a species, probably because of unequal crossing over during meiosis. Differences in the lengths of some simple-sequence tandem arrays form the basis for DNA fingerprinting (see Figure 8-7).

## 8.3 Transposable (Mobile) DNA Elements

Interspersed repeats, the second type of repetitious DNA in eukaryotic genomes, is composed of a very large number of copies of relatively few sequence families (see Table 8-1). Also known as *moderately repeated DNA*, or *intermediate-repeat DNA*, these sequences are interspersed throughout mammalian genomes and make up 25–50 percent of mammalian DNA (~45 percent of human DNA).

Because interspersed repeats have the unique ability to “move” in the genome, they are collectively referred to as **transposable DNA elements** or **mobile DNA elements** (we use these terms interchangeably). Although transposable DNA elements were originally discovered in eukaryotes, they are also found, although less frequently, in prokaryotes. The process by which these sequences are copied and inserted into a new site in the genome is called **transposition**. Transposable DNA elements are essentially molecular symbionts that in most cases appear to have no specific function in the biology of their host organisms, but exist only to maintain themselves. For this reason, Francis Crick referred to them as “selfish DNA.”

When transposition occurs in germ cells, the transposed sequences at their new sites are passed on to succeeding generations. In this way, mobile elements have multiplied and slowly accumulated in eukaryotic genomes over evolutionary time. Since mobile elements are eliminated from eukaryotic genomes very slowly, they now constitute a significant portion of the genomes of many eukaryotes.

Mobile elements are not only the source for much of the DNA in our genomes, but also provide a second mechanism, in addition to meiotic recombination, for bringing about chromosomal DNA rearrangements during evolution (see Figure 8-2). One reason for this is that during transposition of a particular mobile element, adjacent DNA is sometimes also mobilized (see Figure 8-19 below). Transpositions occur rarely: in humans, there is about one new germ-line transposition for every eight individuals. Since 97 percent of our DNA is noncoding, most transpositions have no deleterious effects. But over time, they have played an essential part in the evolution of genes that have multiple exons and of genes whose expression is restricted to specific cell types or developmental periods. In other words, although transposable elements probably evolved as cellular symbionts, they have had an important function in the evolution of complex multicellular organisms.

Transposition may also occur within a somatic cell; in this case, the transposed sequence is transmitted only to the daughter cells derived from that cell. In rare cases, such somatic-cell transposition may lead to a somatic-cell mutation with detrimental phenotypic effects, such as the inactivation of a tumor-suppressor gene (see Chapter 24). In

this section, we first describe the structure and transposition mechanisms of the major types of transposable DNA elements and then consider their likely role in evolution.

## Movement of Mobile Elements Involves a DNA or an RNA Intermediate

Barbara McClintock discovered the first mobile elements while doing classical genetic experiments in maize (corn) during the 1940s. She characterized genetic entities that could move into and back out of genes, changing the phenotypes of corn kernels. Her theories were very controversial until similar mobile elements were discovered in bacteria, where they were characterized as specific DNA sequences, and the molecular basis of their transposition was deciphered.

As research on mobile elements progressed, they were found to fall into two categories: (1) those that transpose directly as DNA and (2) those that transpose via an RNA intermediate transcribed from the mobile element by an RNA polymerase and then converted back into double-stranded DNA by a **reverse transcriptase** (Figure 8-8). Mobile elements that transpose directly as DNA are generally referred to as **DNA transposons**, or simply **transposons**. Eukaryotic DNA transposons excise themselves from one place in the genome, leaving that site and moving to another. Mobile elements that transpose to new sites in the genome via an RNA intermediate are called **retrotransposons**. Retrotransposons make an RNA copy of themselves and introduce this new copy into another site in the genome, while also remaining

**FIGURE 8-8 Two major classes of mobile elements.** (a) Eukaryotic DNA transposons (orange) move via a DNA intermediate, which is excised from the donor site. (b) Retrotransposons (green) are first transcribed into an RNA molecule, which is then reverse-transcribed into double-stranded DNA. In both cases, the double-stranded DNA intermediate is integrated into the target-site DNA to complete movement. Thus DNA transposons move by a cut-and-paste mechanism, whereas retrotransposons move by a copy-and-paste mechanism.

at their original location. The movement of retrotransposons is analogous to the infectious process of retroviruses (see Figure 5-49). Indeed, retroviruses can be thought of as retrotransposons that evolved genes encoding viral coats that allowed them to transpose between cells. Retrotransposons can be further classified on the basis of their specific mechanism of transposition. To summarize, DNA transposons can be thought of as transposing by a “cut-and-paste” mechanism, while retrotransposons move by a “copy-and-paste” mechanism in which the copy is an RNA intermediate.

## DNA Transposons Are Present in Prokaryotes and Eukaryotes

Most mobile elements in bacteria transpose directly as DNA. In contrast, most mobile elements in eukaryotes are retrotransposons, but eukaryotic DNA transposons also occur. Indeed, the original mobile elements discovered by Barbara McClintock are DNA transposons.

**Bacterial Insertion Sequences** The first molecular understanding of mobile elements came from the study of certain *E. coli* mutations caused by the spontaneous insertion of a DNA sequence, about 1–2 kb long, into the middle of a gene. These inserted stretches of DNA are called *insertion sequences*, or *IS elements*. So far, more than 1000 different IS elements have been found in *E. coli* and other bacteria.

Transposition of an IS element is a very rare event, occurring in only one in  $10^5$ – $10^7$  cells per generation, depending on the particular IS element. Often transpositions inactivate essential genes, killing the host cell and the IS elements it carries. Therefore, higher rates of transposition would probably result in too great a mutation rate for the host organism to survive. However, since IS elements transpose more or less randomly, some transposed sequences enter nonessential regions of the host genome (e.g., regions between genes), allowing the host cell to survive. At a very low rate of transposition, most host cells survive and therefore propagate the symbiotic IS element. IS elements can also insert themselves into plasmids or lysogenic viruses and can thus be transferred to other cells. In this way, IS elements can transpose into the chromosomes of new host cells.

The general structure of IS elements is diagrammed in Figure 8-9. An inverted repeat of 10–40 bp is invariably present at each end of an IS element. In an *inverted repeat*, the 5'→3' sequence on one strand is repeated on the other strand, such as

Between the inverted repeats is a region that encodes a *transposase*, an enzyme required for transposition of the IS element to a new site. The transposase is expressed very rarely, accounting for the very low frequency of transposition. An important hallmark of IS elements is the presence of a short *direct repeat* sequence, containing 5–11 bp, depending on the particular IS element, immediately adjacent to both ends

**FIGURE 8-9 General structure of bacterial IS elements.** The relatively large central region of an IS element, which encodes one or two enzymes required for transposition, is flanked by an inverted repeat at each end. The sequences of the inverted repeats are nearly identical, but they are oriented in opposite directions. The sequence is characteristic of a particular IS element. The 5' and 3' short *direct* (as opposed to *inverted*) repeats are not transposed with the insertion element; rather, they are insertion-site sequences that become duplicated, with one copy at each end, during insertion of a mobile element. The length of the direct repeats is constant for a given IS element, but their sequence depends on the site of insertion and therefore varies with each transposition of the IS element. Arrows indicate sequence orientation. The regions in this diagram are not to scale; the coding region makes up most of the length of an IS element.

of the inserted element. The *length* of the direct repeat is characteristic of each type of IS element, but its *sequence* depends on the target site where a particular copy of the IS element inserted. When the sequence of a mutated gene containing an IS element is compared with the wild-type gene sequence, only one copy of the direct repeat is found in the wild-type gene. Duplication of this target-site sequence to create the second direct repeat adjacent to an IS element occurs during the insertion process.

As depicted in Figure 8-10, transposition of an IS element occurs by a “cut-and-paste” mechanism. Transposase performs three functions in this process: it (1) precisely excises the IS element from the donor DNA, (2) makes staggered cuts in a short sequence in the target DNA, and (3) ligates the 3' termini of the IS element to the 5' ends of the cut donor DNA. Finally, a host-cell DNA polymerase fills in the single-stranded gaps, generating the short direct repeats that flank IS elements, and DNA ligase joins the free ends.

**Eukaryotic DNA Transposons** McClintock’s original discovery of mobile elements came from her observation of spontaneous mutations in maize that affect the production of enzymes required to make anthocyanin, a purple pigment in maize kernels. Mutant kernels are white and wild-type kernels are purple. One class of these mutations is revertible at high frequency, whereas a second class does not revert unless they occur in the presence of the first class of mutations. McClintock called the agents responsible for the first class of mutations *activator (Ac) elements* and those responsible for the second class *dissociation (Ds) elements* because they also tended to be associated with chromosome breaks.

Many years after McClintock’s pioneering discoveries, cloning and sequencing revealed that Ac elements are equivalent to bacterial IS elements. Like IS elements, they contain inverted terminal repeat sequences that flank a region encoding a transposase, which recognizes the terminal repeats and catalyzes transposition to a new site in the host DNA.

**FIGURE 8-10 Model for transposition of bacterial insertion sequences.** Step 1: Transposase, which is encoded by the IS element (IS10 in this example), cleaves both strands of the donor DNA next to the inverted repeats (dark red), excising the IS10 element. At a largely random target site, transposase makes staggered cuts in the target DNA. In the case of IS10, the two cuts are 9 bp apart. Step 2: Ligation of the 3' ends of the excised IS element to the staggered sites in the target DNA is also catalyzed by transposase. Step 3: The 9-bp gaps of single-stranded DNA left in the resulting intermediate are filled in by a cellular DNA polymerase; finally, cellular DNA ligase forms the 3'→5' phosphodiester bonds between the 3' ends of the extended target DNA strands and the 5' ends of the IS10 strands. This process results in duplication of the target-site sequence on each side of the inserted IS element. Note that the lengths of the target site and IS10 are not to scale. See H. W. Benjamin and N. Kleckner, 1989, *Cell* **59**:373; and 1992, *Proc. Natl. Acad. Sci. USA* **89**:4648.

Ds elements are deleted forms of Ac elements in which a portion of the sequence encoding transposase is missing. Because it does not encode a functional transposase, a Ds element cannot move by itself. However, in plants that carry Ac elements and thus express a functional transposase, Ds elements can be transposed because they retain the inverted terminal repeats recognized by the transposase.

Since McClintock's early work on mobile elements in corn, DNA transposons have been identified in other

eukaryotes. For instance, approximately half of all the spontaneous mutations observed in *Drosophila* are due to the insertion of mobile elements. Although most of the mobile elements in *Drosophila* function as retrotransposons, at least one—the *P* element—functions as a DNA transposon, moving by a mechanism similar to that used by bacterial insertion sequences. Current methods for constructing transgenic *Drosophila* depend on engineered, high-level expression of the P-element transposase and use of the P-element inverted terminal repeats as targets for transposition, as discussed in Chapter 6 (see Figure 6-20).

DNA transposition by the cut-and-paste mechanism can result in an increase in the copy number of a transposon if it occurs during the S phase of the cell cycle (see Figure 1-21), when DNA synthesis occurs. Such an increase happens when the donor DNA is in one of the two daughter DNA molecules in a region of a chromosome that has replicated but the target DNA is in a region that has not yet replicated. When DNA replication is complete at the end of the S phase, the target DNA in its new location has also been replicated, resulting in a net increase in the total number of transposon copies in the cell (Figure 8-11). When such a transposition occurs during the S phase preceding meiosis, one of the four germ cells produced contains the extra copy of the transposon. Repetition of this process over evolutionary time has resulted in the accumulation of large numbers of DNA transposons in the genomes of some organisms. Human DNA contains about 300,000 copies of full-length and deleted DNA transposons, amounting to about 3 percent of human DNA. As we will see shortly, this mechanism can lead to the transposition of genomic DNA as well as the transposon itself.

**FIGURE 8-11 Mechanism for increasing DNA-transposon copy number.** If a DNA transposon, which transposes by a cut-and-paste mechanism (see Figure 8-10), transposes during S phase from a region of the chromosome that has replicated to a region that has not yet replicated, then when chromosomal replication is completed, one of the two daughter chromosomes will have a net increase of one copy of the transposon.

## LTR Retrotransposons Behave Like Intracellular Retroviruses

The genomes of all eukaryotes studied, from yeast to humans, contain retrotransposons, mobile DNA elements that transpose through an RNA intermediate using a reverse transcriptase (see Figure 8-8b). These mobile elements are divided into two major categories: those containing and those lacking **long terminal repeats (LTRs)**. LTR retrotransposons, which we discuss here, are common in yeast (e.g., Ty elements) and in *Drosophila* (e.g., *copia* elements). Although less abundant in mammals than non-LTR retrotransposons, LTR retrotransposons nonetheless constitute about 8 percent of human genomic DNA. Non-LTR retrotransposons are the most common type of mobile element in mammals; these retrotransposons are described in the next section.

The general structure of LTR retrotransposons found in eukaryotes is depicted in Figure 8-12. In addition to the short 5' and 3' direct repeats that are typical of all transposons, these retrotransposons are marked by the presence of LTRs flanking the central protein-coding region. These *long direct terminal repeats*, containing 250–600 bp depending on the particular LTR retrotransposon, are characteristic of integrated retroviral DNA and are critical to the life cycle of retroviruses. In addition to sharing LTRs with retroviruses, LTR retrotransposons encode all the proteins of the most common type of retroviruses, except for the envelope proteins. Lacking these envelope proteins, LTR retrotransposons cannot bud from their host cell and infect other cells; however, they can transpose to new sites in the DNA of their host cell. Because of their clear relationship with retroviruses, LTR retrotransposons are often called *retrovirus-like elements*.

A key step in the retroviral life cycle is the formation of retroviral genomic RNA from integrated retroviral DNA (see Figure 5-48). We describe this process in some detail here because it serves as a model for the generation of the RNA intermediate during the transposition of LTR retrotransposons. As depicted in Figure 8-13, the leftward retroviral LTR functions as a promoter that directs host-cell RNA polymerase to initiate transcription at the 5' nucleotide of the roughly 20-base R sequence that is repeated at each end of the retroviral RNA. After the entire downstream retroviral

**FIGURE 8-12 General structure of eukaryotic LTR retrotransposons.** The central protein-coding region is flanked by two long terminal repeats (LTRs), which are element-specific direct repeats. Like other mobile elements, integrated retrotransposons have short target-site direct repeats at each end. Note that the different regions are not drawn to scale. The protein-coding region constitutes 80 percent or more of a retrotransposon and encodes reverse transcriptase, integrase, and other retroviral proteins.

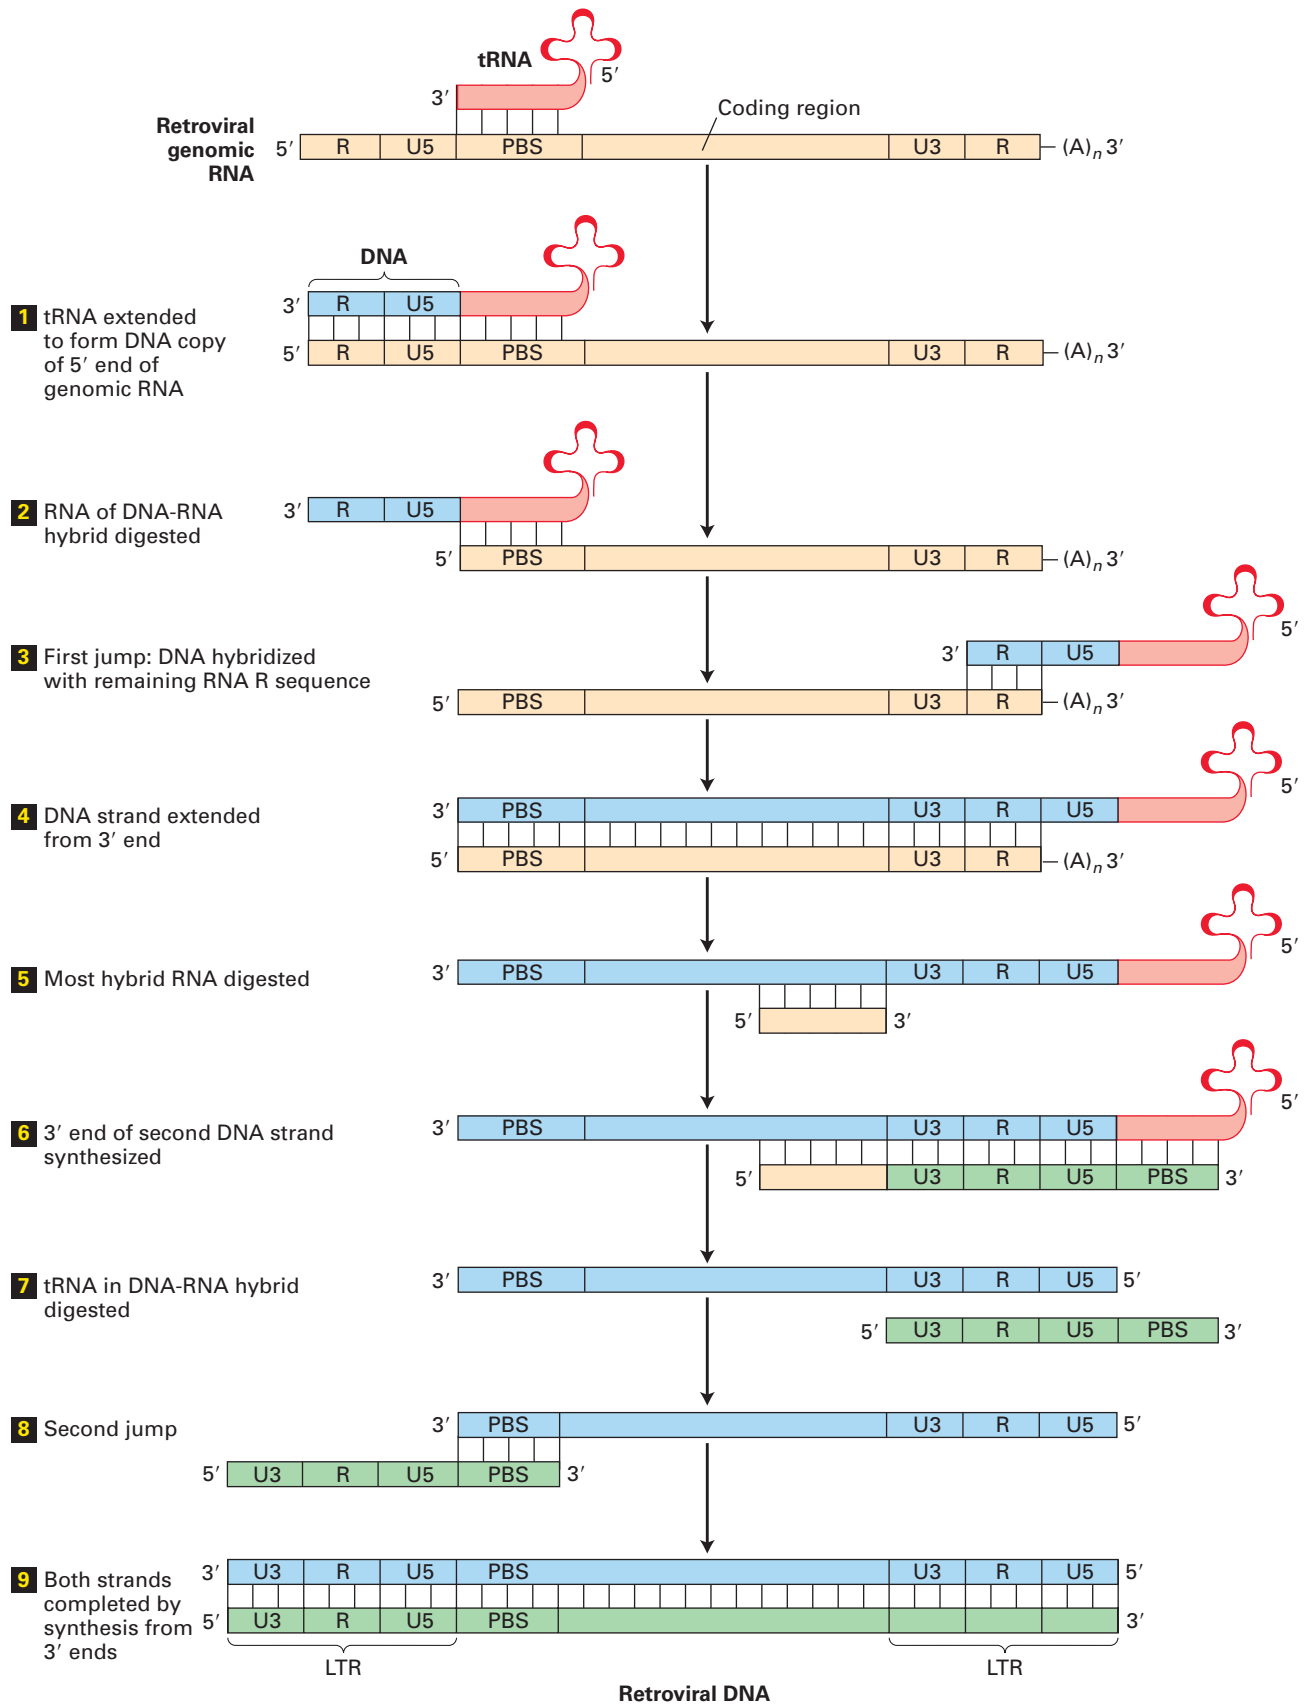

**FIGURE 8-13 Generation of retroviral genomic RNA from integrated retroviral DNA.** The left LTR directs cellular RNA polymerase to initiate transcription at the first nucleotide of the left R region. The resulting primary transcript extends beyond the right LTR. The right LTR, now present in the RNA primary transcript, directs cellular enzymes to cleave the primary transcript at the last nucleotide of the right R region and to add a poly(A) tail, yielding a retroviral RNA genome with the structure shown at the top of Figure 8-14. The R sequence is repeated precisely at the 5' and 3' end [before the poly(A) tail] of the viral genomic RNA. U5 and U3 refer to sequences at the 5' and 3' ends of the viral RNA that are not repeated in the genomic retroviral RNA and hence are unique (see Figure 8-14). A similar mechanism is thought to generate the RNA intermediate during transposition of retrotransposons. The short direct repeat sequences (black) of target-site DNA are generated during integration of the retroviral DNA into the host-cell genome.

DNA has been transcribed, the RNA sequence corresponding to the rightward LTR directs host-cell RNA-processing enzymes to cleave the primary transcript and add a poly(A) tail at the 3' end of the R sequence. The resulting retroviral RNA genome, which lacks a complete LTR, exits the nucleus and is packaged into a virion that buds from the host cell.

After a retrovirus infects a cell, reverse transcription of its RNA genome by the retrovirus-encoded reverse transcriptase yields a double-stranded DNA containing complete LTRs (Figure 8-14). This DNA synthesis takes place

**FIGURE 8-14 Model for reverse transcription of retroviral genomic RNA into DNA.** In this model, a complicated series of nine events generates a double-stranded DNA copy of the single-stranded RNA genome of a retrovirus. The genomic RNA is packaged in the virion with a retrovirus-specific cellular tRNA hybridized to a complementary sequence near its 5' end, called the *primer-binding site (PBS)*. The retroviral RNA has a short direct repeat terminal sequence (R) at each end. The overall reaction is carried out by reverse transcriptase, which catalyzes polymerization of deoxyribonucleotides. RNaseH, also encoded in the viral RNA and packaged into the virion particle, digests the RNA strand in a DNA-RNA hybrid. The entire process yields a double-stranded DNA molecule that is longer than the template RNA and has a long terminal repeat (LTR) at each end. The different regions are not shown to scale. The PBS and R regions are actually much shorter than the U5 and U3 regions, and the central coding region is very much longer than the other regions. See E. Gilboa et al., 1979, *Cell* 18:93.

in the cytosol. The double-stranded DNA, with an LTR at each end, is then transported into the nucleus in a complex with integrase, another enzyme encoded by retroviruses. Retroviral integrases are closely related to the transposases encoded by DNA transposons and use a similar mechanism to insert the double-stranded retroviral DNA into the host-cell genome. In this process, short direct repeats of the target-site sequence are generated at either end of the inserted viral DNA sequence. Although the mechanism of reverse transcription is complex, it is a critical aspect of the retrovirus life cycle. The process generates the complete 5' LTR that functions as a promoter for initiation of transcription precisely at the 5' nucleotide of the R sequence, while the complete 3' LTR functions as a poly(A) site leading to polyadenylation precisely at the 3' nucleotide of the R sequence. Consequently, no nucleotides are lost from an LTR retrotransposon as it undergoes successive rounds of insertion, transcription, reverse transcription, and reinsertion at a new site.

As noted above, LTR retrotransposons encode reverse transcriptase and integrase. By analogy with retroviruses, these mobile elements move by a “copy-and-paste” mechanism whereby reverse transcriptase converts an RNA copy of a donor element into DNA, which is inserted into a target site by integrase. The experiments depicted in Figure 8-15 provided strong evidence for the role of an RNA intermediate in the transposition of Ty elements in yeast.

The most common LTR retrotransposons in humans are called *ERVs*, for *endogenous retroviruses*. Most of the 443,000 ERV-related DNA sequences in the human genome consist only of isolated LTRs. These sequences are derived from full-length proviral DNA by homologous recombination between two LTRs, resulting in deletion of the internal retroviral sequences. Isolated LTRs such as these cannot be transposed to a new position in the genome, but recombination between homologous LTRs at different positions in the genome has probably contributed to the chromosomal DNA rearrangements leading to gene and exon duplications, the evolution of proteins with new combinations of exons, and, as we will see in Chapter 9, the evolution of complex control of gene expression.

## Non-LTR Retrotransposons Transpose by a Distinct Mechanism

The most abundant mobile elements in mammals are retrotransposons that lack LTRs, sometimes called *non-viral retrotransposons*. These moderately repeated DNA sequences form two classes in mammalian genomes: **long interspersed elements (LINEs)** and **short interspersed elements (SINEs)**. In humans, full-length LINEs are about 6 kb long, and SINEs are about 300 bp long (see Table 8-1). Repeated sequences with the characteristics of LINEs have been observed in protozoans, insects, and plants, but for unknown reasons, they are particularly abundant in the genomes of mammals. SINEs too are found primarily in

**EXPERIMENTAL FIGURE 8-15 The yeast Ty element transposes through an RNA intermediate.** When yeast cells are transformed with a Ty-containing plasmid, the Ty element can transpose to new sites, although normally this occurs at a low rate. Using the elements diagrammed at the top, researchers engineered two different recombinant plasmid vectors containing recombinant Ty elements adjacent to a galactose-sensitive promoter. Yeast cells transformed with these plasmids were grown in a galactose-containing and a galactose-free medium. In experiment 1, growth of cells in galactose-containing medium resulted in many more transpositions than in galactose-free medium, indicating that transcription into an mRNA intermediate is required for Ty transposition. In experiment 2, an intron from an unrelated yeast gene was inserted into the putative protein-coding region of the recombinant galactose-responsive Ty element. The observed absence of the intron in transposed Ty elements is strong evidence that transposition involves an mRNA intermediate from which the intron was removed by RNA splicing, as depicted in the box on the right. In contrast, eukaryotic DNA transposons, such as the Ac element of maize, contain introns within the transposase gene, indicating that they do not transpose via an RNA intermediate. See J. Boeke et al., 1985, *Cell* 40:491.

**FIGURE 8-16 General structure of a LINE.** The length of the target-site direct repeats varies among the copies of a LINE at different sites in the genome. Although the full-length L1 element is about 6 kb long, variable amounts of the left end are absent at over 90 percent of the sites where this mobile element is found. The shorter open reading frame (ORF1), about 1 kb in length, encodes an RNA-binding protein. The longer ORF2, about 4 kb in length, encodes a bifunctional protein with reverse transcriptase and DNA endonuclease activity. Note that LINES lack the long terminal repeats found in LTR retrotransposons.

mammalian DNA. Large numbers of LINES and SINEs in higher eukaryotes have accumulated over evolutionary time by repeated copying of sequences at a few positions in the genome and insertion of the copies into new positions.

**LINES** Human DNA contains three major families of LINES that are similar in their mechanism of transposition but differ in their sequences: L1, L2, and L3. Only members of the L1 family transpose in the contemporary human genome; apparently there are no remaining functional copies of L2 or L3. LINE sequences are present at roughly 900,000 sites in the human genome, accounting for a staggering 21 percent of total human DNA. The general structure of a complete LINE is diagrammed in Figure 8-16. LINES are usually flanked by short direct repeats, the hallmark of mobile elements, and contain two long open reading frames (ORFs, which are protein-coding regions; see Section 8.4). ORF1, about 1 kb long, encodes an RNA-binding protein. ORF2, about 4 kb long, encodes a protein that has a long region of homology with the reverse transcriptases of retroviruses and LTR retrotransposons, but also exhibits DNA endonuclease activity.

 Evidence for the mobility of L1 elements first came from analysis of DNA cloned from patients with certain genetic diseases such as hemophilia and myotonic dystrophy. DNA from these patients was found to carry mutations resulting from insertion of an L1 element into a gene, whereas no such element occurred within that gene in either parent. About 1 in 600 mutations that cause significant disease in humans are due to L1 transpositions or SINE transpositions that are catalyzed by L1-encoded proteins. Later experiments similar to those just described with yeast Ty elements (see Figure 8-15) confirmed that L1 elements transpose through an RNA intermediate. In these experiments, an intron was introduced into a cloned mouse L1 element, and the recombinant L1 element was stably transfected into cultured hamster cells. After several cell doublings, a DNA fragment corresponding to the L1 element but lacking the inserted intron was detected in the cells. This finding strongly

suggests that, over time, the recombinant L1 element containing the inserted intron had transposed to new sites in the hamster genome through an RNA intermediate that underwent RNA splicing to remove the intron. ■

Since LINES do not contain LTRs, their mechanism of transposition through an RNA intermediate differs from that of LTR retrotransposons. The proteins encoded by ORF1 and ORF2 are translated from a LINE RNA. In vitro studies indicate that transcription by RNA polymerase is directed by promoter sequences at the left end of integrated LINE DNA. LINE RNA is polyadenylated by the same post-transcriptional mechanism that polyadenylates other mRNAs. The LINE RNA is then exported into the cytosol, where it is translated into ORF1 and ORF2 proteins. Multiple copies of ORF1 protein then bind to the LINE RNA, and ORF2 protein binds to the poly(A) tail. The LINE RNA is then transported back into the nucleus as a complex with ORF1 and ORF2 proteins, where it is reverse-transcribed into LINE DNA by ORF2. The mechanism involves staggered cleavage of cellular DNA at the insertion site, followed by priming of reverse transcription by the resulting cleaved cellular DNA, as detailed in Figure 8-17. The complete process results in insertion of a copy of the original LINE retrotransposon into a new site in chromosomal DNA. A short direct repeat is generated at the insertion site because of the initial staggered cleavage of the two chromosomal DNA strands.

As noted already, the DNA form of an LTR retrotransposon is synthesized from its RNA form in the cytosol using a cellular tRNA as a primer for reverse transcription of the first strand of DNA (see Figure 8-14). The resulting double-stranded DNA with long terminal repeats is then transported into the nucleus, where it is integrated into chromosomal DNA by a retrotransposon-encoded integrase. In contrast, the DNA form of a non-LTR retrotransposon is synthesized in the nucleus. The synthesis of the first strand of the non-LTR retroviral DNA by ORF2, a reverse transcriptase, is primed by the 3' end of cleaved chromosomal DNA, which base-pairs with the poly(A) tail of the non-LTR RNA (see Figure 8-17, step 1). Since its synthesis is primed by the cut end of a cleaved chromosome, and since synthesis of the other strand of the non-LTR retrotransposon DNA is primed by the 3' end of chromosomal DNA on the other side of the initial cut (step 6), the mechanism of synthesis results in integration of the non-LTR retrotransposon DNA. There is no need for an integrase to insert the non-LTR retrotransposon DNA. Because its synthesis begins with reverse transcription of a poly(A) tail on the LINE RNA, one end of a non-LTR retrotransposon is AT-rich.

The vast majority of LINES in the human genome are truncated at their 5' end, suggesting that reverse transcription was terminated before completion and that the resulting fragments, extending variable distances from the poly(A) tail, were inserted. Because of this shortening, the average size of LINE elements is only about 900 bp, even though the full-length sequence is about 6 kb long. Truncated LINE

**FIGURE 8-17 Proposed mechanism of LINE reverse transcription and integration.** Only ORF2 protein is represented here. Newly synthesized LINE DNA is shown in black. ORF1 and ORF2 proteins, produced by translation of LINE RNA in the cytoplasm, bind to LINE RNA and transport it into the nucleus. Step **1**: In the nucleus, ORF2 makes staggered cuts in AT-rich target-site DNA, generating the DNA 3'-OH ends indicated by blue arrowheads. Step **2**: The 3' end of the T-rich DNA strand hybridizes to the poly(A) tail of the LINE RNA and primes DNA synthesis by ORF2. Step **3**: ORF2 extends the DNA strand using the LINE RNA as a template. Steps **4** and **5**: When synthesis of the LINE DNA bottom strand reaches the 5' end of the LINE RNA template, ORF2 extends the newly synthesized LINE DNA using as a template the top-strand cellular DNA generated by the initial ORF2 staggered cleavage. Step **6**: A cellular DNA polymerase extends the 3' end of the top strand generated by the initial ORF2 staggered cut, using the newly synthesized bottom-strand LINE DNA as a template. The LINE RNA is digested as the DNA polymerase extends the upper-strand DNA, just as occurs during removal of lagging-strand primer RNA during cellular DNA synthesis (see Figure 5-29). The 3' ends of the newly synthesized DNA strands are ligated to the 5' ends of the cellular DNA strands as in lagging-strand cellular DNA synthesis. See D. D. Luan et al., 1993, *Cell* **72**:595.

elements, once formed, probably are not further transposed because they lack a promoter for formation of the RNA intermediate. In addition to the fact that most L1 insertions are truncated, nearly all the full-length elements contain stop codons and frameshift mutations in ORF1 and ORF2; these mutations have probably accumulated in most LINE sequences over evolutionary time. As a result, only about 0.01 percent of the LINE sequences in the human genome, or about 60 in total number, are full-length, with intact open reading frames for ORF1 and ORF2.

**SINEs** The most abundant class of mobile elements in the human genome, SINEs constitute about 13 percent of total human DNA. Varying in length from about 100 to 400 base pairs, these retrotransposons do not encode protein, but most contain a 3' AT-rich sequence similar to that in LINES. SINEs are transcribed by the same nuclear RNA polymerase that transcribes genes encoding tRNAs, 5S rRNAs, and other small stable RNAs. Most likely, the ORF1 and ORF2 proteins expressed from full-length LINES mediate reverse transcription and integration of SINEs by the mechanism depicted in Figure 8-17. Consequently, SINEs can be viewed as parasites of the LINE symbionts, competing with LINE RNAs for binding, reverse transcription, and integration by LINE-encoded ORF1 and ORF2.

SINEs occur at about 1.6 million sites in the human genome. Of these, about 1.1 million are *Alu* elements, so named because most of them contain a single recognition site for the restriction enzyme *AluI*. *Alu* elements exhibit considerable sequence homology with, and probably evolved from, 7SL RNA, a cytosolic RNA in a ribonucleoprotein complex called the signal recognition particle. This abundant cytosolic ribonucleoprotein particle aids in targeting certain polypeptides to the membranes of the endoplasmic reticulum (see Chapter 13). *Alu* elements are scattered throughout

the human genome at sites where their insertion has not disrupted gene expression: between genes, within introns, and in the 3' untranslated regions of some mRNAs. For instance, nine *Alu* elements are located within the human  $\beta$ -globin gene cluster (see Figure 8-4a). Of the new germ-line non-LTR retrotranspositions that are estimated to occur about once in every eight individuals, about 40 percent involve L1 elements and 60 percent involve SINES, of which about 90 percent are *Alu* elements.

Like other mobile elements, most SINES have accumulated mutations from the time of their insertion in the germ line of an ancient ancestor of modern humans. Like LINES, many SINES are truncated at their 5' ends.

### Other Retroposed RNAs Are Found in Genomic DNA

In addition to the mobile elements listed in Table 8-1, DNA copies of a wide variety of mRNAs appear to have become integrated into chromosomal DNA. Since these sequences lack introns and do not have flanking sequences similar to those of functional gene copies, they clearly are not simply duplicated genes that have drifted into nonfunctionality and become pseudogenes, as discussed earlier (see Figure 8-4a). Instead, these DNA segments appear to be retrotransposed copies of spliced and polyadenylated mRNA. Compared with normal genes encoding mRNAs, these inserted segments generally contain multiple mutations, which are thought to have accumulated since they were first reverse-transcribed and randomly integrated into the genome of a germ cell in an ancient ancestor. These nonfunctional genomic copies of mRNAs are referred to as *processed pseudogenes*. Most processed pseudogenes are flanked by short direct repeats, supporting the hypothesis that they were generated by rare retrotransposition events involving cellular mRNAs.

Other interspersed repeats representing partial or mutant copies of genes encoding small nuclear RNAs (snRNAs) and tRNAs are found in mammalian genomes. Like processed pseudogenes derived from mRNAs, these nonfunctional copies of small RNA genes are flanked by short direct repeats and most likely result from rare retrotransposition events that have accumulated through the course of evolution. Enzymes expressed from a LINE are thought to have carried out all these retrotransposition events involving mRNAs, snRNAs, and tRNAs.

### Mobile DNA Elements Have Significantly Influenced Evolution

Although mobile DNA elements appear to have no direct function other than to maintain their own existence, their presence has had a profound effect on the evolution of modern-day organisms. As mentioned earlier, about half the spontaneous mutations in *Drosophila* result from insertion of a mobile DNA element into or near a transcription unit. In mammals, mobile elements cause a much smaller proportion of spontaneous mutations: about 10 percent in mice, and only 0.1–0.2 percent in humans. Still, mobile elements have been found in mutant alleles associated with several human genetic diseases. For example, insertions into the clotting factor IX gene cause hemophilia, and insertions into the gene encoding the muscle protein dystrophin lead to Duchenne muscular dystrophy. The genes encoding clotting factor IX and dystrophin are both on the X chromosome. Consequently, disease resulting from a transposition into these genes occurs primarily in males, in which there is no second copy of the normal gene to complement the resulting mutation.

In lineages leading to higher eukaryotes, homologous recombination between mobile DNA elements dispersed throughout ancestral genomes may have generated gene duplications and other DNA rearrangements during evolution (see Figure 8-2b). For instance, cloning and sequencing of the  $\beta$ -globin gene clusters from various primate species has provided strong evidence that the human *HGB1* and *HGB2* genes encoding fetal  $\beta$ -globins arose from an unequal homologous crossover between two L1 elements flanking an ancestral globin gene. Subsequent divergence of such duplicated genes could lead to the acquisition of distinct, beneficial functions by each member of a gene family. Unequal crossing over between mobile elements located within introns of a particular gene could lead to the duplication of exons within that gene (see Figure 8-2a). This process most likely influenced the evolution of genes that contain multiple copies of similar exons encoding similar protein domains, such as the fibronectin gene (see Figure 5-16).

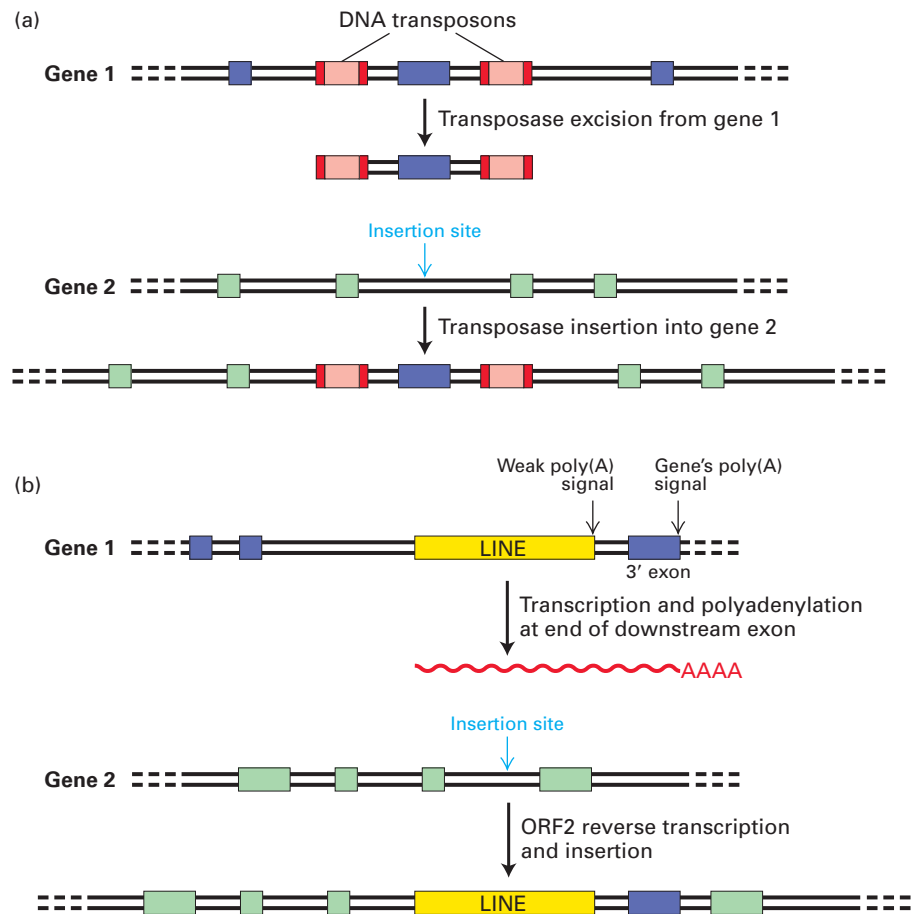

Some evidence suggests that during the evolution of higher eukaryotes, recombination between mobile DNA elements (e.g., *Alu* elements) in introns of *two separate* genes also occurred, generating new genes made from novel combinations of preexisting exons (Figure 8-18). This evolutionary

**FIGURE 8-18 Exon shuffling via recombination between homologous interspersed repeats.** Recombination between interspersed repeats in the introns of separate genes produces transcription units with new combinations of exons. In the example shown here, a double crossover between two sets of *Alu* repeats results in an exchange of exons between two genes.

**FIGURE 8-19 Exon shuffling by transposition.**

(a) Transposition of an exon flanked by homologous DNA transposons into an intron on a second gene. As we saw in Figure 8-10, step 1, transposase can recognize and cleave the DNA at the ends of the transposon inverted repeats. In gene 1, if the transposase cleaves at the left end of the transposon on the left and at the right end of the transposon on the right, it can transpose all the intervening DNA, including the exon from gene 1, to a new site in an intron of gene 2. The net result is an insertion of the exon from gene 1 into gene 2. (b) Integration of an exon into another gene via LINE transposition. Some LINEs have weak poly(A) signals. If such a LINE is in the 3'-most intron of gene 1, during transposition its transcription may continue beyond its own poly(A) signals and extend into the 3' exon, transcribing the cleavage and polyadenylation signals of gene 1 itself. This RNA can then be reverse-transcribed and integrated by the LINE ORF2 protein (see Figure 8-17) into an intron on gene 2, introducing a new 3' exon (from gene 1) into gene 2.

process, termed **exon shuffling**, may have occurred during the evolution of the genes encoding tissue plasminogen activator, the Neu receptor, and epidermal growth factor, all of which contain an EGF domain (see Figure 3-12). In this case, exon shuffling presumably resulted in the insertion of an EGF domain-encoding exon into an intron of the ancestral form of each of these genes.

Both DNA transposons and LINE retrotransposons have been shown to occasionally carry unrelated flanking sequences—including exons—when they transpose to new sites by the mechanisms diagrammed in Figure 8-19. These mechanisms probably also contributed to exon shuffling during the evolution of contemporary genes.

In addition to causing changes in coding sequences, recombination between mobile elements and transposition of DNA adjacent to mobile elements probably played a significant role in the evolution of regulatory sequences that control gene expression. As noted earlier, eukaryotic genes have transcription-control regions called enhancers that can operate over distances of tens of thousands of base pairs. The transcription of many genes is controlled through the combined effects of several enhancer elements. Insertion of mobile elements near such transcription-control regions probably contributed to the evolution of new combinations of enhancer sequences. These combinations, in turn, control which specific genes are expressed in particular cell types

and the amount of the encoded protein produced in modern organisms, as we discuss in the next chapter.

These considerations suggest that the early view of mobile DNA elements as completely selfish molecular parasites misses the mark. Rather, these elements have contributed profoundly to the evolution of higher organisms by promoting (1) the generation of gene families via gene duplication, (2) the creation of new genes via shuffling of preexisting exons, and (3) the formation of more complex regulatory regions that provide multifaceted control of gene expression. Today researchers are attempting to harness transposition mechanisms to insert therapeutic genes into patients as a form of gene therapy.

A process analogous to that shown in Figure 8-19a is largely responsible for the rapid spread of antibiotic resistance among pathogenic bacteria, a major problem in modern medicine. Bacterial genes encoding enzymes that inactivate antibiotics (drug resistance genes) have become flanked by insertion sequences, generating drug resistance transposons. The widespread use of antibiotics in medicine, often unnecessarily in the treatment of viral infections, and to prevent infections in healthy agricultural animals has led to positive selection on such drug resistance transposons, which have inserted into conjugating plasmids. Conjugating plasmids encode proteins

that result in their replication and transfer to other bacterial cells—even cells of other related bacterial species—through a complex macromolecular tube called a pilus. These plasmids, called R factors (for drug *resistance*), can contain multiple drug resistance genes introduced by transposition and selected in environments, such as hospitals, where antibiotics are used to sterilize surfaces. These R factors have led to the rapid spread of resistance to multiple antibiotics between pathogenic bacteria. Coping with the spread of R factors is a major challenge for modern medicine. ■

## KEY CONCEPTS OF SECTION 8.3

### Transposable (Mobile) DNA Elements

- Transposable DNA elements are moderately repeated sequences interspersed at multiple sites throughout the genomes of higher eukaryotes. They are present less frequently in prokaryotic genomes.
- DNA transposons move to new sites directly as DNA; retrotransposons are first transcribed into an RNA copy of the element, which is then reverse-transcribed into DNA (see Figure 8-8).
- A common feature of all mobile elements is the presence of short direct repeats flanking the element, generated as the result of staggered cuts in the target-site DNA that are filled in by a DNA polymerase during transposition (see Figure 8-10).
- Enzymes encoded by transposons themselves catalyze insertion of these sequences at new sites in genomic DNA.
- Although DNA transposons, similar in structure to bacterial IS elements, occur in eukaryotes (e.g., the *Drosophila* P element), retrotransposons are generally much more abundant, especially in vertebrates.
- LTR retrotransposons are flanked by long terminal repeats (LTRs) similar to those in retroviral DNA; like retroviruses, they encode reverse transcriptase and integrase. They move in the genome by being transcribed into RNA, which then undergoes reverse transcription in the cytosol, nuclear import of the resulting DNA with LTRs, and integration into a host-cell chromosome (see Figure 8-14).
- Non-LTR retrotransposons, including long interspersed elements (LINEs) and short interspersed elements (SINEs), lack LTRs and have an AT-rich stretch at one end. They are thought to move by a nonviral retrotransposition mechanism mediated by LINE-encoded proteins involving priming of reverse transcription by chromosomal DNA (see Figure 8-17).
- SINE sequences exhibit extensive homology with small cellular RNAs and are transcribed by the same RNA polymerase. *Alu* elements, the most common SINEs in humans, are sequences of about 300 bp found scattered throughout the human genome at about 1.6 million sites (see Figure 8-4a).
- Some interspersed repeats are derived from cellular RNAs that were reverse-transcribed and inserted into genomic

DNA at some time in evolutionary history. Processed pseudogenes derived from mRNAs lack introns, a feature that distinguishes them from pseudogenes, which arose by sequence drift of duplicated genes.

- Mobile DNA elements most likely influenced evolution significantly by serving as sites for homologous recombination during unequal crossing over, leading to gene and exon duplication (see Figure 8-2) and exon shuffling (see Figure 8-18), and by mobilizing adjacent DNA sequences (see Figure 8-19).

## 8.4 Genomics: Genome-Wide Analysis of Gene Structure and Function

By using automated DNA sequencing techniques and computer algorithms to piece together sequence data, researchers have determined vast amounts of DNA sequence, including nearly the entire genomic sequence of humans and of many key experimental organisms. This enormous volume of data, which is growing at a rapid pace, has been stored and organized by the National Center for Biotechnology Information (NCBI), US National Institutes of Health, the European Bioinformatics Institute at the European Molecular Biology Laboratory in Heidelberg, Germany, and the DNA Data Bank of Japan. These databases continuously exchange newly reported sequences and make them available to scientists throughout the world on the Internet. By now, the genomic sequences have been completely, or nearly completely, determined for hundreds of viruses and bacteria; scores of archaea; yeasts (eukaryotes); plants, including rice and maize; important model multicellular eukaryotes such as the roundworm *C. elegans*, the fruit fly *Drosophila melanogaster*, and mice; humans; and representatives of all of the 35 or so metazoan phyla. The cost of sequencing a megabase of DNA has fallen so low that the entire genomes of cancer cells have been sequenced and compared with the genomes of normal cells from the patients from which they came in order to determine all the mutations that have accumulated in that patient's tumor cells. This approach is revealing genes that are commonly mutated in all cancers, as well as genes that are commonly mutated in tumors from different patients with the same type of cancer (e.g., breast or colon cancer). This approach may eventually lead to highly individualized cancer treatments tailored to the specific mutations in the tumor cells of a particular patient. The latest automated DNA sequencing techniques are so powerful that a project known as the "1000 Genomes Project" is currently under way, with the goal of sequencing most of the genomes of 2500 randomly chosen individuals from 25 populations around the world in order to determine the extent of human genetic variation as a basis for investigating the relationship between genotype and phenotype in humans. Moreover, privately owned companies have been founded that will sequence much of an individual's genome for about \$100 in

order to search for sequence variations that may influence that individual's probability of developing specific diseases.

In this section, we examine some of the ways in which researchers are mining this treasure trove of data to provide insights about gene function and evolutionary relationships, to identify new genes whose encoded proteins have never been isolated, and to determine when and where genes are expressed. This use of computers to analyze sequence data has led to the emergence of a new field of biology: *bioinformatics*.

## Stored Sequences Suggest Functions of Newly Identified Genes and Proteins

As discussed in Chapter 3, proteins with similar functions often contain similar amino acid sequences that correspond to important functional domains in the three-dimensional structure of the proteins. By comparing the amino acid sequence of the protein encoded by a newly cloned gene with the sequences of proteins of known function, an investigator can look for sequence similarities that provide clues to the function of the encoded protein. Because of the degeneracy in the genetic code, related proteins invariably exhibit more sequence similarity than the genes encoding them. For this reason, protein sequences, rather than the corresponding DNA sequences, are usually compared.

The most widely used computer program for this purpose is known as BLAST (*basic local alignment search tool*). The BLAST algorithm divides the “new” protein sequence (known as the *query sequence*) into shorter segments and then searches the database for significant matches to any of

the stored sequences. The matching program assigns a high score to identically matched amino acids and a lower score to matches between amino acids that are related (e.g., hydrophobic, polar, positively charged, negatively charged) but not identical. When a significant match is found for a segment, the BLAST algorithm searches locally to extend the region of similarity. After searching is completed, the program ranks the matches between the query protein and various known proteins according to their *p-values*. This parameter is a measure of the probability of finding such a degree of similarity between two protein sequences by chance. The lower the *p-value*, the greater the sequence similarity between two sequences. A *p-value* less than about  $10^{-3}$  is usually considered significant evidence that two proteins share a common ancestor. Many alternative computer programs have been developed that can detect relationships between proteins that are more distantly related to each other than can be detected by BLAST. The development of such methods is currently an active area of bioinformatics research.

 To illustrate the power of this sequence comparison approach, let's consider the human gene *NF1*. Mutations in *NF1* are associated with the inherited disease neurofibromatosis 1, in which multiple tumors develop in the peripheral nervous system, causing large protuberances in the skin. After a cDNA clone of *NF1* was isolated and sequenced, the deduced sequence of the NF1 protein was checked against all other protein sequences in GenBank. A region of NF1 protein was discovered to have considerable homology to a portion of the yeast protein called Ira (Figure 8-20). Previous studies had shown that Ira is a GTPase-activating protein

**FIGURE 8-20 Comparison of the regions of human NF1 protein and *S. cerevisiae* Ira protein that show significant sequence similarity.** The NF1 and the Ira sequences are shown on the top and bottom lines of each row, respectively, in the one-letter amino acid code (see Figure 2-14). Amino acids that are identical in the two proteins are highlighted in dark blue. Amino acids with chemically similar but

nonidentical side chains are highlighted in light blue. Black dots indicate “gaps” in the upper and lower protein sequences, inserted in order to maximize the alignment of homologous amino acids. The BLAST *p-value* for these two sequences is  $10^{-28}$ , indicating a high degree of similarity.

[Data from G. Xu et al., 1990, *Cell* 62:599.]

(GAP) that modulates the GTPase activity of the monomeric G protein called Ras (see Figure 3-34). As we examine in detail in Chapter 16, GAP and Ras proteins normally function to control cell replication and differentiation in response to signals from neighboring cells. Functional studies on the normal NF1 protein, obtained by expression of the cloned wild-type gene, showed that it did, indeed, regulate Ras activity, as suggested by its homology with Ira. These findings suggest that patients with neurofibromatosis express a mutant NF1 protein in cells of the peripheral nervous system, leading to abnormally high signaling through RAS protein leading to excessive cell division and formation of the tumors characteristic of the disease. ■

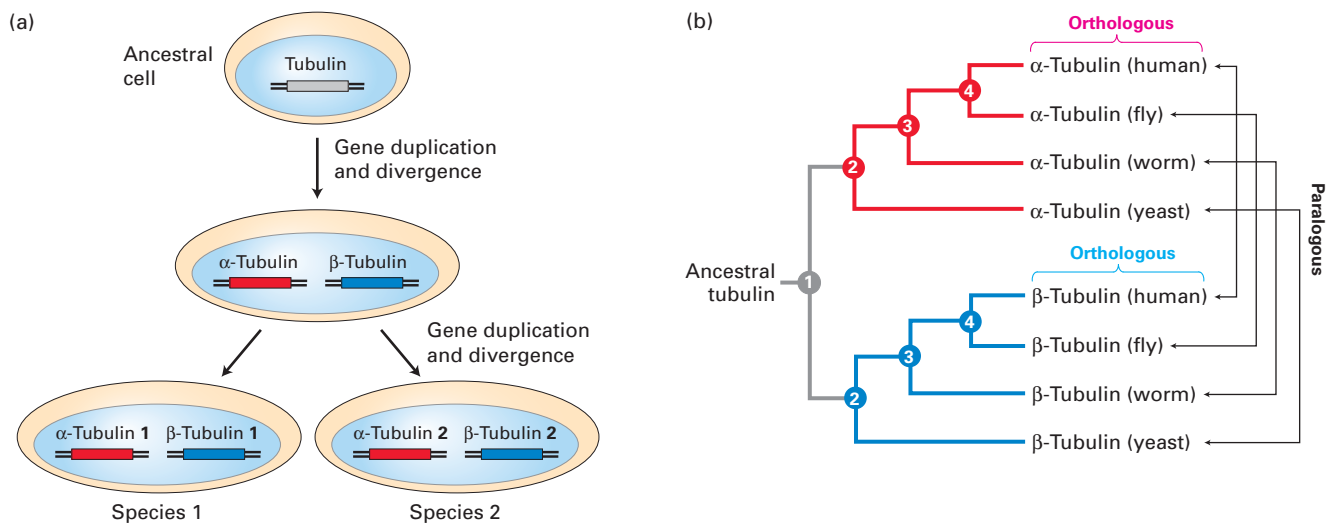

Even when the BLAST algorithm finds no significant similarities, a query sequence may nevertheless share a short sequence with known proteins that is functionally important. Such short segments recurring in many different proteins, referred to as **structural motifs**, generally have similar functions. Several such motifs are described in Chapter 3 and illustrated in Figure 3-10. To search for these and other motifs in a new protein, researchers compare the query protein sequence with a database of known motif sequences.

### Comparison of Related Sequences from Different Species Can Give Clues to Evolutionary Relationships Among Proteins

BLAST searches for related protein sequences may reveal that proteins belong to a protein family. Earlier, we considered

gene families in a single organism, using the  $\beta$ -globin genes in humans as an example (see Figure 8-4a). But in a database that includes the genomic sequences of multiple organisms, protein families can also be recognized as being shared among related organisms. Consider, for example, the **tubulin** proteins, the basic subunits of microtubules, which are important components of the cytoskeleton (see Chapter 18). According to the simplified scheme in Figure 8-21a, the earliest eukaryotic cells are thought to have contained a single tubulin gene that was duplicated early in evolution; subsequent divergence of the different copies of the original tubulin gene formed the ancestral versions of the  $\alpha$ - and  $\beta$ -tubulin genes. As different species diverged from these early eukaryotic cells, each of these gene sequences further diverged, giving rise to the slightly different forms of  $\alpha$ -tubulin and  $\beta$ -tubulin now found in each species.

All the different members of the tubulin family of genes (and proteins) are sufficiently similar in sequence to suggest a common ancestral sequence. Thus all these sequences are considered to be *homologous*. More specifically, sequences that presumably diverged as a result of gene duplication (e.g., the  $\alpha$ - and  $\beta$ -tubulin sequences) are described as *paralogous*. Sequences that arose because of speciation (e.g., the  $\alpha$ -tubulin genes in different species) are described as *orthologous*. From the degree of sequence relatedness of the tubulins present in different organisms today, evolutionary relationships can be deduced, as illustrated in Figure 8-21b. Of the three types of sequence relationships, orthologous sequences are the most likely to share the same function.

**FIGURE 8-21 Generation of diverse tubulin sequences during the evolution of eukaryotes.** (a) Probable mechanism giving rise to the tubulin genes found in existing species. It is possible to deduce that a gene duplication event occurred before speciation because the  $\alpha$ -tubulin sequences from different species (e.g., humans and yeast) are more alike than are the  $\alpha$ -tubulin and  $\beta$ -tubulin sequences within a species. (b) A phylogenetic tree representing the relationship between the tubulin sequences. The branch points (nodes), indicated by small numbers, represent common ancestral genes at the time that two

sequences diverged. For example, node 1 represents the duplication event that gave rise to the  $\alpha$ -tubulin and  $\beta$ -tubulin families, and node 2 represents the divergence of yeast from multicellular species. Braces and arrows indicate, respectively, the orthologous tubulin genes, which differ as a result of speciation, and the paralogous genes, which differ as a result of gene duplication. This diagram is simplified somewhat because flies, worms, and humans actually contain multiple  $\alpha$ -tubulin and  $\beta$ -tubulin genes that arose from later gene duplication events.

## Genes Can Be Identified Within Genomic DNA Sequences

The complete genomic sequence of an organism contains within it the information needed to deduce the sequence of every protein made by the cells of that organism. For organisms such as bacteria and yeast, whose genomes have few introns and short intergenic regions, most protein-coding sequences can be found simply by scanning the genomic sequence for **open reading frames (ORFs)** of significant length. An ORF is usually defined as a stretch of DNA containing at least 100 codons that begins with a start codon and ends with a stop codon. Because the probability that a random DNA sequence will contain no stop codons for 100 codons in a row is very small, most ORFs encode proteins.

ORF analysis correctly identifies more than 90 percent of the genes in yeast and bacteria. Some of the very shortest genes, however, are missed by this method, and occasionally long open reading frames that are not actually genes arise by chance. Both types of mis-assignments can be corrected by more sophisticated analysis of the sequence and by genetic tests for gene function. Of the *Saccharomyces* genes identified in this manner, about half were already known by some functional criterion such as mutant phenotype. The functions of some of the proteins encoded by the remaining putative (suspected) genes identified by ORF analysis have been assigned based on their sequence similarity to known proteins in other organisms.

Identification of genes in organisms with a more complex genome structure requires more sophisticated algorithms than searching for open reading frames. Because most genes in higher eukaryotes are composed of multiple, relatively short exons separated by often quite long non-coding introns, scanning for ORFs is a poor method for finding genes in these organisms. The best gene-finding algorithms combine all the available data that might suggest the presence of a gene at a particular genomic site. Relevant data include alignment of the query sequence to

a full-length cDNA sequence; alignment to a partial cDNA sequence, generally 200–400 bp in length, known as an *expressed sequence tag (EST)*; fitting to models for exon, intron, and splice-site sequences; and sequence similarity to genes from other organisms. Using these computer-based bioinformatic methods, computational biologists have identified approximately 21,000 protein-coding genes in the human genome.

A particularly powerful method for identifying human genes is to compare the human genomic sequence with that of the mouse. Humans and mice are sufficiently related to have most genes in common, although largely nonfunctional DNA sequences, such as intergenic regions and introns, tend to be very different because these sequences are not under strong selective pressure. Thus corresponding segments of the human and mouse genome that exhibit high sequence similarity are likely to be functionally important: exons, transcription-control regions, or sequences with other functions that are not yet understood.

## The Number of Protein-Coding Genes in an Organism's Genome Is Not Directly Related to Its Biological Complexity

The combination of genomic sequencing and gene-finding computer algorithms has yielded the complete inventory of protein-coding genes for a variety of organisms. Figure 8-22 shows the total number of protein-coding genes in several eukaryotic genomes that have been completely sequenced. The functions of about half the proteins encoded in these genomes are known or have been predicted on the basis of sequence comparisons. One of the surprising features of this comparison is that the number of protein-coding genes within different organisms does not seem proportional to our intuitive sense of their biological complexity. For example, the roundworm *C. elegans* apparently has more genes than the fruit fly *Drosophila*, which has a much more complex body

**FIGURE 8-22 Comparison of the number and types of proteins encoded in the genomes of different eukaryotes.** For each organism, the area of the entire pie chart represents the total number of protein-coding genes, all shown at roughly the same scale. In most cases, the functions of the proteins encoded by about half the genes are still unknown (light blue). The functions of the remainder are

known or have been predicted by sequence similarity to genes of known function. [Data from ENCODE Project Consortium, 2012, *Nature* **489**:57; J. D. Hollister, 2014, *Chromosome Res.* **22**:103; L. W. Hillier et al., 2005, *Genome Res.* **15**:1651; FlyBase: FB2015\_02 Release Notes, [http://flybase.org/static\\_pages/docs/release\\_notes.html](http://flybase.org/static_pages/docs/release_notes.html); *Saccharomyces* Genome Data Base 2015, <http://www.yeastgenome.org/genomesnapshot>.]

plan and more complex behavior. And humans have only about 5 percent more protein-coding genes than *C. elegans*. When it first became apparent that humans have so few more protein-coding genes than the simple roundworm, it was difficult to understand how such a small increase in the number of proteins could generate such a staggering difference in complexity.

Clearly, simple quantitative differences in the number of protein-coding genes in the genomes of different organisms are inadequate for explaining differences in biological complexity. However, several phenomena can generate more complexity in the expressed proteins of higher eukaryotes than is predicted from their genomes. First, alternative splicing of a pre-mRNA can yield multiple functional mRNAs corresponding to a particular gene (see Chapter 10). In humans, the mean number of alternatively spliced mRNAs expressed per gene is about 6. Second, variations in the post-translational modification of many proteins may produce functional differences. Finally, increased biological complexity results from increased numbers of cells built of the same kinds of proteins. Larger numbers of cells can interact in more complex combinations, as we can see by comparing the cerebral cortices of mouse and human. Similar cells are present in the mouse and in the human cerebral cortex, but in humans more of them make more complex connections. Evolution of the increasing biological complexity of multicellular organisms probably required increasingly complex regulation of cell replication and temporal and spatial regulation of gene expression in the cells that make up the organisms, leading to increasing complexity of embryological development.

The specific functions of many genes and proteins identified by analysis of genomic sequences still have not been determined. As researchers unravel the functions of individual proteins in different organisms and further detail their interactions with other proteins, the resulting advances will become immediately applicable to all homologous proteins in other organisms. When the function of every protein is known, no doubt, a more sophisticated understanding of the molecular basis of complex biological systems will emerge.

## KEY CONCEPTS OF SECTION 8.4

### Genomics: Genome-Wide Analysis of Gene Structure and Function

- The function of a protein that has not been isolated (a query sequence) can often be predicted on the basis of similarity of its amino acid sequence to the sequences of proteins of known function.
- A computer algorithm known as BLAST rapidly searches databases of known protein sequences to find those with significant similarity to a query protein.
- Proteins with common functional motifs, which can often be quite short, may not be identified in a typical BLAST

search. Such short sequences may be located by searches of structural motif databases.

- A protein family comprises multiple proteins all derived from the same ancestral protein. The genes encoding these proteins, which constitute the corresponding gene family, arose by an initial gene duplication event and subsequent divergence during speciation (see Figure 8-21).
- Related genes and their encoded proteins expressed in one organism that derive from a gene duplication event are paralogous, such as the  $\alpha$ - and  $\beta$ -globins that combine in hemoglobin ( $\alpha_2\beta_2$ ). Those that derive from mutations that accumulated during speciation are orthologous. Proteins that are orthologous usually have a similar function in different organisms.
- Open reading frames (ORFs) are regions of genomic DNA containing at least 100 codons located between a start codon and stop codon.
- Computer searching of the entire bacterial and yeast genomic sequences for open reading frames (ORFs) correctly identifies most protein-coding genes. Several types of additional data must be used to identify probable (putative) genes in the genomic sequences of humans and other higher eukaryotes because of their more complex gene structure, in which relatively short coding exons are separated by relatively long noncoding introns.
- Analysis of the complete genomic sequences of several different organisms indicates that biological complexity is not directly related to the number of protein-coding genes (see Figure 8-22).

## 8.5 Structural Organization of Eukaryotic Chromosomes

Now that we have examined the various types of DNA sequences found in eukaryotic genomes and how they are organized within genomes, we turn to the question of how DNA molecules as a whole are organized within eukaryotic cells. Because the total length of cellular DNA is up to a hundred thousand times a cell's diameter, the packing of DNA is crucial to cell architecture. It is also essential to prevent the long DNA molecules from getting knotted or tangled with each other during cell division, when they must be precisely segregated to daughter cells. The task of compacting and organizing chromosomal DNA is performed by abundant nuclear proteins called **histones**. The complex of histones and DNA is called **chromatin**.

Chromatin, which is about half DNA and half protein by mass, is dispersed throughout much of the nucleus in interphase cells (those that are not undergoing mitosis). Further folding and compaction of chromatin during mitosis (see Figure 6-3) produces the visible *metaphase chromosomes* whose morphology and staining characteristics were detailed by early cytogeneticists. Although every eukaryotic

**EXPERIMENTAL FIGURE 8-23** The extended and condensed forms of extracted chromatin have very different appearances in electron micrographs. (a) Chromatin isolated in low-ionic-strength buffer has an extended “beads-on-a-string” appearance. The “beads” are nucleosomes (10 nm in diameter) and the “string” is connecting (linker) DNA. (b) Chromatin isolated in buffer with a physiological ionic strength (0.15 M KCl) appears as a condensed fiber 30 nm in diameter. [Part (a) courtesy of Steven McKnight and Oscar Miller, Jr. Part (b) courtesy of Barbara Hamkalo and J. B. Rattner.]

chromosome includes millions of individual protein molecules, each chromosome contains just one, extremely long, linear DNA molecule. The longest DNA molecules in human chromosomes, for instance, are  $2.8 \times 10^8$  bp, or almost 10 cm, in length! The structural organization of chromatin allows this vast length of DNA to be compacted into the microscopic constraints of a cell nucleus (see Figure 8-1). Yet chromatin is organized in such a way that specific DNA sequences within the chromatin are readily available for cellular processes such as the transcription, replication, repair, and recombination of DNA molecules. In this section, we consider the properties of chromatin and its organization into chromosomes. Important features of chromosomes in their entirety are covered in the next section.

## Chromatin Exists in Extended and Condensed Forms

Histones, the most abundant proteins in chromatin, constitute a family of small, basic proteins. The five major types of histone proteins—termed *H1*, *H2A*, *H2B*, *H3*, and *H4*—are rich in positively charged basic amino acids, which interact with the negatively charged phosphate groups in DNA.

When chromatin is extracted from nuclei and examined in the electron microscope, its appearance depends on the salt concentration to which it is exposed. At low salt concentrations and in the absence of divalent cations such as  $Mg^{2+}$ , isolated chromatin resembles beads on a string (Figure 8-23a). In this extended form, the “string” is composed of free DNA, called “linker” DNA, connecting bead-like structures termed **nucleosomes**. Composed of DNA and histones, nucleosomes are about 10 nm in diameter and are the primary structural units of chromatin. If chromatin is isolated at a physiological salt concentration, it assumes a more condensed fiberlike form that is about 30 nm in diameter (Figure 8-23b).

**Structure of Nucleosomes** The DNA component of nucleosomes is much less susceptible to nuclease digestion than is the linker DNA between them. If nuclease treatment is carefully controlled, all the linker DNA can be digested,

releasing individual nucleosomes with their DNA component. A nucleosome consists of a protein core with DNA wound around its surface like thread around a spool. The core is an octamer containing two copies each of histones H2A, H2B, H3, and H4. X-ray crystallography has shown that the octameric histone core is a roughly disk-shaped structure made of interlocking histone subunits (Figure 8-24). Histones H3 and H4 fold into a tetramer in the absence of histones H2A and H2B. Two heterodimers of H2A and H2B then associate with the H3-H4 tetramer. Positive charges on the surface of the histone octamer in the region interacting with DNA hold the negatively charged DNA against the surface of the histone octamer at the center of the nucleosome. Nucleosomes from all eukaryotes contain about 147 bp of DNA wrapped one and two-thirds turns around the globular histone core. The length of the linker DNA is more variable among species, and even between different cells of the same organism, ranging from about 10 to 90 base pairs. During cell replication, DNA is assembled into nucleosomes shortly after the replication fork passes (see Figure 5-32). This process depends on specific **chaperone** molecules that bind to histones and assemble them, together with newly replicated DNA, into nucleosomes.

**Structure of the 30-nm Fiber** When extracted from cells in isotonic buffers (i.e., buffers with the same salt concentration found in cells, about 0.15 M KCl, 0.004 M  $MgCl_2$ ), most chromatin appears as fibers about 30 nm in diameter (see Figure 8-23b). Despite many years of study, the arrangement of nucleosomes in the 30-nm chromatin fiber remains controversial. In one widely accepted model with considerable experimental support, nucleosomes are arranged in a helical conformation forming a *solenoid* with six or more nucleosomes per turn of the helix (Figure 8-25a). In a second strongly supported model, the *two-start helix*, nucleosomes alternately stack like coins into two “strands,” and those strands wind into a left-handed double helix (Figure 8-25b). The 30-nm fibers also include H1, the fifth major histone. H1 is bound to the DNA as it enters and exits the nucleosome core, but its structure in the 30-nm fiber is not known at atomic resolution.

**FIGURE 8-24 Structure of the nucleosome based on x-ray crystallography.** (a) Nucleosome with space-filling model of the histones. The sugar-phosphate backbones of the DNA strands are represented as white tubes to allow better visualization of the histones. Nucleosome shown from the top (*left*) and from the side (*right*, rotated clockwise 90°). H2A subunits are yellow; H2Bs are red; H3s are blue; H4s are green. The N-terminal tails of the eight histones and the H2A and H2B C-terminal tails, involved in condensation of the chromatin, are not visible because they are disordered in the crystal. One H2A, H2B heterodimer projects out of the page on the lower right of the side view, while the

other H2A, H2B heterodimer projects into the page, on the lower left of the side view. Only one H2A, H2B heterodimer is visible in the top view. The other H2A, H2B dimer is not visible in this view because it is behind the H3, H4 tetramer, on the lower right. (See also the ribbon diagram of the histone polypeptide chains in Figure 8-26, where only one H2A, H2B heterodimer is clearly visible on the lower left of the top view of the nucleosome.) (b) Space-filling model of histones and DNA (white) viewed from the side of the nucleosome. See also <http://lugerlab.org> for a rotating movie of the nucleosome core. [Data from K. Luger et al., 1997, *Nature* **389**:251, PDB ID 1aoi.]

The chromatin in chromosomal regions that are not being transcribed or replicated exists predominantly in the condensed, 30-nm fiber form and in higher-order folded structures whose detailed conformation is not currently understood. The regions of chromatin actively being transcribed and replicated are thought to assume the extended beads-on-a-string form.

**Conservation of Chromatin Structure** The general structure of chromatin is remarkably similar in the cells of all eukaryotes, including fungi, plants, and animals, indicating that the structure of chromatin was optimized early in the evolution of eukaryotic cells. The amino acid sequences for the four core histones (H2A, H2B, H3, and H4) are highly conserved between distantly related species. For example, the sequences of histone H3 from sea urchin tissue and calf thymus differ by only a single amino acid, and H3 from the garden pea and calf thymus differ by only four amino acids. Apparently, significant deviations from the histone amino acid sequences were selected against strongly during evolution. The amino acid sequence of H1, however, varies more from organism to organism than do the sequences of the other major histones. The similarity in sequence among histones from all eukaryotes indicates that they fold into very

similar three-dimensional conformations, which were optimized for histone function early in evolution in a common ancestor of all modern eukaryotes.

Minor histone variants encoded by genes that differ from the highly conserved major types also exist, particularly in vertebrates. For example, a special form of H2A, designated H2AX, is incorporated into nucleosomes in place of H2A in a small fraction of nucleosomes in all regions of chromatin. At sites of double-stranded breaks in chromosomal DNA, H2AX becomes phosphorylated and participates in the chromosome-repair process, probably by functioning as a binding site for repair proteins. In the nucleosomes at centromeres, H3 is replaced by another variant histone called CENP-A, which participates in the binding of spindle microtubules during mitosis. A variant of histone H3, known as H3.3, replaces the major histone H3 in transcribed regions of DNA, probably when the histone octamer must be moved out of the way by histone chaperones as RNA polymerase transcribes the DNA in chromatin. Most minor histone variants differ only slightly in sequence from the major histones. These slight changes in histone sequence may influence the stability of the nucleosome as well as its tendency to fold into the 30-nm fiber and other higher-order structures.

**FIGURE 8-25 Models of the structure of the 30-nm chromatin fiber.** (a) In the solenoid model, nucleosomes are arranged in a left-handed helix with six or more nucleosomes per turn. See M. Kruithof et al., 2009, *Nature Struct. Mol. Biol.* **16**:534. (b) In the two-start helix model, a “zigzag ribbon” of nucleosomes (*top*) folds into a two-start

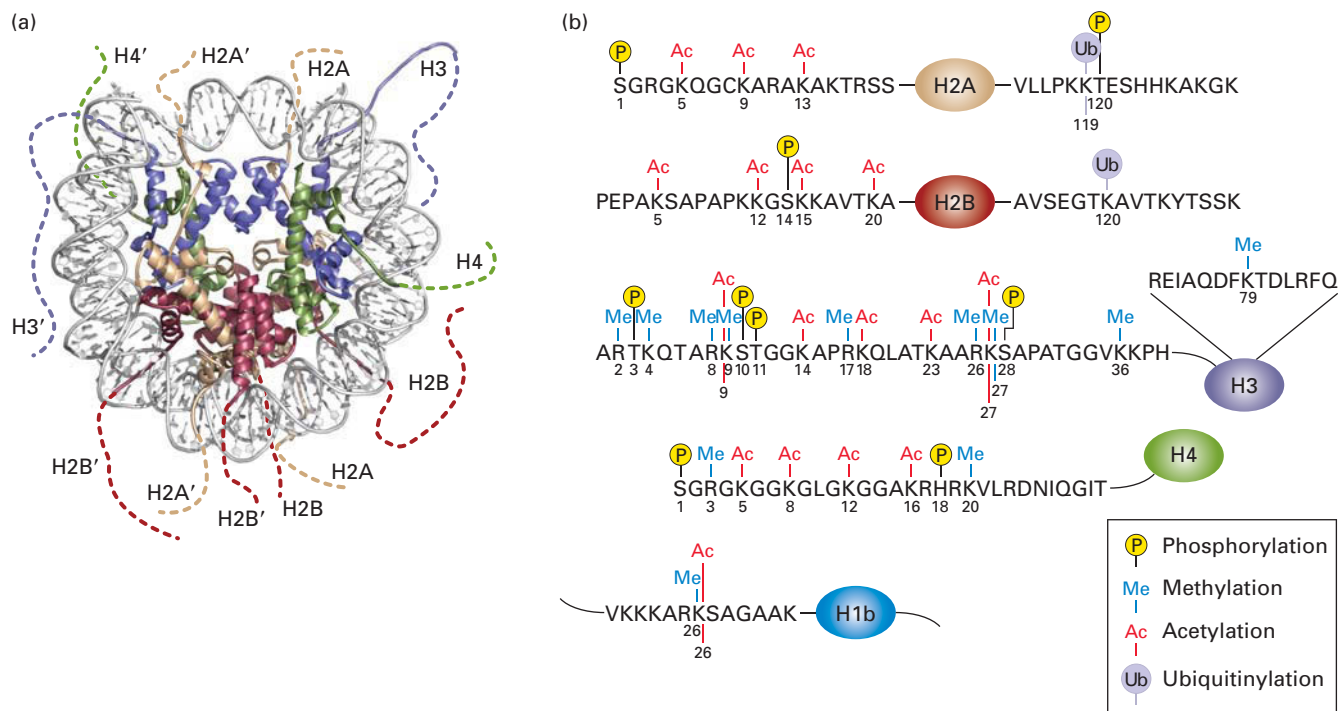

helix (*bottom*). For simplicity, DNA is not represented in the two-start helix. See C. L. F. Woodcock et al., 1984, *J. Cell Biol.* **99**:42. [Part (b) *top* data from K. Luger et al., 1997, *Nature* **389**:251, PDB ID 1aoi. Part (b) *bottom* data from T. Schalch et al., 2005, *Nature* **436**:138, PDB ID 1zbb.]

## Modifications of Histone Tails Control Chromatin Condensation and Function

Each of the histone proteins making up the nucleosome core contains an intrinsically disordered, flexible N-terminus (see Figure 3-8) of 19–39 residues extending from the globular structure of the nucleosome; the H2A and H2B proteins also contain a flexible C-terminus extending from the globular histone octamer core. These termini, called *histone tails*, are represented in the model shown in Figure 8-26a. The histone tails are required for chromatin to condense from the beads-on-a-string conformation into the 30-nm fiber. For example, recent experiments indicate that the N-terminal tails of

histone H4, particularly lysine16, are critical for forming the 30-nm fiber. This positively charged lysine interacts with a negative patch at the H2A–H2B interface of the next nucleosome in the stacked nucleosomes of the 30-nm fiber.

Histone tails are subject to multiple post-translational modifications such as acetylation, methylation, phosphorylation, and ubiquitylation. Figure 8-26b summarizes the types of post-translational modifications observed in human histones. A particular histone protein never has all of these modifications simultaneously, but the histones in a single nucleosome usually contain several of these modifications simultaneously. The particular combinations of post-transcriptional modifications found in different regions

**FIGURE 8-26 Post-translational modifications observed on human histones.** (a) Model of a nucleosome viewed from the top with histones shown as ribbon diagrams. This model depicts the lengths of the histone tails (dotted lines), which are not visible in the crystal structure (see Figure 8-24). The H2A N-terminal tails are at the bottom, and the H2A C-terminal tails are at the top. The H2B N-terminal tails are on the right and left, and the H2B C-terminal tails are at the bottom center. Histones H3 and H4 have short C-terminal tails that are not modified. (b) Summary of post-translational modifications observed

in human histones. Histone-tail sequences are shown in the one-letter amino acid code (see Figure 2-14). The main portion of each histone is depicted as an oval. These modifications do not all occur simultaneously on a single histone molecule. Rather, specific combinations of a few of these modifications are observed on any one histone. See K. Luger and T. J. Richmond, 1998, *Curr. Opin. Genet. Dev.* **8**:140. [Part (a) data from K. Luger et al., 1997, *Nature* **389**:251, PDB ID 1aoi. Part (b) data from R. Margueron et al., 2005, *Curr. Opin. Genet. Dev.* **15**:163.]

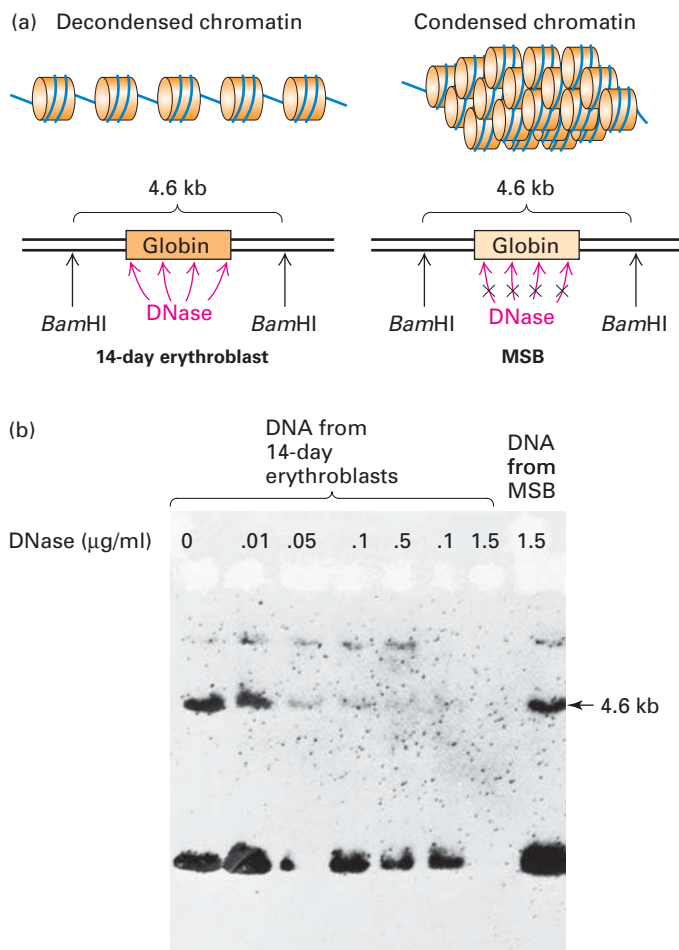

of chromatin constitute a *histone code* that influences chromatin function by creating or removing binding sites for chromatin-associated proteins depending on the specific combinations of these modifications present. Here we describe the most abundant kinds of modifications found in histone tails and how these modifications control chromatin condensation and function. We end with a discussion of a special case of chromatin condensation, the inactivation of X chromosomes in female mammals.

**Histone Acetylation** Histone-tail lysines undergo reversible acetylation and deacetylation by enzymes that act on specific lysines in the histone N-termini. In the acetylated form, the positive charge of the lysine  $\epsilon$ -amino group is neutralized. As mentioned above, lysine 16 in histone H4 is particularly important for the folding of the 30-nm fiber because it interacts with a negatively charged patch on the surface of the neighboring nucleosome in the fiber. Consequently, when H4 lysine 16 is acetylated, the chromatin tends to form the less condensed “beads-on-a-string” conformation conducive for transcription and replication.

Histone acetylation at other sites in H4 and in other histones (see Figure 8-26b) is correlated with increased

sensitivity of chromatin DNA to digestion by nucleases—an observation indicating that histone acetylation is associated with a less condensed form of chromatin. This correlation can be demonstrated by conducting experiments in which isolated nuclei are digested with DNase I. Following digestion, the DNA is completely separated from chromatin protein, digested to completion with a restriction enzyme, and analyzed by Southern blotting. An intact gene treated with a restriction enzyme yields fragments of characteristic sizes. If the nuclei are exposed first to DNase, however, the gene may be cleaved at random sites within the boundaries of the restriction enzyme cut sites. Consequently, any Southern blot bands normally seen with that gene will be lost. This method was first used to show that the  $\beta$ -globin gene in non-erythroid cells, in which it is transcriptionally inactive and in which it is associated with relatively nonacetylated histones, is much more resistant to DNase I than it is in erythroid progenitor cells, in which it is actively transcribed and in which it is associated with acetylated histones (Figure 8-27). These results indicate that the chromatin structure of nontranscribed DNA in *hypocetylated* chromatin makes the DNA less accessible to DNase I than it is in transcribed, *hyperacetylated* chromatin. This is thought to

**EXPERIMENTAL FIGURE 8-27 Nontranscribed genes are less susceptible to DNase I digestion than active genes.** Chick embryo erythroblasts at 14 days actively synthesize globin, whereas undifferentiated chicken lymphoblastic leukemia (MSB) cells do not. (a) Nuclei from each type of cell were isolated and exposed to increasing concentrations of DNase I. The nuclear DNA was then extracted and treated with the restriction enzyme *Bam*HI, which cleaves the DNA around the globin sequence and normally releases a 4.6-kb globin fragment. (b) The DNase I- and *Bam*HI-digested DNA was subjected to Southern blot analysis with a probe of labeled cloned adult globin DNA, which hybridizes to the 4.6-kb *Bam*HI fragment. If the globin gene is susceptible to the initial DNase digestion, it should be cleaved repeatedly and would not be expected to show this fragment. As seen in the Southern blot, the transcriptionally active DNA from the 14-day globin-synthesizing cells was sensitive to DNase I digestion, indicated by the absence of the 4.6-kb band at high nuclease concentrations. In contrast, the inactive DNA from MSB cells was resistant to digestion. These results suggest that the inactive DNA is in a more condensed form of chromatin in which the globin gene is shielded from DNase digestion. See J. Stalder et al., 1980, *Cell* 19:973. [Part (b) republished with permission of Elsevier, from Stalder, J. et al., "Hb switching in chickens," *Cell*, 1980, 19(4):973-80; permission conveyed through Copyright Clearance Center, Inc.]

be because chromatin containing the repressed gene is folded into condensed structures that sterically inhibit access to the associated DNA by the nuclease. In contrast, the transcribed gene is associated with a more unfolded form of chromatin, which allows better access of the nuclease to the associated

DNA. Presumably, the condensed chromatin structure in non-erythroid cells also sterically inhibits access of the promoter and other transcription-control sequences in DNA to the proteins involved in transcription, contributing to transcriptional repression (see Chapter 9).

Genetic studies in yeast indicated that *histone acetyl transferases* (HATs), which acetylate specific lysine residues in histones, are required for the full activation of transcription of a number of genes. These enzymes are now known to have other substrates that influence gene expression in addition to histones. Consequently, they are more generally known as *nuclear lysine acetyl transferases*, or KATs, because K represents lysine in the single-letter code for amino acids (see Figure 2-14). Conversely, early genetic studies in yeast indicated that complete repression of many yeast genes requires the action of *histone deacetylases* (HDACs) that remove acetyl groups of acetylated lysines from histone tails, as discussed further in Chapter 9.

**Other Histone Modifications** As shown in Figure 8-26b, histone tails in chromatin can undergo a variety of other covalent modifications at specific amino acids. Lysine  $\epsilon$ -amino groups can be methylated, a process that prevents acetylation, thus maintaining their positive charge. Moreover, the N of lysine  $\epsilon$ -amino groups can be methylated once, twice, or three times. Arginine side chains can also be methylated. The O in hydroxyl groups ( $-\text{OH}$ ) of serine and threonine side chains can be reversibly phosphorylated, introducing two negative charges. Each of these post-translational modifications contributes to the binding of chromatin-associated proteins that participate in the control of chromatin folding and the ability of DNA and RNA polymerases to replicate or transcribe the associated DNA. Finally, a single 76-amino-acid ubiquitin molecule can be reversibly added to a lysine in the C-terminal tails of H2A and H2B. Recall that addition of multiple linked ubiquitin molecules to a protein can mark it for degradation by the proteasome (see Figure 3-31). In this case, however, the addition of a single ubiquitin molecule does not affect the stability of a histone, although it does influence chromatin structure.

As mentioned previously, it is the precise combination of modified amino acids in histone tails that helps control the condensation, or compaction, of chromatin and its ability to be transcribed, replicated, and repaired. The extent of DNA compaction can be observed by electron microscopy and by light microscopy using dyes that bind DNA. Condensed regions of chromatin, known as **heterochromatin**, stain much more darkly than less condensed chromatin, known as **euchromatin** (Figure 8-28a). Heterochromatin does not fully decondense following mitosis, remaining in a compacted state during interphase and usually associating with the nuclear envelope, nucleoli, and additional distinct foci. Heterochromatin includes centromeres and telomeres of chromosomes as well as transcriptionally inactive genes. In contrast, areas of euchromatin, which are in a less compacted state during interphase, stain lightly with DNA dyes. Most transcribed

**FIGURE 8-28 Heterochromatin versus euchromatin.** (a) In this electron micrograph of a bone marrow stem cell, the dark-staining areas in the nucleus (N) outside the nucleolus (n) are heterochromatin. The light-staining, whitish areas are euchromatin. (b) The modifications of histone N-terminal tails in heterochromatin and euchromatin differ, as illustrated here for histone H3. Note in particular that histone tails are generally much more extensively acetylated in euchromatin than in heterochromatin. Heterochromatin is much more condensed (thus less accessible to proteins) and is much less transcriptionally active than is euchromatin. [Part (a) Don W Fawcett/Science Source/Getty Images. Part (b) data from T. Jenuwein and C. D. Allis, 2001, *Science* **293**:1074.]

regions of DNA are found in euchromatin. Heterochromatin usually contains histone H3 modified by methylation of lysine 9, while euchromatin generally contains histone H3 extensively acetylated on lysine 9 and other H3 lysines, especially at promoters and enhancers where there is also methylation of lysine 4, and phosphorylation of serine 10 (Figure 8-28b). Other histone tails are also differently modified in euchromatin and in heterochromatin. For example, H4 lysine 16 is generally nonacetylated in heterochromatin, which allows it to interact with neighboring nucleosomes and stabilize chromatin folding into the 30-nm fiber (see Figure 8-25).

**Reading the Histone Code** The histone code of modified amino acids in the histone tails is “read” by proteins that bind to the modified tails and in turn promote condensation or decondensation of chromatin. Eukaryotes express a number of proteins containing a so-called *chromodomain* that binds to histone tails when they are methylated at specific lysines. One example of such a protein is *heterochromatin protein 1 (HP1)*. The chromodomain of HP1 binds the H3 N-terminal tail only when it is di- or trimethylated at lysine 9 (see Figure 8-28b). HP1 also contains a second domain called a *chromoshadow domain* because it is frequently found in proteins that contain a chromodomain. The chromoshadow domain binds to other chromoshadow domains. Consequently, chromatin containing H3 di- and trimethylated at lysine 9 (H3K9Me<sub>2/3</sub>) is assembled into a condensed chromatin structure by HP1, although the structure of this chromatin is not well understood.

In addition to binding to itself, the chromoshadow domain of HP1 also binds the enzyme that methylates H3 lysine 9, an H3K9 *histone methyl transferase (HMT)* (Figure 8-29a). As a consequence, nucleosomes adjacent to a region of HP1-containing heterochromatin also become methylated at lysine 9 (Figure 8-29b). This methylation creates a binding site for another HP1 that can bind the H3K9 HMT, resulting in “spreading” of the heterochromatin structure along the chromosome until a *boundary element* is encountered that blocks further spreading. Boundary elements so far characterized are generally regions in chromatin where several nonhistone proteins bind to DNA, possibly blocking histone methylation on the other side of the boundary.

**Epigenetic Memory** Significantly, the model of heterochromatin formation in Figure 8-29b provides an explanation for how heterochromatic regions of a chromosome are reestablished following DNA replication during the S phase of the cell cycle. When DNA in heterochromatin is replicated, the histone octamers that are di- or trimethylated at H3 lysine 9 become distributed to both daughter chromosomes along with an equal number of newly assembled histone octamers. The H3K9 HMT associated with the H3K9 di- and trimethylated nucleosomes methylates lysine 9 of the newly assembled nucleosomes, regenerating the heterochromatin in both daughter chromosomes. Consequently, heterochromatin is marked with an *epigenetic code*, so called because it does not depend on the sequence of bases in DNA, that maintains the repression of associated genes in replicated daughter cells.

Other protein domains associate with histone-tail modifications typical of euchromatin. For example, the *bromodomain* binds to acetylated histone tails and therefore is associated with transcriptionally active chromatin. Several proteins involved in stimulating gene transcription contain bromodomains, such as the largest subunit of TFIID (see Chapter 9). This *transcription factor* contains two closely spaced bromodomains that probably help TFIID to associate with transcriptionally active chromatin (i.e., euchromatin). TFIID and other bromodomain-containing proteins also have histone acetylase activity, which helps to maintain

**FIGURE 8-29 Model for the formation of heterochromatin by the binding of HP1 to histone H3 trimethylated at lysine 9.** (a) HP1 contributes to the condensation of heterochromatin by binding to histone H3 N-terminal tails trimethylated at lysine 9, then associating with other histone-bound HP1 molecules. (b) Heterochromatin condensation can spread along a chromosome because HP1 binds the histone methyltransferase (HMT) that methylates lysine 9 of histone H3. This creates a binding site for HP1 on the neighboring nucleosome. The spreading process continues until a “boundary element” is encountered. See G. Thiel et al., 2004, *Eur. J. Biochem.* **271**:2855, and A. J. Bannister et al., 2001, *Nature* **410**:120.

the chromatin in a hyperacetylated state conducive to transcription. Consequently, an epigenetic code associated with euchromatin helps to maintain the transcriptional activity of genes in euchromatin through successive cell divisions. These epigenetic codes for heterochromatin and euchromatin help to maintain the patterns of gene expression established in different cell types during early embryonic development as specific differentiated cell types increase in numbers by cell division. Importantly, abnormal alterations in these epigenetic codes have been found to contribute to the pathogenic replication and behavior of cancer cells (see Chapter 24).

In summary, multiple types of covalent modifications of histone tails can influence chromatin structure by altering nucleosome–nucleosome interactions and interactions with additional proteins that participate in or regulate processes such as transcription and DNA replication. The mechanisms and molecular processes governing chromatin modifications that regulate transcription are discussed in greater detail in the next chapter.

**X-Chromosome Inactivation in Mammalian Females** One important example of epigenetic gene control through repression by heterochromatin is the random inactivation and condensation of one of the two X chromosomes in female mammals. Each female mammal has two X chromosomes, one contributed by the egg from which it developed ( $X_m$ ) and one contributed by the sperm ( $X_p$ ). Early during embryonic development, random inactivation of either the  $X_m$  or the  $X_p$  chromosome occurs in each somatic cell. In the female embryo, about half the cells have an inactive  $X_m$ , and the other half have an inactive  $X_p$ . All subsequent daughter cells maintain the same inactive X chromosomes as their parent cells. As a result, the adult female is a mosaic of clones, some expressing the genes from the  $X_m$  and some expressing the genes from the  $X_p$ . This inactivation of one X chromosome in female mammals results in *dosage compensation*, a process that ensures that cells of females express proteins encoded on the X chromosome at the same levels as the cells of males, which have only one X chromosome.

Histones associated with the inactive X chromosome have post-translational modifications characteristic of other regions of heterochromatin: hypoacetylation of lysines, di- and trimethylation of histone H3 lysine 9, trimethylation of H3 lysine 27, and a lack of methylation at histone H3 lysine 4 (see Figure 8-28b). X-chromosome inactivation at an early stage in embryonic development is controlled by the X-inactivation center, a complex locus on the X chromosome that determines which of the two X chromosomes will be inactivated and in which cells. The X-inactivation center also contains the *XIST* gene, which encodes a remarkable long nonprotein-coding RNA that coats only the X chromosome it was transcribed from, thereby triggering silencing of that chromosome.

Although the mechanism of X-chromosome inactivation is not fully understood, it involves several processes, including the action of *Polycomb* protein complexes, which are discussed further in Chapter 9. One subunit of the Polycomb

**EXPERIMENTAL FIGURE 8-30** Fluorescent-labeled probes hybridized to interphase chromosomes demonstrate chromatin loops and permit their measurement. In situ hybridization to interphase cells was carried out with several different probes specific for sequences separated by known distances in linear, cloned DNA. Lettered circles represent probes. Measurement of the distances between different hybridized probes, which could be distinguished by their color, showed that some sequences (e.g., A and B), separated from one another by millions of base pairs, appear located near one another within nuclei. For some sets of sequences, the measured distances in nuclei between one probe (e.g., C) and sequences successively farther away initially appear to increase (e.g., D, E, and F) and then appear to decrease (e.g., G and H). See H. Yokota et al., 1995, *J. Cell Biol.* **130**:1239.

complex contains a chromodomain that binds to histone H3 tails when they are trimethylated at lysine 27. The Polycomb complex also contains a histone methyl transferase specific for H3 lysine 27. This finding helps to explain how the X-inactivation process spreads along large regions of the X chromosome and how it is maintained through DNA replication, apparently in a manner similar to heterochromatization by the binding of HP1 to histone H3 tails methylated at lysine 9 (see Figure 8-29b).

X-chromosome inactivation is another example of an epigenetic process; that is, a process that affects the expression of specific genes and is inherited by daughter cells, but is not the result of a change in DNA sequence. In other words, the activity of genes on the X chromosome in female mammals is controlled by chromatin structure, rather than by the nucleotide sequence of the underlying DNA. And the inactivated X chromosome (either  $X_m$  or  $X_p$ ) is maintained as the inactive chromosome in the progeny of all future cell divisions because the histones are modified in a specific, repressing manner that is faithfully inherited through each cell division.

### Nonhistone Proteins Organize Long Chromatin Loops

Although histones are the predominant proteins in chromatin, other, less abundant, nonhistone chromatin-associated

proteins, as well as the DNA molecule itself, are also crucial to chromosome structure. Recent results indicate that it is not protein alone that gives a metaphase chromosome its structure. Micromechanical studies of large metaphase chromosomes from newts in the presence of proteases or nucleases indicate that DNA, not protein, is responsible for the mechanical integrity of a metaphase chromosome when it is pulled from its ends. These results are inconsistent with a continuous protein scaffold at the chromosome axis. Rather, the integrity of chromosome structure requires the complete chromatin complex of DNA, histone octamers, and nonhistone chromatin-associated proteins.

Experiments in which several different fluorescent-labeled probes were hybridized to the DNA of one chromosome in human interphase cells support a model in which chromatin is arranged in large loops. In these experiments, some sequences separated by millions of base pairs in linear DNA appeared very close to one another in interphase nuclei (Figure 8-30). These closely spaced probe sites are postulated to lie at the bases of the chromatin loops. Loops of chromatin can also be directly visualized by light microscopy in the active chromatin of growing amphibian oocytes ("lampbrush chromosomes") (Figure 8-31). These cells are enormous compared to most cells (~1 mm in diameter) because they stockpile all of the nuclear and cytoplasmic material required for division of the fertilized egg into the thousands of differentiated cells required to generate a feeding

**EXPERIMENTAL FIGURE 8-31** Loop of chromatin in a lampbrush chromosome. A short segment of a lampbrush chromosome in the nucleus of an oocyte from the newt *Notophthalmus viridescens*. (a) Differential interference contrast (DIC) microscopy of a portion of the lampbrush chromosome and a loop with transcribed RNA associated with hnRNP proteins (arrow; see Chapter 10). (b) The same field observed by immunofluorescence after staining with antibody to RNA polymerase II. [Republished with permission of Elsevier, from Gall, J.G. et al., "Structure in the amphibian germinal vesicle," *Exp. Cell Res.*, 2004, **296**(1):28-34; permission conveyed through Copyright Clearance Center, Inc.]

embryo that can ingest additional nutrients. The nuclei of these amphibian oocytes are 50 times the diameter of most vertebrate somatic cells. The chromatin of these cells is not constrained by a closely associated nuclear envelope, but rather "floats" in a volume of nucleoplasm about  $10^5$  times greater than in most somatic cells. Microscopy of chromatin from these cells stained with antibody to RNA polymerase II shows long loops of chromatin densely packed with polymerase extending from a central core of highly condensed, transcriptionally inactive chromatin. As discussed below, the loops are tethered at their bases by a mechanism that does not interrupt the duplex DNA molecule that extends the entire length of the chromosome.

**Ringlike Structure of SMC Protein Complexes** The bases of chromatin loops (see Figure 8-30) in interphase chromosomes may be held in place by proteins called **structural maintenance of chromosome (SMC) proteins**. These non-histone proteins are critical for maintaining the structure of condensed chromosomes during mitosis. In extracts prepared from the large nuclei of *Xenopus laevis* (African frog) eggs, chromosomes can be induced to condense as they do in intact cells as they enter prophase of mitosis. This condensation fails to occur when one type of SMC protein is depleted from the extract with specific antibodies. Yeast with mutations in another type of SMC protein fail to properly associate sister chromatids following DNA replication in the S phase. As a result, chromosomes do not properly segregate to daughter cells during mitosis. Related SMC proteins are required for proper segregation of chromosomes in bacteria and archaea, indicating that SMCs are an ancient class of proteins vital to chromosome structure and segregation in all kingdoms of life.

Each SMC monomer contains a hinge region where the polypeptide folds back on itself, forming a very long coiled-coil region and bringing the N- and C-termini together so they can interact to form a globular head domain (Figure 8-32a). The hinge domain of one monomer (blue in Figure 8-32) binds to the hinge domain of a second monomer (red), forming a roughly U-shaped dimeric complex. The head domains of the monomers have ATPase activity and are linked by members of another small protein family called *kleisins*. The overall SMC complex is a ring with a diameter large enough to accommodate two 30-nm chromatin fibers (Figure 8-32b) and is capable of linking two circular DNA molecules in vitro. SMC proteins are proposed to form the bases of chromatin loops by forming topologically constrained knots in 30-nm chromatin fibers, as diagrammed in Figure 8-32c. This model can explain why cleavage of the DNA at a relatively small number of sites leads to rapid dissolution of condensed metaphase chromosome structure, whereas protease cleavage of proteins has only a minor effect on chromosome structure until most of the protein is digested. When the DNA is cut anywhere in a long region of chromatin containing several chromatin loops, the broken ends can slip through the SMC protein rings, "untying" the topological knots that constrain the loops of chromatin. In contrast, most of the individual rings of SMC proteins must be broken

**FIGURE 8-32 Model of SMC complexes bound to chromatin.** (a) Model of an SMC protein complex. (b) Model of SMC complex topologically linking two 30-nm chromatin fibers (represented by cylinders). (c) Model for the binding of SMC complexes to the base of a loop of transcribed chromatin. See K. Nasmyth and C. H. Haering, 2005, *Ann. Rev. Biochem.* **74**:595.

before the topological constraints holding the bases of the loops together are released.

**Interphase Chromosome Territories** In the small nuclei of most cells, individual interphase chromosomes, which are less condensed than metaphase chromosomes, cannot be resolved by standard microscopy or electron microscopy. Nonetheless, the chromatin of an interphase chromosome is not spread throughout the nucleus. Rather, interphase chromatin is organized into *chromosome territories*. As illustrated in Figure 8-33, in situ hybridization of interphase nuclei with chromosome-specific fluorescent-labeled probes shows that the probes are localized within restricted regions of the nucleus, rather than appearing throughout the nucleus. Use of probes specific for different chromosomes shows that there is little overlap between chromosomes in interphase nuclei. The precise positions of chromosomes are not reproducible between cells, although large chromosomes tend to lie at the periphery of the nucleus and small chromosomes toward the center. Also, repeats of rRNA transcription units on chromosomes 13, 14, 15, 21, and 22, known as *nucleolar organizers*, associate with nucleoli found near the center of the nucleus.

**Topological Domains Within Chromosome Territories** A group of related methods referred to as *chromosome conformation capture* ("3C") methods have been made possible by the advent of massively parallel DNA sequencing

**EXPERIMENTAL FIGURE 8-33** During interphase, human chromosomes remain in non-overlapping territories in the nucleus. (a) Fixed interphase human fibroblasts were hybridized in situ to fluorescently labeled probes specific for sequences along the full length of human chromosomes 7 (cyan) and 8 (purple). DNA is stained blue with DAPI. In the diploid cell, each of the two chromosome 7s and two chromosome 8s is restricted to a territory or domain within the nucleus, rather than stretching throughout the entire nucleus.

(b) This image from a fixed interphase fibroblast from a human male was made with a method similar to that used in (a), except that chromosome paint probes specific for each chromosome were hybridized to the cell to reveal the locations of nearly all the chromosomes. Some of the chromosomes are not observed in this confocal slice through the nucleus. [Part (a) courtesy of Dr. Irina Solovei. Part (b) from A. Bolzer et al., 2005, Three-dimensional maps of all chromosomes in human male fibroblast nuclei and prometaphase rosettes. *PLoS Biol.* **3**:826.]

and the ability to sequence tens of millions of 50–100-bp DNA fragments (see Chapter 6). The goal of these methods is to determine the three-dimensional spatial organization of chromatin within nuclei of interphase cells. In human interphase cells, about 2 m of DNA is folded and refolded to fit within a nucleus only about 20  $\mu\text{m}$  in diameter! The general strategy of chromosome conformation capture is illustrated in Figure 8-34, where associations between distant regions of chromatin are represented in (a), and regions of chromatin not specifically associated with another region are shown in (b). First (step 1), intact cells are treated with chemical cross-linkers such as formaldehyde that diffuse through cell membranes and covalently cross-link protein to protein and protein to DNA. Next 2, the cross-linked chromatin is isolated and either digested with a restriction enzyme or subjected to intense sonication to mechanically shear the DNA into fragments of 200–600 bp. 3 Short oligonucleotide linkers are then ligated to the ends of the DNA fragments. These linkers contain a cytosine linked to a biotin at the 5' position (see Figure 2-17). 4 After removal of excess linker, the preparation is diluted considerably and subjected to treatment with DNA ligase. Because the preparation is diluted, ligations occur preferentially between the ends of fragments held in close proximity by cross-links. 5 After ligation, the protein-DNA cross-linking reaction is reversed, the protein is digested with proteases, and the DNA is isolated and further sonicated. Ligated fragments are separated from other fragments using streptavidin, which binds the biotin in the linkers added in step 3.

The purified, ligated fragments are then sequenced. Ligation points are marked by the duplicated sequence of the oligonucleotide linker (see Figure 8-34, step 4). Sequences on each side of the ligation point are mapped to the genome. In cases in which the two ends of a single fragment were linked together (Figure 8-34b), the sequences on either side of the oligonucleotide linker sequence will map within a few hundred bases of each other on the genome, since the ligated fragments were only a few hundred bases long. But in cases in which fragments that are distant in the genomic sequence were ligated together because they were cross-linked to proteins holding them together (Figure 8-34a), the sequences will map far apart. The observation of distant ( $>10$  kb) sequences repeatedly ligated to each other implies that their respective regions of chromatin were associated with each other in vivo.

The data from a chromatin conformation capture assay can be plotted on a two-dimensional heat map (Figure 8-34c). In this plot, the sequence of the same portion of the genome is plotted on both the  $x$  and  $y$  axes, with each pixel equivalent to 10 kb. The pixel at coordinates  $x, y$  is colored red where a sequence at coordinate  $x$  was ligated to a sequence at coordinate  $y$ . The intensity of the red color is proportional to the numbers of ligation events observed that linked a sequence in the 10-kb interval  $x$  with a sequence in the 10-kb interval  $y$ .

Figure 8-34c shows the plot generated for a roughly 5.5-Mb region of chromosome 6 in mouse embryonic stem cells. It is immediately apparent that the genome is divided into

**FIGURE 8-34 Chromosome conformation capture.** (a, b) Strategy of chromatin conformation capture methods. See text for explanation. Gray and blue tubes represent regions of DNA separated by >10 kb in the genome sequence. Biotin is represented by red flags. See E. Lieberman-Aiden, 2009, *Science* **326**:289. (c) Heat map of chromosome conformation capture data for a region of chromosome 6 in mouse embryonic stem cells. The sequence from 49 to 54 Mb from the left end of chromosome 6 is represented on both axes. Each pixel shows data from a 10-kb sequence. The number of times a sequence from one 10-kb region indicated on the x axis was ligated to a sequence from a second 10-kb region on the y axis is indicated by the intensity of red color, as shown in the key at the lower left. A value of 100 (dark red) indicates that a sequence anywhere within the 10-kb region on the x axis was found ligated to a sequence from anywhere in the 10-kb region on the y axis 100 times. Since the probability that two ends generated by sonication will be ligated together is higher for ends that are close together than for ends that are far apart, the intensity of the red color in any pixel indicates the relative proximity of the sequences in the two 10-kb intervals in the nuclei at the time of cross-linking. Inset shows a model of chromatin folding that is consistent with these results. [Part (c) data from J. R. Dixon, 2012, *Nature* **485**:376.]

regions called *topological domains*, in which a chromosomal region is far more likely to be ligated to another sequence within the same topological domain than it is to be ligated to a sequence in another topological domain. These topological domains are on the order of 200 kb to 1.5 Mb in length, with

a median size of 880 kb. For example, sequences in the interval of chromosome 6 between 50.9 Mb and 51.3 Mb (see Figure 8-34c, topological domain A) are much more likely to be ligated to each other than to sequences in the interval from 51.3 Mb to 52.2 Mb (topological domain B), or to sequences from any of the other topological domains that are apparent. In situ hybridization studies showed that sequences within a topological domain lie much closer to each other in the fixed cell nucleus than to sequences the same distance away in base pairs, but in a neighboring topological domain. These results have been interpreted to indicate that the chromatin fiber is folded into topological domains, as represented in the inset of Figure 8-34c. The topological domains are separated by shorter regions of chromatin, called *boundary elements*, that do not interact with distant regions of chromatin. Since the topological domains are on the order of 200 kb–1.5 Mb in length, they are long enough to contain several average-sized genes. The topological domains identified by these chromatin conformation capture assays may correspond to

the loops of chromatin observed in the lampbrush chromosomes described above, which are not constrained by the nuclear envelope of a vastly smaller nucleus and have an opportunity to unfold (see Figure 8-31). Current research is exploring what protein-DNA interactions might be responsible for establishing boundary elements between topological domains. As we will see in Chapter 9, related chromosome conformation capture techniques have provided strong evidence that proteins bound to enhancers interact with proteins bound to promoters many kilobases away.

**Metaphase Chromosome Structure** Condensation of chromosomes during prophase (see Figure 18-37) may involve the formation of many more loops of chromatin, so that the length of each loop is greatly reduced compared with chromatin loops in interphase cells. As a result, chromosomes condense into structures of much greater width than interphase chromosomes and decrease in length severalfold, generating the condensed chromosomes observed during metaphase (Figure 8-35).

The geometry of chromatin in metaphase chromosomes is not well understood. Experiments with frog egg extracts have shown that a protein complex called *condensin*, composed of SMC subunits (see Figure 8-32 and Chapter 19), contributes to chromosome condensation using energy from ATP hydrolysis. Microscopic analysis of mammalian chromosomes as they condense during prophase indicates that in the initial period of prophase, the 30-nm chromatin fiber folds into a 100–130-nm *chromonema* fiber associated with the nuclear envelope (Figure 8-36). Chromonema fibers then fold into structures with a diameter of 200–250 nm, called *middle prophase chromatids* (Figure 8-36a, **3**), which then fold into the 500–750-nm-diameter chromatids observed during metaphase when the nuclear envelope retracts into the endoplasmic reticulum (Figure 8-36a, **4**) (see also Chapter 19). Ultimately, the full lengths of the two associated daughter chromosomes generated by DNA replication during the previous S phase of the cell cycle (see Figure 1-21) condense into bar-shaped structures (chromatids) that in most eukaryotes are linked at the central constriction called the centromere (see Figure 8-35). An electron micrograph of a section through a metaphase chromosome stained with anti-SMC antibodies linked to small gold spheres (Figure 8-36b) shows that condensin, proposed to be at the bases of chromatin loops (see Figure 8-32c), occupies approximately one-third of the chromatid diameter (Figure 8-36c, *right*), where it contributes to the shaping of each chromatid.

### Additional Nonhistone Proteins Regulate Transcription and Replication

As we have seen, the total mass of the histones associated with DNA in chromatin is about equal to that of the DNA. Interphase chromatin and metaphase chromosomes also contain small amounts of a complex set of other proteins. For instance, thousands of different **transcription factors** are associated with interphase chromatin. The structure and

**FIGURE 8-35 Typical metaphase chromosome.** As seen in this scanning electron micrograph, the chromosome has replicated and comprises two chromatids, each containing one of two identical DNA molecules. The centromere, where the chromatids are attached at a constriction, is required for their separation late in mitosis. Special telomere sequences at the ends function in preventing chromosome shortening. [Andrew Syred/Science Source.]

function of these critical nonhistone proteins, which regulate transcription, are examined in Chapter 9. Other low-abundance nonhistone proteins associated with chromatin regulate DNA replication during the eukaryotic cell cycle (see Chapter 19).

A few other nonhistone DNA-binding proteins are present in much larger amounts than the transcription or replication factors. Some of these proteins exhibit high mobility during electrophoretic separation and thus have been designated *HMG (high-mobility group) proteins*. When genes encoding the most abundant HMG proteins are deleted from yeast cells, normal transcription is disturbed in most genes examined. Some HMG proteins have been found to assist in the cooperative binding of several transcription factors to specific DNA sequences that are close to each other, stabilizing multiprotein complexes that regulate transcription of a neighboring gene, as discussed in Chapter 9.

**FIGURE 8-36 Model for mitotic chromosome condensation.** (a) Stages of chromosome condensation during mitosis. Changes in large-scale chromatin folding (blue) versus distribution of Smc2, a subunit of condensin (red), from early prophase **1** to middle prophase **2** to late prophase **3** to metaphase **4**. (b) Transmission electron micrograph of immunogold staining of Smc2 in a section through a metaphase chromosome reveals axial staining of Smc2 of about 0.15–0.2 μm in width. (c) “Hierarchical folding, axial glue” model of metaphase chromosome structure. (Left) 30-nm fiber folds into 100–130-nm chromonema fiber, which folds into 200–250-nm middle prophase chromatid, which folds into 500–750-nm metaphase chromatid. Only one chromatid is shown. (Right) Axial condensin distribution (red) occupies approximately one-third of the chromatid diameter, acting as a cross-linking “glue” to stabilize the structure of the metaphase chromosome. ## KEY CONCEPTS OF SECTION 8.5

### Structural Organization of Eukaryotic Chromosomes

- In eukaryotic cells, DNA is associated with about an equal mass of histone proteins in a highly condensed nucleoprotein complex called chromatin. The building block of chromatin is the nucleosome, consisting of a histone octamer around which is wrapped about 147 bp of DNA (see Figure 8-24).
- The chromatin in transcriptionally inactive regions of DNA within cells is thought to exist in a condensed, 30-nm fiber form and higher-order structures built from it (see Figure 8-25 and 8-36).
- The chromatin in transcriptionally active regions of DNA within cells is thought to exist in an open, extended form.
- The flexible, intrinsically disordered N-terminal tails of histones, particularly H4 lysine 16, are required for

beads-on-a-string chromatin (the 10-nm chromatin fiber) to fold into a 30-nm fiber.

- Histone tails can be modified by acetylation, methylation, phosphorylation, and ubiquitinylation (see Figure 8-26). These modifications influence chromatin structure by regulating the binding of histone tails to other, less abundant chromatin-associated proteins.
- The reversible acetylation and deacetylation of lysine residues in the N-terminal tails of the core histones regulate chromatin condensation. Proteins involved in transcription, replication, and repair, and enzymes such as DNase I, can more easily access chromatin with hyperacetylated histone tails (euchromatin) than chromatin with hypoacetylated histone tails (heterochromatin).
- When metaphase chromosomes decondense during interphase, areas of heterochromatin remain much more condensed than regions of euchromatin.

- Heterochromatin protein 1 (HP1) uses a chromodomain to bind to histone H3 trimethylated at lysine 9. The chromoshadow domain of HP1 associates with itself and with the histone methyl transferase that methylates H3 lysine 9. These interactions cause condensation of the 30-nm chromatin fiber and spreading of the heterochromatic structure along the chromosome until a boundary element is encountered (see Figure 8-29).

- One X chromosome in nearly every cell of mammalian females consists of highly condensed heterochromatin, resulting in repression of expression of nearly all genes on that inactive chromosome. This inactivation results in dosage compensation so that genes on the X chromosome are expressed at the same level in both males and females.

- Each eukaryotic chromosome contains a single DNA molecule packaged into nucleosomes and folded into a 30-nm chromatin fiber, which is associated with structural maintenance of chromosome (SMC) proteins thought to organize it into the megabase loops observed by hybridization to fluorescently labeled DNA probes and in lampbrush chromosomes observed in oocytes (see Figures 8-30, 8-31, and 8-32c). Additional folding of the chromosomes further compacts the structure into the highly condensed form of metaphase chromosomes (see Figure 8-36).

- In interphase cells, chromosomes are localized to largely non-overlapping “territories” in the nucleus (see Figure 8-33).

- Chromosome conformation capture methods indicate that chromatin is organized into topological domains separated by boundary elements (see Figure 8-34c). These topological domains may correspond to the loops in lampbrush chromosomes observed in the giant nuclei of oocytes (see Figure 8-31) and inferred by studies of fluorescently labeled DNA probes hybridized to interphase nuclei (see Figure 8-30).

- During mitosis, chromosomes condense greatly, decreasing their lengths severalfold and increasing their diameter to generate metaphase chromosomes visible by light microscopy. The geometry of the 30-nm chromatin fiber in metaphase chromosomes is not well understood, but intermediates of increasing diameter and decreasing length have been observed during prophase.

## 8.6 Morphology and Functional Elements of Eukaryotic Chromosomes

Having examined the detailed structural organization of chromosomes in the previous section, we now view them from a more global perspective. Early microscopic observations on the number and size of chromosomes and their staining patterns led to the discovery of many important general characteristics of chromosome structure. Researchers subsequently identified specific regions of chromosomes that are critical to their replication and segregation to

daughter cells during cell division. In this section, we discuss these functional elements of chromosomes and consider how chromosomes evolved through rare rearrangements of ancestral chromosomes.

### Chromosome Number, Size, and Shape at Metaphase Are Species-Specific

In interphase cells, as noted previously, chromosome territories can be visualized with chromosome-specific fluorescently labeled hybridization probes (see Figure 8-33), but the detailed structure of individual chromosomes cannot be observed, even with the aid of electron microscopy. During mitosis and meiosis, however, the chromosomes condense and become visible in the light microscope. Therefore, almost all cytogenetic work (i.e., studies of chromosome morphology) has been done with condensed metaphase chromosomes obtained from dividing cells—either somatic cells in mitosis or dividing gametes during meiosis.

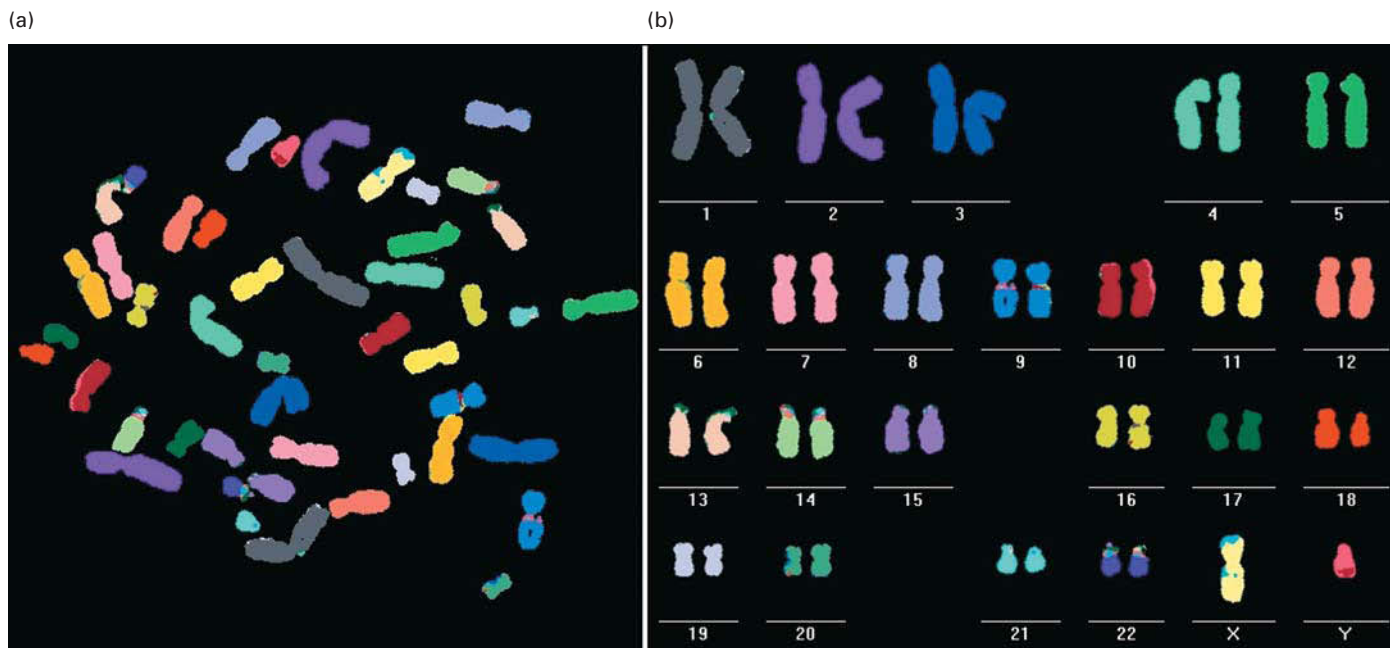

The condensation of metaphase chromosomes probably results from several orders of folding of 30-nm chromatin fibers (see Figure 8-36). At the time of mitosis, cells have already progressed through the S phase of the cell cycle and have replicated their DNA. Consequently, the chromosomes that become visible during metaphase are *duplicated* structures. Each metaphase chromosome consists of two sister **chromatids**, which are linked at a constricted region, the centromere (see Figure 8-35).

The number, sizes, and shapes of the metaphase chromosomes constitute the **karyotype**, which is distinctive for each species. In most organisms, all somatic cells have the same karyotype. However, species that appear quite similar can have very different karyotypes, indicating that similar genetic potential can be organized on chromosomes in very different ways. For example, two species of small deer—the Indian muntjac and Reeves muntjac—contain about the same total amount of genomic DNA. In one species, however, this DNA is organized into 22 pairs of homologous **autosomes** and two physically separate sex chromosomes. In contrast, the other species contains the smallest number of chromosomes of any mammal, only three pairs of autosomes; one sex chromosome is physically separate, but the other is joined to the end of one autosome.

### During Metaphase, Chromosomes Can Be Distinguished by Banding Patterns and Chromosome Painting

Certain dyes selectively stain some regions of metaphase chromosomes more intensely than other regions, producing characteristic banding patterns that are specific for individual chromosomes. The regularity of chromosome bands provides useful visible landmarks along the length of each chromosome and can help to distinguish chromosomes of similar size and shape, as we will see later in this section.

Today the method of *chromosome painting* greatly simplifies the identification and differentiation of individual

**EXPERIMENTAL FIGURE 8-37** Human chromosomes are readily identified by chromosome painting. (a) Image of human chromosomes from a male cell in mitosis made by fluorescence in situ

hybridization (FISH) using chromosome paint probes. (b) Alignment of these painted chromosomes by computer graphics to reveal the normal human male karyotype. [Courtesy of Dr. Michael R. Speicher.]

chromosomes within a karyotype, many of which have similar sizes and shapes. This technique, a variation of fluorescence in situ hybridization (FISH), makes use of probes specific for sites scattered along the length of each chromosome. The probes are labeled with several different fluorescent dyes with distinct excitation and emission wavelengths. Probes specific for each chromosome are labeled with a predetermined fraction of each of the dyes. After the probes are hybridized to chromosomes and the excess removed, the sample is observed with a fluorescence microscope in which a detector determines the fraction of each dye present at each fluorescing position in the microscopic field. This information is conveyed to a computer, and a special program assigns a false-color image to each type of chromosome (Figure 8-37a). Computer graphics allows the two homologs of each chromosome to be placed next to each other and numbered according to their decreasing size. Such an image clearly displays the cell's karyotype (Figure 8-37b).

Chromosome painting is a powerful method for detecting an abnormal number of chromosomes, such as chromosome 21 trisomy in patients with Down syndrome, or chromosomal translocations that occur in rare individuals and in cancer cells (Figure 8-38). The use of probes with different ratios of fluorescent dyes that hybridize to distinct positions along each normal human chromosome allows finer structural analysis of the chromosomes that can more readily reveal deletions or duplications of chromosomal regions. The chapter-opening figure illustrates the use of such *multi-color FISH* in analysis of the karyotype of a normal human female.

## Chromosome Painting and DNA Sequencing Reveal the Evolution of Chromosomes

Analysis of chromosomes from different species has provided considerable insight into how chromosomes evolved. For example, hybridization of chromosome paint probes for chromosome 16 of the tree shrew (*Tupaia belangeri*) to tree shrew metaphase chromosomes revealed the two copies of chromosome 16, as expected (Figure 8-39a). However, when the same chromosome paint probes were hybridized to human metaphase chromosomes, most of the probes hybridized to the long arm of chromosome 10 (Figure 8-39b). Further, when multiple probes for the long arm of human chromosome 10 with different fluorescent dye labels were hybridized to tree shrew metaphase chromosomes, these probes bound to sequences along tree shrew chromosome 16 in the same order in which they bind to human chromosome 10.

These results indicate that during the evolution of humans and tree shrews from a common ancestor that lived as recently as 85 million years ago, a long, continuous DNA sequence on one of the ancestral chromosomes became chromosome 16 in tree shrews, but evolved into the long arm of chromosome 10 in humans. The phenomenon of genes occurring in the same order on a chromosome in two different species is referred to as conserved **synteny** (derived from Latin for “on the same ribbon”). The presence of two or more genes in a common chromosomal region in two or more species indicates a conserved syntenic segment.

The relationships between the chromosomes of many primates have been determined by cross-species application of chromosome paint probes, as shown for human and tree

**EXPERIMENTAL FIGURE 8-38 Chromosomal translocations can be analyzed using chromosome painting.** Characteristic chromosomal translocations are associated with certain genetic disorders and specific types of cancers. For example, in nearly all patients with chronic myelogenous leukemia, the leukemic cells contain the Philadelphia chromosome, a shortened chromosome 22 [der (22)], and an

abnormally long chromosome 9 [der (9)] ("der" stands for derivative). These forms result from a translocation between normal chromosomes 9 and 22. This translocation can be detected (a) by classical banding analysis or (b) by chromosome painting. [Part (b) courtesy of J. Rowley and R. Espinosa.]

shrew in Figure 8-39a, b. Using these relationships, as well as higher-resolution analyses of regions of synteny by DNA sequencing and other methods, it has been possible to propose the karyotype of the common ancestor of all primates based on the minimum number of chromosomal rearrangements necessary to generate the regions of synteny in chromosomes of contemporary primates.

Human chromosomes are thought to have been derived from a common primate ancestor with 23 autosomes plus the X and Y sex chromosomes by several different mechanisms (Figure 8-39c). Some human chromosomes were derived without large-scale rearrangements of chromosome structure. Others are thought to have evolved by breakage of an ancestral chromosome into two chromosomes or, conversely, by fusion of two ancestral chromosomes. Still other human chromosomes appear to have been generated by exchanges of parts of the arms of distinct chromosomes; that is, by reciprocal translocation involving two ancestral chromosomes. Analysis of regions of conserved synteny between the chromosomes of many mammals indicates that chromosomal rearrangements by breakage, fusion, and translocations occurred rarely in mammalian evolution, about once every 5 million years. When such chromosomal rearrangements did occur, they very likely contributed to the evolution of new species that could not interbreed with the species from which they evolved.

Chromosomal rearrangements similar to those inferred for the primate lineage have been inferred for other groups of related organisms, including the invertebrate, plant, and fungus lineages. The excellent agreement between predictions of evolutionary relationships based on analysis of

syntenic regions of chromosomes from organisms with related morphology (i.e., among mammals, among insects with similar body organization, among similar plants, etc.) and evolutionary relationships based on the fossil record and on the extent of divergence of DNA sequences for homologous genes is a strong argument for the validity of evolution as the process that generated the diversity of contemporary organisms.

### Interphase Polytene Chromosomes Arise by DNA Amplification

The larval salivary glands of *Drosophila* species and other dipteran insects contain enlarged interphase chromosomes that are visible in the light microscope. When fixed and stained with a dye that stains DNA, these **polytene chromosomes** are characterized by a large number of reproducible, well-demarcated bands, which have been assigned standardized numbers (Figure 8-40a). The densely staining bands represent regions where the chromatin is more condensed, and the light interband areas are regions where the chromatin is less condensed. Although the molecular mechanisms that control the formation of bands in polytene chromosomes are not yet understood, the highly reproducible banding pattern seen in *Drosophila* salivary gland chromosomes provides an extremely powerful method for locating specific DNA sequences along the chromosomes of this species. Not only are chromosomal translocations and inversions readily detectable in polytene chromosomes, but specific chromosomal proteins can be localized on interphase polytene chromosomes by immunostaining with specific antibodies raised

**FIGURE 8-39 Evolution of primate chromosomes.** (a) Chromosome paint probes (yellow) for chromosome 16 of the tree shrew (*T. belangeri*, distantly related to humans) hybridized to tree shrew metaphase chromosomes (red). (b) The same tree shrew chromosome 16 paint probes hybridized to human metaphase chromosomes. (c) Proposed evolution of human chromosomes (*bottom*) from the chromosomes of the common ancestor of all primates (*top*). The proposed common primate ancestor chromosomes are numbered according to their sizes, with each chromosome represented by a different color. The human chromosomes are also numbered according to their relative sizes and labeled with colors taken from the colors of the proposed common primate ancestor chromosomes from which they were derived. Small numbers to the left of the colored regions of the human chromosomes indicate the number of the ancestral chromosome from which the region was derived. Various human chromosomes were derived from the proposed chromosomes of the common primate ancestor without significant rearrangements (e.g., human chromosome 1); by fusion (e.g., human chromosome 2 by fusion of ancestral chromosomes 9 and 11); by breakage (e.g., human chromosomes 14 and 15 by breakage of ancestral chromosome 5); or by chromosomal translocations (e.g., a reciprocal translocation between ancestral chromosomes 14 and 21 generated human chromosomes 12 and 22). [Parts (a) and (b) republished with permission of Springer, from Muller, S., et al., "Defining the ancestral karyotype of all primates by multidirectional chromosome painting between tree shrews, lemurs and humans," *Chromosoma*, 1999, **108**(6):393-400; permission conveyed through Copyright Clearance Center. Part (c) data from L. Froenicke, 2005, *Cytogenet. Genome Res.* **108**:122.]

against them (see Figure 9-15). Insect polytene chromosomes offer one of the only experimental systems in all of nature in which such immunolocalization studies on decondensed interphase chromosomes are possible.

A generalized amplification of DNA gives rise to the polytene chromosomes found in the salivary glands of

*Drosophila*. This process, termed *polytenization*, occurs when the DNA repeatedly replicates everywhere except at the telomeres and centromere, but the daughter chromosomes do not separate. The result is an enlarged chromosome composed of many parallel copies of itself, 1024 resulting from ten such replications in *Drosophila melanogaster* salivary

**EXPERIMENTAL FIGURE 8-40 Banding on *Drosophila* polytene salivary gland chromosomes.** (a) In this light micrograph of *Drosophila melanogaster* larval salivary gland chromosomes, four chromosomes can be observed (X, 2, 3, and 4), with a total of approximately 5000 distinguishable bands. The banding pattern results from reproducible patterns of DNA and protein packing within each site along the chromosome. Dark bands are regions of more highly compacted chromatin. The centromeres of all four chromosomes often appear fused at the chromocenter. The tips of chromosomes 2 and 3 are labeled (L = left arm; R = right arm), as is the tip of the X chromosome. (b) The pattern of amplification of chromosome 4 during five replications. Double-stranded DNA is represented by a single line. Telomere and centromere DNA are not amplified. In salivary gland polytene chromosomes, each parental chromosome undergoes about 10 replications ( $2^{10} = 1024$  strands). See C. D. Laird et al., 1973, *Cold Spring Harbor Symp. Quant. Biol.* **38**:311. [Part (a) courtesy of Joseph Gall, Carnegie Institution for Science.]

glands (Figure 8-40b). The amplification of chromosomal DNA greatly increases gene copy number, presumably to supply sufficient mRNA for protein synthesis in the massive salivary gland cells. The bands in *Drosophila* polytene chromosomes each represent some 50,000–100,000 bp, and the banding pattern reveals that the condensation of DNA varies greatly along these relatively short regions of an interphase chromosome.

## Three Functional Elements Are Required for Replication and Stable Inheritance of Chromosomes

Although eukaryotic chromosomes differ in length and number among species, cytogenetic studies have shown that they all behave similarly at the time of cell division. Moreover, any eukaryotic chromosome must contain three functional elements in order to replicate and segregate correctly: (1) **replication origins** at which DNA polymerases and other proteins initiate synthesis of DNA (see Figures 5-31 and 5-33); (2) the **centromere**, the constricted region required for proper segregation of daughter chromosomes; and (3) the two ends, or **telomeres**. The yeast transformation studies depicted in Figure 8-41 demonstrated the functions of these three chromosomal elements and established their importance for chromosome function.

As discussed in Chapter 5, replication of DNA begins from sites that are scattered throughout eukaryotic chromosomes. The yeast genome contains many 100-bp sequences, called *autonomously replicating sequences* (ARSs), that act as replication origins. The observation that insertion of an ARS into a circular plasmid allows the plasmid to replicate in yeast cells provided the first functional identification of replication origins in eukaryotic DNA (Figure 8-41a).

Even though circular ARS-containing plasmids can replicate in yeast cells, only about 5–20 percent of progeny cells contain the plasmid because mitotic segregation of the plasmids is faulty. However, plasmids that also carry a CEN sequence, derived from the centromeres of yeast chromosomes, segregate equally, or nearly so, to both mother and daughter cells during mitosis (Figure 8-41b).

If circular plasmids containing an ARS and a CEN sequence are cut once with a restriction enzyme, the resulting linear plasmids do not transform yeast cells generating *LEU*<sup>+</sup> colonies that grow on medium lacking leucine unless they contain special telomeric (TEL) sequences ligated to their ends (Figure 8-41c). The first successful experiments involving transfection of yeast cells with linear plasmids were achieved by using the ends of a DNA molecule that was known to replicate as a linear molecule in the ciliated protozoan *Tetrahymena*. During part of the life cycle of *Tetrahymena*, much of the nuclear DNA is repeatedly copied in short pieces to form a so-called *macronucleus*. One of these repeated fragments was identified as a dimer of ribosomal DNA, the ends of which contained a repeated sequence  $(G_4T_2)_n$ . When a section of this repeated TEL sequence was ligated to the ends of linear yeast plasmids containing ARS and CEN, replication and good segregation of the linear plasmids occurred. This first cloning and characterization of telomeres garnered the Nobel Prize in Physiology or Medicine in 2009.

## Centromere Sequences Vary Greatly in Length and Complexity

Once the yeast centromere regions that confer mitotic segregation were cloned, their sequences could be determined and

**EXPERIMENTAL FIGURE 8-41** Yeast transformation experiments were used to identify the functional chromosomal elements necessary for normal chromosome replication and segregation. In these experiments, plasmids containing the *LEU* gene from normal yeast cells are constructed and introduced into *leu<sup>-</sup>* cells by transfection. If the plasmid is maintained in the *leu<sup>-</sup>* cells, they are transformed to *LEU<sup>+</sup>* cells by the *LEU* gene on the plasmid and can form colonies on medium lacking leucine. (a) Sequences that allow autonomous replication (ARS) of a plasmid were identified because their insertion into a plasmid vector containing a cloned *LEU* gene resulted in a high frequency of transformation to *LEU<sup>+</sup>*. However, even plasmids with ARS exhibit poor segregation during mitosis and therefore do not appear in each of the daughter cells. (b) When randomly broken pieces of yeast DNA are inserted into plasmids containing ARS and *LEU*, some of the subsequently transfected cells produce large colonies, indicating that a high rate of mitotic segregation among their plasmids is facilitating the continuous growth of daughter cells. The DNA recovered from plasmids in these large colonies contains yeast centromere (CEN) sequences. (c) When *leu<sup>-</sup>* yeast cells are transfected with linear plasmids containing *LEU*, ARS, and CEN, no colonies grow. Addition of telomere (TEL) sequences to the ends of the linear DNA gives the linearized plasmids the ability to replicate as new chromosomes that behave very much like a normal chromosome in both mitosis and meiosis. See A. W. Murray and J. W. Szostak, 1983, *Nature* **305**:89, and L. Clarke and J. Carbon, 1985, *Ann. Rev. Genet.* **19**:29.

compared. The results revealed three regions (I, II, and III) that are conserved among the centromeres on different yeast chromosomes (Figure 8-42a). Short, fairly well-conserved nucleotide sequences are present in regions I and III. Region II does not have a specific sequence, but is AT-rich with a fairly constant length, probably so that regions I and III will lie on the same side of a specialized centromere-associated histone octamer. This specialized centromere-associated histone octamer contains the usual histones H2A, H2B, and H4, but a variant form of histone H3. Centromeres from all eukaryotes similarly contain nucleosomes with a specialized, centromere-specific form of histone H3, called CENP-A in humans. In the simple kinetochore of *S. cerevisiae*, a protein

complex called CBF3 associates with this specialized nucleosome. The CBF3 complex, in turn, associates with several copies of an elongated multiprotein complex called Ndc80 (Figure 8-42b). The Ndc80 complexes initially make lateral interactions with a spindle microtubule and subsequently interact with a Dam1 complex, which forms a ring around the end of the microtubule (Figure 8-42c). This interaction results in an end-on attachment of the centromere to the spindle microtubule. *S. cerevisiae* has by far the simplest centromere known in nature.

In the fission yeast *S. pombe*, centromeres are 40–100 kb in length and are composed of repeated copies of sequences similar to those in *S. cerevisiae* centromeres. Multiple

**FIGURE 8-42 Kinetochore-microtubule interaction in *S. cerevisiae*.** (a) Sequence of the simple centromeres of *S. cerevisiae*. See L. Clarke and J. Carbon, 1985, *Ann. Rev. Genet.* **19**:29. (b) Ndc80 complexes associate with both the microtubule and the CBF3 complex. (c) Diagram of the centromere-associated CBF3 complex and its associated Ndc80 complexes, which associate with a ring of Dam1 proteins at the end of a spindle microtubule. The Ndc80 complexes initially make lateral interactions with the side of a spindle microtubule (top) and then associate with the Dam1 ring, making an end-on attachment (bottom) to the microtubule. See T. U. Tanaka, 2010, *EMBO J.* **29**:4070.

copies of proteins homologous to those that interact with *S. cerevisiae* centromeres bind to these complex *S. pombe* centromeres, and in turn bind the much longer *S. pombe* chromosomes to several microtubules of the mitotic spindle apparatus. In plants and animals, centromeres are megabases in length and are composed of multiple repeats of simple-sequence DNA. In humans, centromeres contain 2–4-Mb arrays of a 171-bp simple-sequence DNA called *alphoid* DNA, which is bound by nucleosomes containing

the CENP-A histone H3 variant, as well as other repeated simple-sequence DNAs.

In higher eukaryotes, a complex protein structure called the *kinetochore* assembles at centromeres and associates with multiple mitotic spindle fibers during mitosis (see Figure 18-40). Homologs of many of the centromere-associated proteins found in the yeasts occur in humans and other higher eukaryotes. For those yeast proteins for which clear homologs are not evident in higher cells based on amino acid sequence comparisons (such as the Dam1 complex), alternative complexes with similar properties have been proposed to function at kinetochores. The functions of the centromere and of the kinetochore proteins that bind to it during the segregation of sister chromatids in mitosis and meiosis are described in Chapters 18 and 19.

### Addition of Telomeric Sequences by Telomerase Prevents Shortening of Chromosomes

Sequencing of telomeres from multiple organisms, including humans, has shown that most are repetitive oligomers with a high G content located in the strand with its 3' end at the end of the chromosome. The telomere repeat sequence in humans and other vertebrates is TTAGGG. These simple sequences are repeated at the very termini of chromosomes for a total of a few hundred base pairs in yeasts and protozoans and a few thousand base pairs in vertebrates. The 3' end of the G-rich strand extends 12–16 nucleotides beyond the 5' end of the complementary C-rich strand. This region is bound by specific proteins that protect the ends of linear chromosomes from attack by exonucleases.

The need for a specialized region at the ends of eukaryotic chromosomes is apparent when we consider that all known DNA polymerases elongate DNA chains at the 3' end, and all require an RNA or DNA primer. As the replication fork approaches the end of a linear chromosome, synthesis of the leading strand continues to the end of the DNA template strand, completing one daughter DNA double helix. However, because the lagging-strand template is copied in a discontinuous fashion, it cannot be replicated in its entirety (Figure 8-43). When the final RNA primer is removed, there is no upstream strand onto which DNA polymerase can build to fill the resulting gap. Without some special mechanism, the daughter DNA strand resulting from lagging-strand synthesis would be shortened at each cell division.

The problem of telomere shortening is solved by an enzyme that adds telomeric repeat sequences to the ends of each chromosome. The enzyme is a protein–RNA complex called *telomere terminal transferase*, or *telomerase*. Because the sequence of the telomerase-associated RNA, as we will see, serves as the template for addition of deoxyribonucleotides to the ends of telomeres, the source of the enzyme, and not the source of the telomeric DNA primer, determines the sequence added. This was proved by transforming *Tetrahymena* with a mutated form of the gene encoding

**FIGURE 8-43 Standard DNA replication leads to loss of DNA at the 5' end of each strand of a linear DNA molecule.** Replication of the right end of a linear DNA is shown; the same process occurs at the left end (as can be shown by inverting the figure). As the replication fork approaches the end of the parental DNA molecule, the leading strand can be synthesized all the way to the end of the template strand without the loss of deoxyribonucleotides. However, since synthesis of the lagging strand requires RNA primers, the right end of the lagging daughter DNA strand would remain as ribonucleotides, which are removed and therefore cannot serve as the template for a replicative DNA polymerase. Alternative mechanisms must be used to prevent successive shortening of the lagging strand with each round of replication.

the telomerase-associated RNA. The resulting telomerase added a DNA sequence complementary to the mutated RNA sequence to the ends of telomeric primers. Thus telomerase is a specialized form of a reverse transcriptase that carries its own internal RNA template to direct DNA synthesis. These experiments also earned the Nobel Prize in Physiology or Medicine for the structure and function of telomeres in 2009.

Figure 8-44 depicts how telomerase, by reverse transcription of its associated RNA, elongates the 3' end of the single-stranded DNA at the end of the G-rich strand mentioned above. Cells from knockout mice that cannot produce the telomerase-associated RNA exhibit no telomerase activity, and their telomeres shorten successively with each cell generation. Such mice can breed and reproduce normally for three generations before the long telomere repeats become substantially eroded. Then, the absence of telomere DNA

**FIGURE 8-44 Mechanism of action of telomerase.** The single-stranded 3' terminus of a telomere is extended by telomerase, counteracting the inability of the DNA replication mechanism to synthesize the extreme terminus of linear DNA. Telomerase elongates this single-stranded end by a reiterative reverse-transcription mechanism. The action of the telomerase from the protozoan *Tetrahymena*, which adds a T<sub>2</sub>G<sub>4</sub> repeat unit, is depicted here; other telomerases add slightly different sequences. The telomerase contains an RNA template (red) that base-pairs to the 3' end of the lagging-strand template. The telomerase catalytic site then adds deoxyribonucleotides TTG (blue), using the RNA molecule as a template (step 1). The strands of the resulting DNA-RNA duplex are then thought to slip (translocate) relative to each other so that the TTG sequence at the 3' end of the replicating DNA base-pairs to the complementary RNA sequence in the telomerase RNA (step 2). The 3' end of the replicating DNA is then again extended by telomerase (step 3). Telomerases can add multiple repeats by repetition of steps 2 and 3. DNA polymerase  $\alpha$ -primase can prime synthesis of new Okazaki fragments on this extended template strand. The net result prevents shortening of the lagging strand at each cycle of DNA replication. See C. W. Greider and E. H. Blackburn, 1989, *Nature* **337**:331.

results in adverse effects, including fusion of chromosome termini and chromosome loss. By the fourth generation, the reproductive potential of these knockout mice declines, and they cannot produce offspring after the sixth generation.

 The human genes expressing the telomerase protein and the telomerase-associated RNA are active in germ cells and stem cells, but are turned off in most cells of adult

tissues that replicate only a limited number of times, or will never replicate again (such cells are called *postmitotic*). However, these genes are activated in most human cancer cells, where telomerase is required for the multiple cell divisions necessary to form a tumor. This phenomenon has stimulated a search for inhibitors of human telomerase as potential therapeutic agents for treating cancer. ■

While telomerase prevents telomere shortening in most eukaryotes, some organisms use alternative strategies. *Drosophila* species maintain telomere lengths by the regulated insertion of non-LTR retrotransposons into telomeres. This is one of the few instances in which a mobile element has a specific function in its host organism.

## KEY CONCEPTS OF SECTION 8.6

### Morphology and Functional Elements of Eukaryotic Chromosomes

- During metaphase, eukaryotic chromosomes become sufficiently condensed that they can be visualized individually in the light microscope.
- The chromosomal karyotype is characteristic of each species. Closely related species can have dramatically different karyotypes, indicating that similar genetic information can be organized on chromosomes in different ways.
- Banding analysis and chromosome painting are used to identify the different human metaphase chromosomes and to detect translocations and deletions (see Figure 8-37 and 8-38).
- Analysis of chromosomal rearrangements and regions of conserved synteny between related species allows scientists to make predictions about the evolution of chromosomes (see Figure 8-39c). The evolutionary relationships between organisms indicated by these studies are consistent with proposed evolutionary relationships based on the fossil record and DNA sequence analysis.
- The highly reproducible banding patterns of polytene chromosomes make it possible to visualize chromosomal deletions and rearrangements as changes in the normal pattern of bands.
- Three types of DNA sequences are required for a long linear DNA molecule to function as a chromosome: a replication origin, called ARS in yeast; a centromere (CEN) sequence; and two telomere (TEL) sequences at the ends of the DNA (see Figure 8-41).
- Telomerase, a protein–RNA complex, has a special reverse transcriptase activity that completes replication of telomeres during DNA synthesis (see Figure 8-44). In the absence of telomerase, the daughter DNA strand resulting from lagging-strand synthesis would be shortened at each cell division in most eukaryotes (see Figure 8-43).

## Key Terms

centromere 345	nucleosome 328
chromatid 341	open reading frame (ORF) 326
chromatin 327	polytene chromosome 343
DNA transposon 313	protein family 306
euchromatin 332	pseudogene 307
exon shuffling 322	retrotransposon 313
fluorescence in situ hybridization (FISH) 342	simple-sequence (satellite) DNA 310
gene family 306	SINEs 318
genomics 302	SMC proteins 336
heterochromatin 332	telomere 345
histones 327	transcription unit 303
karyotype 341	transposable (mobile) DNA element 312
LINEs 318	
long terminal repeats (LTRs) 316	

## Review the Concepts

1. Genes can be transcribed into mRNA, in the case of protein-coding genes, or into RNA, in the case of genes such as those that encode ribosomal or transfer RNAs. Define a gene. For the following characteristics, state whether they apply to (a) continuous, (b) simple, or (c) complex transcription units.
  - i. Found in eukaryotes
  - ii. Contain introns
  - iii. Capable of making only a single protein from a given gene
2. Sequencing of the human genome has revealed much about the organization of genes. Describe the differences between solitary genes, gene families, pseudogenes, and tandemly repeated genes.
3. Much of the human genome consists of repetitious DNA. Describe the difference between microsatellite and minisatellite DNA. How is this repetitious DNA useful for identifying individuals by the technique of DNA fingerprinting?

4. Mobile DNA elements that can move or transpose to a new site directly as DNA are called DNA transposons. Describe the mechanism by which a bacterial DNA transposon, called an insertion sequence, can transpose.
5. Retrotransposons are a class of mobile elements that transpose via an RNA intermediate. Contrast the mechanism of transposition between retrotransposons that contain long terminal repeats (LTRs) and those that lack LTRs.
6. Discuss the role that transposons may have played in the evolution of modern organisms. What is exon shuffling? What role do transposons play in the process of exon shuffling?
7. What are paralogous and orthologous genes? What are some of the explanations for the finding that humans are a much more complex organism than the roundworm *C. elegans*, yet have only about 5 percent more protein-coding genes (21,000 versus 20,000)?
8. The DNA in a cell associates with proteins to form chromatin. What is a nucleosome? What role do histones play in nucleosomes? How are nucleosomes arranged in condensed 30-nm fibers?
9. How do chromatin modifications regulate transcription? What modifications are observed in regions of the genome that are being actively transcribed? In regions that are not actively transcribed?
10. What is FISH? Briefly describe how it works. How is FISH used to characterize chromosomal translocations associated with certain genetic disorders and specific types of cancers?
11. What is chromosome painting, and how is this technique useful? How can chromosome paint probes be used to analyze the evolution of mammalian chromosomes?
12. Certain organisms contain cells that possess polytene chromosomes. What are polytene chromosomes, where are they found, and what function do they serve?
13. Replication and segregation of eukaryotic chromosomes require three functional elements: replication origins, a centromere, and telomeres. How would a chromosome be affected if it lacked (a) replication origins or (b) a centromere?
14. Describe the problem that occurs during DNA replication at the ends of chromosomes. How are telomeres related to this problem?

In previous chapters, we have seen that the properties and functions of each cell type are determined by the proteins it contains. In this chapter and the next, we consider how the kinds and amounts of the various proteins produced by a particular cell type in a multicellular organism are regulated. This regulation of *gene expression* is the fundamental process that controls the development of multicellular organisms such as ourselves from a single fertilized egg cell into the thousands of cell types of which we are made. When gene expression goes awry, cellular properties are altered, a process that all too often leads to the development of cancer. As discussed further in Chapter 24, genes encoding proteins that restrain cell growth are abnormally repressed in cancer cells, whereas genes encoding proteins that promote cell growth and replication are inappropriately activated in cancer cells. Abnormalities in gene expression also result in developmental defects such as cleft palate, tetralogy of Fallot (a serious developmental defect of the heart that can be treated surgically), and many others. Regulation of gene expression

# Transcriptional Control of Gene Expression

also plays a vital role in bacteria and other single-celled microorganisms, in which it allows cells to adjust their enzymatic machinery and structural components in response to their changing nutritional and physical environment. Consequently, to understand how microorganisms respond to their environment and how multicellular organisms normally develop, as well as how pathological abnormalities of gene expression occur, it is essential to understand the molecular interactions that control protein production.

The basic steps in gene expression—that is, the entire process whereby the information encoded in a particular gene is decoded into a particular protein—are reviewed in Chapter 5. Synthesis of mRNA requires that an *RNA polymerase* initiate transcription (**initiation**), polymerize ribonucleoside triphosphates complementary to the DNA coding strand (**elongation**), and then terminate transcription (**termination**) (see Figure 5-11). In bacteria, ribosomes and translation initiation factors have immediate access to newly formed RNA transcripts, which function as mRNA without further modification.

## OUTLINE

### 9.1 Control of Gene Expression in Bacteria

### 9.2 Overview of Eukaryotic Gene Control

### 9.3 RNA Polymerase II Promoters and General Transcription Factors

### 9.4 Regulatory Sequences in Protein-Coding Genes and the Proteins Through Which They Function

### 9.5 Molecular Mechanisms of Transcription Repression and Activation

### 9.6 Regulation of Transcription-Factor Activity

### 9.7 Epigenetic Regulation of Transcription

### 9.8 Other Eukaryotic Transcription Systems

In eukaryotes, however, the initial RNA transcript is subjected to processing that yields a functional mRNA (see Figure 5-15). The mRNA then is transported from its site of synthesis in the nucleus to the cytoplasm, where it is translated into protein with the aid of ribosomes, tRNAs, and translation factors (see Figures 5-23, 5-24, and 5-26).

Regulation may occur at several of the various steps in gene expression outlined above: transcription initiation, elongation, RNA processing, and mRNA export from the nucleus, as well as through control of mRNA degradation, mRNA translation into protein, and protein degradation. This regulation results in *differential* protein expression in different cell types or developmental stages or in response to external conditions. Although examples of regulation at each step in gene expression have been found, control of transcription initiation and of elongation—the first two steps—are the most important mechanisms for determining whether most genes are expressed and how much of the encoded mRNAs and, consequently, proteins are produced (Figure 9-1). The molecular mechanisms that regulate transcription initiation and elongation are critical to numerous biological phenomena, including the development of a multicellular organism, as mentioned above, the immune responses that protect us from pathogenic microorganisms, and neurological processes such as learning and memory. When these regulatory mechanisms controlling transcription function improperly, pathological processes may occur. For example, dominant mutations of the *HOXD13* gene result in *polydactyly*, the embryological development of extra digits of the feet, hands, or both (Figure 9-2a). *HOXD13* encodes a *transcription factor* that normally regulates the transcription of multiple genes involved in development of the extremities. Other mutations affecting the function or expression of transcription factors cause an extra pair of wings to develop in *Drosophila* (Figure 9-2b),

alter the structures of flowers in plants (Figure 9-2c), and are responsible for multiple other developmental abnormalities.

Transcription is a complex process involving many layers of regulation. In this chapter, we focus on the molecular events that determine when transcription of a gene occurs. First, we consider the mechanisms of gene expression in bacteria, in which DNA is not bound by histones and packaged into nucleosomes. **Repressor** and **activator** proteins recognize and bind to specific DNA sequences to control the transcription of a nearby gene, and in many cases, specific tertiary structures in nascent mRNAs, called **riboswitches**, bind metabolites to regulate transcription elongation. The remainder of the chapter focuses on eukaryotic regulation of transcription and how the basic tenets of bacterial regulation are applied in more complex ways in higher organisms. In addition, eukaryotic regulation mechanisms make use of the association of DNA with histone octamers, forming chromatin structures with varying degrees of condensation, and of post-translational modifications of histone tails such as acetylation and methylation (see Figure 8-26). Figure 9-3 provides an overview of transcriptional regulation in metazoans (multicellular animals) and of the processes outlined in this chapter. We discuss how the RNA polymerases responsible for the transcription of different classes of eukaryotic genes bind to promoter sequences to initiate the synthesis of an RNA molecule, and how specific DNA sequences function as **transcription-control regions** by serving as the binding sites for the transcription factors that regulate transcription. Next we consider how eukaryotic activators and repressors influence transcription through interactions with large multiprotein complexes. Some of these multiprotein complexes modify chromatin condensation, altering the accessibility of chromosomal DNA to transcription factors and RNA polymerases. Other complexes directly influence the frequency at which RNA polymerases bind to promoters and initiate transcription. Very recent research has revealed that, for many genes in multicellular animals, the RNA polymerase pauses after transcribing a short RNA, and that one transcriptional regulation mechanism involves a release of the paused polymerase, allowing it to transcribe the rest of the gene. We discuss how transcription of specific genes can be specified by particular combinations of the roughly 1400 transcription factors encoded in the human genome, giving rise to cell-type-specific gene expression. We consider the various ways in which the activities of transcription factors themselves are controlled to ensure that genes are expressed only in the correct cell types and at the appropriate time during their differentiation.

We also discuss recent studies revealing that RNA-protein complexes in the nucleus can regulate transcription. New methods for sequencing DNA, coupled with reverse transcription of RNA into DNA *in vitro*, have revealed that much of the genome of eukaryotes is transcribed into low-abundance RNAs that do not encode proteins. Several nuclear *long noncoding RNAs* (*lncRNAs*) have recently been discovered to regulate the transcription of other protein-coding genes. This finding raises the possibility that transcriptional control by such noncoding RNAs may be much more general than is currently understood. Recent advances in mapping the association of transcription factors with

**FIGURE 9-1 Contributions of the major processes that regulate protein concentrations.** The concentration of a protein is controlled by regulation of the frequency with which the mRNA encoding the protein is synthesized (gene transcription), the rate at which that mRNA is degraded, the rate at which that mRNA is translated into protein, and the rate at which that protein is degraded. The relative contributions of these four rates to determining the concentrations of thousands of proteins in cultured mouse fibroblasts were determined by mass spectrometry to measure protein concentrations (see Chapter 3), mRNA sequencing (RNA-seq) to measure mRNA levels (see Chapter 6), protection of mRNA from ribonuclease digestion by associated ribosomes (ribosome footprinting) to estimate translation rates, stable isotope labeling to determine degradation rates, and statistical analysis of the data to correct for inherent biases and errors in these methods.

[Data from J. J. Li and M. D. Biggin, 2014, *Science* **347**:1066.]

specific regions of chromatin across the entire genome in a variety of cell types have provided the first glimpses of how transcription factors regulate embryonic development from the pluripotent stem cells of the early embryo to the fully differentiated cells that make up most of our tissues. RNA processing and various post-transcriptional mechanisms

for controlling eukaryotic gene expression are covered in Chapter 10. Subsequent chapters, particularly Chapters 15, 16, and 21, provide examples of how transcription is regulated by interactions between cells and how the resulting **gene control** contributes to the development and function of specific types of cells in multicellular organisms.

**FIGURE 9-2 Phenotypes of mutations in genes encoding transcription factors.** (a) A dominant mutation in the human *HOXD13* gene results in the development of extra digits, a condition known as polydactyly. (b) Homozygous recessive mutations that prevent expression of the *Ubx* gene in the third thoracic segment of *Drosophila* result in transformation of that segment, which normally has a balancing organ called a haltere, into a second copy of the thoracic segment that develops wings. (c) Mutations in *Arabidopsis thaliana* that inactivate both copies of three floral organ-identity genes transform the normal parts of the flower into leaflike structures. In each case, these mutations

affect master regulatory transcription factors that regulate multiple genes, including many genes encoding other transcription factors. **FIGURE 9-3 Overview of eukaryotic transcriptional control.**

Inactive genes are assembled into regions of condensed chromatin that inhibit RNA polymerases and their associated general transcription factors from interacting with promoters. A pioneer transcription factor is able to bind to a specific regulatory sequence within the condensed chromatin and interact with chromatin-remodeling enzymes and histone acetylases that decondense the chromatin, making it accessible to RNA polymerase II and the general transcription factors. Additional activator proteins then bind to specific transcription-control elements in both promoter-proximal sites and distant enhancers, where they interact with one another and with the multisubunit Mediator complex to assemble RNA polymerase II (Pol II) and general transcription factors on promoters. Alternatively, repressor proteins bind to other transcription-control elements to inhibit transcription initiation by Pol II and interact with multiprotein co-repressor complexes to condense chromatin. During transcriptional activation, Pol II initiates transcription, but pauses after transcribing fewer than 100 nucleotides due to the action of the elongation inhibitor NELF associated with DSIF. Activators promote the association of the Pol II-NELF-DSIF complex with elongation factor P-TEFb, which releases NELF and allows productive elongation through the gene. DSIF is the DRB sensitivity-inducing factor, NELF is the negative elongation factor, and P-TEFb is a protein kinase made up of CDK9 and cyclin T. See S. Malik and R. G. Roeder, 2010, *Nat. Rev. Genet.* **11**:761.

## 9.1 Control of Gene Expression in Bacteria

Because the structure and function of a cell are determined by the proteins it contains, the control of gene expression is a fundamental aspect of molecular cell biology. Most commonly, the “decision” to transcribe the gene encoding a particular protein is the major mechanism for controlling production of the encoded protein in a cell. By controlling transcription, a cell can regulate which proteins it produces

and how rapidly they are synthesized. When transcription of a gene is *repressed*, the corresponding mRNA and encoded protein or proteins are synthesized at low rates. Conversely, when transcription of a gene is *activated*, both the mRNA and encoded protein or proteins are produced at much higher rates.

In most bacteria and other single-celled organisms, gene expression is highly regulated in order to adjust the cell’s enzymatic machinery and structural components to changes in the nutritional and physical environment. Thus at any given

time, a bacterial cell normally synthesizes only those proteins that are required for its survival under the current conditions. Here we describe the basic features of transcriptional control in bacteria, using the *lac* operon and the glutamine synthetase gene in *E. coli* and the *xpt-pbuX* operon in *Bacillus subtilis* as our primary examples. Many of the same features are involved in eukaryotic transcriptional control, which will be the subject of the remainder of this chapter.

## Transcription Initiation by Bacterial RNA Polymerase Requires Association with a Sigma Factor

In *E. coli*, about half the genes are clustered into **operons**, each of which encodes enzymes involved in a particular metabolic pathway or proteins that interact to form one multisubunit protein complex. For instance, the *trp* operon discussed in Chapter 5 encodes five polypeptides needed in the biosynthesis of tryptophan (see Figure 5-13). Similarly, the *lac* operon encodes three proteins required for the metabolism of lactose, a sugar present in milk. Because a bacterial operon is transcribed from one start site into a single mRNA, all the genes within an operon are **coordinately regulated**; that is, they are all activated or repressed at the same time to the same extent.

The transcription of operons, as well as that of isolated genes, is controlled by interplay between RNA polymerase and specific repressor and activator proteins. In order to initiate transcription, *E. coli* RNA polymerase must associate with one of a small number of  $\sigma$  (*sigma*) **factors**. The most common one in eubacterial cells is  $\sigma^{70}$ . This  $\sigma$ -factor binds to both RNA polymerase and promoter DNA sequences, bringing the RNA polymerase enzyme to the promoter. It recognizes and binds to both a six-base-pair sequence centered at about 10 bp and a seven-base-pair sequence centered at about 35 bp upstream from the +1 transcription start. Consequently, the –10 sequence and the –35 sequence together constitute a promoter for *E. coli* RNA polymerase associated with  $\sigma^{70}$  (see Figure 5-10b). Although the promoter sequences contacted by  $\sigma^{70}$  are located at –35 and –10, *E. coli* RNA polymerase binds to the promoter-region DNA from roughly –50 to +20 through interactions with DNA that do not depend on the sequence. The  $\sigma$ -factor also assists the RNA polymerase in separating the DNA strands at the transcription start site and in inserting the coding strand into the active site of the polymerase so that transcription starts at +1 (see Figure 5-11, step 2). The optimal  $\sigma^{70}$ -RNA polymerase promoter sequence, determined as the “consensus sequence” of multiple strong promoters, is

–35 region                      –10 region  
TTGACAT—15–17 bp—TATAAT

This consensus sequence shows the most commonly occurring base at each of the positions in the –35 and –10 regions. The size of the font indicates the importance of the base at that position, as determined by the influence of mutations of these bases on the frequency of transcription

initiation (i.e., the number of times per minute that RNA polymerases initiate transcription). The sequence shows the strand of DNA that has the same 5'→3' orientation as the transcribed RNA (i.e., the nontemplate strand). However, the  $\sigma^{70}$ -RNA polymerase initially binds to double-stranded DNA. After the polymerase transcribes a few tens of base pairs,  $\sigma^{70}$  is released. Thus  $\sigma^{70}$  acts as an *initiation factor* that is required for transcription initiation, but not for RNA strand elongation once initiation has taken place.

## Initiation of *lac* Operon Transcription Can Be Repressed or Activated

When *E. coli* is in an environment that lacks lactose, synthesis of *lac* mRNA is repressed so that cellular energy is not wasted synthesizing enzymes the cell does not require. In an environment containing both lactose and glucose, *E. coli* cells preferentially metabolize glucose, the central molecule of carbohydrate metabolism. The cells metabolize lactose at a high rate only when lactose is present and glucose is largely depleted from the medium. They achieve this metabolic adjustment by repressing transcription of the *lac* operon until lactose is present and allowing synthesis of only low levels of *lac* mRNA until the cytosolic concentration of glucose falls to low levels. Transcription of the *lac* operon under different conditions is controlled by *lac* repressor protein and catabolite activator protein (CAP) (also called CRP, for cAMP receptor protein), each of which binds to a specific DNA sequence in the *lac* transcription-control region; these two sequences are called the **operator** and the **CAP site**, respectively (Figure 9-4, top).

For transcription of the *lac* operon to begin, the  $\sigma^{70}$  subunit of the RNA polymerase must bind to the *lac* promoter at the –35 and –10 promoter sequences. When no lactose is present, the *lac* repressor binds to the *lac* operator, which overlaps the transcription start site. Therefore, the *lac* repressor bound to the operator site blocks  $\sigma^{70}$  binding and hence transcription initiation by RNA polymerase (Figure 9-4a). When lactose is present, it binds to specific binding sites in each subunit of the tetrameric *lac* repressor, causing a conformational change in the protein that makes it dissociate from the *lac* operator. As a result, the polymerase can bind to the promoter and initiate transcription of the *lac* operon. However, when glucose is also present, the frequency of transcription initiation is very low, resulting in the synthesis of only low levels of *lac* mRNA and thus of the proteins encoded by the *lac* operon (Figure 9-4b). The frequency of transcription initiation is low because the –35 and –10 sequences in the *lac* promoter differ from the ideal  $\sigma^{70}$ -binding sequences shown previously.

Once glucose is depleted from the medium and the intracellular glucose concentration falls, *E. coli* cells respond by synthesizing cyclic AMP (cAMP). As the concentration of cAMP increases, it binds to a site in each subunit of the dimeric CAP protein, causing a conformational change that allows the protein to bind to the CAP site in the *lac* transcription-control region. The bound CAP-cAMP complex interacts with the polymerase bound to the promoter, greatly increasing the

**FIGURE 9-4 Regulation of transcription from the *lac* operon of *E. coli*.** (Top) The transcription-control region, composed of roughly a hundred base pairs, includes three protein-binding regions: the CAP site, which binds catabolite activator protein; the *lac* promoter, which binds the  $\sigma^{70}$ -RNA polymerase complex; and the *lac* operator, which binds *lac* repressor. The *lacZ* gene encoding the enzyme  $\beta$ -galactosidase, the first of the three genes in the operon, is shown to the right. (a) In the absence of lactose, very little *lac* mRNA is produced because the *lac* repressor binds to the operator, inhibiting transcription initiation by  $\sigma^{70}$ -RNA polymerase. (b) In the presence of glucose and lactose, *lac* repressor binds lactose and dissociates from the operator, allowing  $\sigma^{70}$ -RNA polymerase to initiate transcription at a low rate. (c) Maximal transcription of the *lac* operon occurs in the presence of lactose and the absence of glucose. In this situation, cAMP increases in response to the low glucose concentration and forms a CAP-cAMP complex, which binds to the CAP site, where it interacts with RNA polymerase to increase the rate of transcription initiation. (d) The tetrameric *lac* repressor binds to the primary *lac* operator ( $O_1$ ) and one of two secondary operators ( $O_2$  or  $O_3$ ) simultaneously. The two structures are in equilibrium. See B. Muller-Hill, 1998, *Curr. Opin. Microbiol.* **1**:145. [Part (d) data from M. Lewis et al., 1996, *Science* **271**:1247-1254, PDB IDs 1lbh and 1lbg; and R. Daber et al., 2007, *J. Mol. Biol.* **370**:609-619, PDB ID 2pe5.]

frequency of transcription initiation. This activation leads to synthesis of high levels of *lac* mRNA and subsequently of the enzymes encoded by the *lac* operon (Figure 9-4c).

In fact, the *lac* operon is more complex than depicted in the simplified model in Figure 9-4a–c. The tetrameric *lac* repressor actually binds to two DNA sequences simultaneously, one at the primary operator (*lacO*1), which overlaps the region of DNA bound by RNA polymerase at the promoter, and the other at one of two secondary operators centered at +412 (*lacO*2), within the *lacZ* protein-coding region, and –82 (*lacO*3) (Figure 9-4d). The *lac* repressor tetramer is a dimer of dimers. Each dimer binds to one operator (Figure 9-4d). Simultaneous binding of the tetrameric *lac* repressor to the primary *lac* operator and one of the two secondary operators is possible because DNA is quite flexible, as we saw in the wrapping of DNA around the surface of a histone octamer in the nucleosomes of eukaryotes (see Figure 8-24). The secondary operators function to increase the local concentration of *lac* repressor in the micro-vicinity of the primary operator where repressor binding blocks RNA polymerase binding. Since the equilibrium of binding reactions depends on the concentrations of the binding partners, the resulting increased local concentration of *lac* repressor in the vicinity of *O*1 increases repressor binding to *O*1. There are approximately 10 *lac* repressor tetramers per *E. coli* cell. Because of binding to *O*2 and *O*3, there is nearly always a *lac* repressor tetramer much closer to *O*1 than would otherwise be the case if the 10 repressor tetramers were diffusing randomly through the cell. If both *O*2 and *O*3 are mutated so that the *lac* repressor no longer binds to them with high affinity, repression at the *lac* promoter is reduced by a factor of 70. Mutation of only *O*2 or only *O*3 reduces repression twofold, indicating that either one of these secondary operators can provide most of the increase in repression.

Although the promoters for different *E. coli* genes exhibit considerable homology, their exact sequences differ. The promoter sequence determines the intrinsic frequency at which RNA polymerase– $\sigma$  complexes initiate transcription of a gene in the absence of a repressor or activator protein. Promoters that support a high frequency of transcription initiation have –10 and –35 sequences similar to the ideal promoter shown previously and are called *strong promoters*. Those that support a low frequency of transcription initiation differ from this ideal sequence and are called *weak promoters*. The *lac* operon, for instance, has a weak promoter whose sequence differs from the consensus strong promoter at several positions. Its low intrinsic frequency of initiation is further reduced by the *lac* repressor and substantially increased by the cAMP–CAP complex.

## Small Molecules Regulate Expression of Many Bacterial Genes via DNA-Binding Repressors and Activators

Transcription of most *E. coli* genes is regulated by processes similar to those described for the *lac* operon, although the detailed interactions differ at each promoter. The general mechanism involves a specific repressor that binds to the operator

region of a gene or operon, thereby blocking transcription initiation. A small-molecule ligand binds to the repressor controlling its DNA-binding activity, and consequently the frequency of transcription initiation and therefore the rate of synthesis of the mRNA and encoded proteins as appropriate for the needs of the cell. As for the *lac* operon, many eubacterial transcription-control regions contain one or more secondary operators that contribute to the level of repression.

Specific activator proteins, such as CAP in the *lac* operon, also control transcription of a subset of bacterial genes that have binding sites for the activator. Like CAP, other activators bind to DNA together with RNA polymerase, stimulating transcription from a specific promoter. The DNA-binding activity of an activator can be modulated in response to cellular needs by the binding of specific small-molecule ligands (e.g., cAMP) or by post-translational modifications, such as phosphorylation, that alter the conformation of the activator.

### Transcription Initiation from Some Promoters Requires Alternative Sigma Factors

Most *E. coli* promoters interact with  $\sigma^{70}$ -RNA polymerase, the major initiating form of the bacterial enzyme. The transcription of certain groups of genes, however, is initiated by *E. coli* RNA polymerases containing one of several

alternative sigma factors that recognize different consensus promoter sequences than  $\sigma^{70}$  does (Table 9-1). These alternative  $\sigma$ -factors are required for the transcription of sets of genes with related functions, such as those involved in the response to heat shock or nutrient deprivation, motility, or sporulation in gram-positive eubacteria. In *E. coli*, there are 6 alternative  $\sigma$ -factors in addition to the major “house-keeping”  $\sigma$ -factor,  $\sigma^{70}$ . The genome of the gram-positive, sporulating bacterium *Streptomyces coelicolor* encodes 63  $\sigma$ -factors, the current record, based on sequence analysis of hundreds of eubacterial genomes. Most are structurally and functionally related to  $\sigma^{70}$ . Transcription initiation by RNA polymerases containing  $\sigma^{70}$ -like factors is regulated by repressors and activators that bind to DNA near the region where the polymerase binds. But one class, represented in *E. coli* by  $\sigma^{54}$ , is unrelated to  $\sigma^{70}$  and functions differently.

### Transcription by $\sigma^{54}$ -RNA Polymerase Is Controlled by Activators That Bind Far from the Promoter

The sequence of  $\sigma^{54}$  is distinctly different from that of all the  $\sigma^{70}$ -like factors. Transcription of genes by RNA polymerases containing  $\sigma^{54}$  is regulated solely by activators whose binding sites in DNA, referred to as **enhancers**, are generally located 80–160 bp upstream from the transcription start site.

**TABLE 9-1** Sigma Factors of *E. coli*

Sigma Factor	Promoters Recognized	Promoter Consensus	
		– 35 Region	– 10 Region
$\sigma^{70}$ ( $\sigma^D$ )	Housekeeping genes, most genes in exponentially replicating cells	TTGACA	TATAAT
$\sigma^S$ ( $\sigma^{38}$ )	Stationary-phase genes and general stress response	TTGACA	TATAAT
$\sigma^{32}$ ( $\sigma^H$ )	Induced by unfolded proteins in the cytoplasm; genes encoding chaperones that refold unfolded proteins and protease systems leading to the degradation of unfolded proteins in the cytoplasm	TCTCNCCCTTGAA	CCCCATNTA
$\sigma^E$ ( $\sigma^{24}$ )	Activated by unfolded proteins in the periplasmic space and cell membrane; genes encoding proteins that restore integrity to the cellular envelope	GAAGTT	TCTGA
$\sigma^F$ ( $\sigma^{28}$ )	Genes involved in flagellum assembly	CTAAA	CCGATAT
FecI ( $\sigma^{18}$ )	Genes required for iron uptake	TTGGAAA	GTAATG
		– 24 Region	– 12 Region
$\sigma^{54}$ ( $\sigma^N$ )	Genes for nitrogen metabolism and other functions	CTGGNA	TTGCA

Data from T. M. Gruber and C. A. Gross, 2003, *Annu. Rev. Microbiol.* 57:441, and B. K. Cho et al., 2014, *BMC Biol.* 12:4.

Even when enhancers are moved more than a kilobase away from a start site,  $\sigma^{54}$ -activators can activate transcription.

The best-characterized  $\sigma^{54}$ -activator—the NtrC protein (nitrogen regulatory protein C)—stimulates transcription of the *glnA* gene. The *glnA* gene encodes the enzyme glutamine synthetase, which synthesizes the amino acid glutamine, the central molecule of nitrogen metabolism, from glutamic acid and ammonia. The  $\sigma^{54}$ -RNA polymerase binds to the *glnA* promoter but does not melt the DNA strands and initiate transcription until it is activated by NtrC, a dimeric protein. NtrC, in turn, is regulated by a protein kinase called NtrB. In response to low levels of glutamine, NtrB phosphorylates dimeric NtrC, which then binds to an enhancer upstream of the *glnA* promoter. Enhancer-bound phosphorylated NtrC then stimulates the  $\sigma^{54}$ -polymerase bound at the promoter to separate the DNA strands and initiate transcription.

Electron microscopy studies have shown that phosphorylated NtrC bound at enhancers and  $\sigma^{54}$ -polymerase bound at the promoter interact directly, forming a loop in the DNA between the binding sites (Figure 9-5). As discussed

later in this chapter, this activation mechanism resembles the predominant mechanism of transcriptional activation in eukaryotes.

NtrC has ATPase activity, and ATP hydrolysis is required for activation of bound  $\sigma^{54}$ -RNA polymerase by phosphorylated NtrC. Mutants with an NtrC that is defective in ATP hydrolysis are invariably defective in stimulating the  $\sigma^{54}$ -RNA polymerase to melt the DNA strands at the transcription start site. It is postulated that ATP hydrolysis supplies the energy required for melting the DNA strands. In contrast, the  $\sigma^{70}$ -polymerase does not require ATP hydrolysis to separate the strands at a start site.

## Many Bacterial Responses Are Controlled by Two-Component Regulatory Systems

As we have just seen, control of the *E. coli glnA* gene depends on two proteins, NtrC and NtrB. Such two-component regulatory systems control many responses of bacteria to changes in their environment. At high concentrations of glutamine, glutamine binds to a sensor domain of NtrB, causing a

**EXPERIMENTAL FIGURE 9-5 DNA looping permits interaction of bound NtrC and  $\sigma^{54}$ -RNA polymerase.** (a) Drawing (left) and electron micrograph (right) of DNA restriction fragment with phosphorylated NtrC dimers bound to the enhancer region near one end and  $\sigma^{54}$ -RNA polymerase bound to the *glnA* promoter near the other end.

(b) Drawing (left) and electron micrograph (right) of the same fragment preparation, showing NtrC dimers and  $\sigma^{54}$ -RNA polymerase bound to each other, with the intervening DNA forming a loop between them. See W. Su et al., 1990, *Proc. Natl. Acad. Sci. USA* **87**:5504. [Micrographs courtesy Harrison Echols and Carol Gross.]

conformational change in the protein that inhibits its histidine kinase activity (Figure 9-6a). At the same time, the regulatory domain of NtrC blocks its DNA-binding domain from binding the *glnA* enhancers. At low concentrations of glutamine, glutamine dissociates from the sensor domain in the NtrB protein, leading to activation of a histidine kinase transmitter domain in NtrB that transfers the  $\gamma$ -phosphate of ATP to a histidine residue (H) in the transmitter domain. This phosphohistidine then transfers the phosphate to an aspartic acid residue (D) in the NtrC protein. This causes a conformational change in NtrC that unmask the NtrC DNA-binding domain so that it can bind to the *glnA* enhancers.

Many other bacterial responses are regulated by two proteins with homology to NtrB and NtrC (Figure 9-6b).

**FIGURE 9-6 Two-component regulatory systems.** (a) At low cytoplasmic concentrations of glutamine, glutamine dissociates from NtrB, resulting in a conformational change that activates a protein kinase transmitter domain that transfers an ATP  $\gamma$ -phosphate to a conserved histidine (H) in the transmitter domain. This phosphate is then transferred to an aspartic acid (D) in the regulatory domain of the response regulator NtrC. This converts NtrC into its activated form, which binds the enhancer sites upstream of the *glnA* promoter (see Figure 9-5). (b) General organization of two-component histidyl-aspartyl phospho-relay regulatory systems in bacteria and plants. See A. H. West and A. M. Stock, 2001, *Trends Biochem. Sci.* **26**:369.

In each of these regulatory systems, one protein, called a *histidine kinase sensor*, contains a latent histidine kinase transmitter domain that is regulated in response to environmental changes detected by a sensor domain. When activated, the transmitter domain transfers the  $\gamma$ -phosphate of ATP to a histidine residue in the transmitter domain. The second protein, called a *response regulator*, contains a *receiver* domain homologous to the region of NtrC containing the aspartic acid residue that is phosphorylated by activated NtrB. The response regulator contains a second functional domain that is regulated by phosphorylation of the receiver domain. In many cases, this domain of the response regulator is a sequence-specific DNA-binding domain that binds to related DNA sequences and functions either as a repressor, like the *lac* repressor, or as an activator, like CAP or NtrC, regulating the transcription of specific genes. However, the effector domain can have other functions as well, such as controlling the direction in which the bacterium swims in response to a concentration gradient of nutrients. Although all transmitter domains are homologous (as are receiver domains), the transmitter domain of a specific sensor protein will phosphorylate only the receiver domains of specific response regulators, allowing specific responses to different environmental changes. Similar two-component histidyl-aspartyl phospho-relay regulatory systems are also found in plants.

## Expression of Many Bacterial Operons Is Controlled by Regulation of Transcriptional Elongation

In addition to regulation of transcription initiation by activators and repressors, expression of many bacterial operons is controlled by regulation of transcriptional elongation in the promoter-proximal region. This mechanism of control was first discovered in studies of *trp* operon transcription in *E. coli* (see Figure 5-13). Transcription of the *trp* operon is repressed by the *trp* repressor when the concentration of tryptophan in the cytoplasm is high. But the low level of transcription initiation that still occurs is further controlled by a process called *attenuation* when the concentration of charged tRNA<sup>Trp</sup> is sufficient to support a high rate of protein synthesis. The first 140 nt of the *trp* operon does not encode proteins required for tryptophan biosynthesis, but rather consists of a short peptide “leader sequence,” as diagrammed in Figure 9-7a. Region 1 of this leader sequence contains two successive Trp codons. Region 3 can base-pair with either region 2 or region 4. A ribosome follows closely behind the RNA polymerase, initiating translation of the leader peptide shortly after the 5' end of the *trp* leader sequence emerges from the RNA polymerase. When the concentration of tRNA<sup>Trp</sup> is sufficient to support a high rate of protein synthesis, the ribosome translates quickly through region 1 into region 2, blocking the ability of region 2 to base-pair with region 3 as it emerges from the surface of the transcribing RNA polymerase (Figure 9-7b, *left*). Instead, region 3 base-pairs with region 4 as soon as it emerges from the surface of the polymerase, forming a stem-loop (see Figure 5-9a) followed by several uracils, which is a signal for

**FIGURE 9-7 Transcriptional control by regulation of RNA polymerase elongation and termination in the *E. coli trp* operon.** (a) Diagram of the 140-nucleotide *trp* leader RNA. The numbered regions are critical to attenuation. (b) Translation of the *trp* leader sequence begins near the 5' end soon after it is transcribed, while transcription of the rest of the polycistronic *trp* mRNA molecule continues.

bacterial RNA polymerase to pause transcription and terminate. As a consequence, the remainder of the long *trp* operon is not transcribed, and the cell does not waste the energy required for tryptophan synthesis, or for the translation of the encoded proteins, when the concentration of tryptophan is high.

However, when the concentration of  $tRNA^{Trp}$  is not sufficient to support a high rate of protein synthesis, the ribosome stalls at the two successive Trp codons in region 1 (Figure 9-7b, right). As a consequence, region 2 base-pairs with region 3 as soon as it emerges from the transcribing RNA polymerase. This prevents region 3 from base-pairing with region 4, so the 3–4 hairpin does not form and does not cause RNA polymerase pausing or transcription termination. As a result, the proteins required for tryptophan synthesis are translated by ribosomes that initiate translation at the start codons for each of these proteins in the long polycistronic *trp* mRNA.

Attenuation of transcription elongation also occurs at some operons and single genes encoding enzymes involved in the biosynthesis of other amino acids and metabolites through the function of *riboswitches*. Riboswitches are sequences of RNA most commonly found in the 5' untranslated region of bacterial mRNAs. They fold into complex tertiary structures called **aptamers** that bind small-molecule metabolites when those metabolites are present at sufficiently high concentrations. In some cases, this binding results in the formation of stem-loop structures that lead to early termination of transcription, as in the *Bacillus subtilis xpt-pbuX* operon, which encodes enzymes involved in purine synthesis (Figure 9-8). When the concentration of small-molecule metabolites is lower, the metabolites are

At high concentrations of charged  $tRNA^{Trp}$ , formation of the 3–4 stem-loop followed by a series of uracils causes termination of transcription. At low concentrations of charged  $tRNA^{Trp}$ , region 3 is sequestered in the 2–3 stem-loop and cannot base-pair with region 4. In the absence of the stem-loop structure required for termination, transcription of the *trp* operon continues. See C. Yanofsky, 1981, *Nature* **289**:751.

not bound by the aptamers, and alternative RNA structures form that do not induce transcription termination, allowing transcription of genes encoding enzymes involved in the synthesis of the metabolites. As we will see below, although the mechanism in eukaryotes is different, regulation of promoter-proximal transcriptional pausing and termination has recently been discovered to occur frequently in the regulation of gene expression in multicellular organisms as well.

## KEY CONCEPTS OF SECTION 9.1

### Control of Gene Expression in Bacteria

- Gene expression in both prokaryotes and eukaryotes is regulated primarily by mechanisms that control gene transcription.
- The first step in the initiation of transcription in *E. coli* is the binding of a  $\sigma$ -factor complexed with an RNA polymerase to a promoter.
- The nucleotide sequence of a promoter determines its strength, that is, how frequently different RNA polymerase molecules can bind and initiate transcription per minute.
- Repressors are proteins that bind to operator sequences that overlap or lie adjacent to promoters. Binding of a repressor to an operator inhibits transcription initiation or elongation.
- The DNA-binding activity of most bacterial repressors is modulated by small-molecule ligands. This allows bacterial cells to regulate transcription of specific genes in response

**FIGURE 9-8 Riboswitch control of transcription termination in *B. subtilis*.** (a) During transcription of the *Bacillus subtilis xpt-pbuX* operon, which encodes enzymes involved in purine synthesis, the 5' untranslated region of the mRNA can fold into alternative structures depending on the concentration of purines in the cytoplasm, forming the "purine riboswitch." At high concentrations of purines, the riboswitch folds into an aptamer that binds a purine ligand (cyan circle), allowing formation of a stem-loop transcription termination signal similar to the termination signal that forms in the *E. coli trp* operon mRNA at high

tryptophan concentrations (see Figure 9-7), i.e., a stem loop followed by a run of Us. At low purine concentrations, an alternative RNA structure forms that prevents formation of the transcription termination signal, permitting transcription of the operon. Note the alternative base pairing of the red and blue regions of the RNA. (b) Structure of the purine riboswitch bound to a purine (cyan) as determined by X-ray crystallography. See A. D. Garst, A. L. Edwards, and R. T. Batey, 2011, *Cold Spring Harb. Perspect. Biol.* **3**:a003533. [Part (b) data from R. T. Batey, S. D. Gilbert, and R. K. Montagne, 2004, *Nature* **432**:411, PDB ID 4fe5.]

to changes in the concentration of various nutrients in the environment and metabolites in the cytoplasm.

- The *lac* operon and some other bacterial genes are also regulated by activator proteins that bind next to a promoter and increase the frequency of transcription initiation by interacting directly with RNA polymerase bound to that promoter.
- The major sigma factor in *E. coli* is  $\sigma^{70}$ , but several other, less abundant sigma factors are also found, each recognizing different consensus promoter sequences or interacting with different activators.
- Transcription initiation by all *E. coli* RNA polymerases, except those containing  $\sigma^{54}$ , can be regulated by repressors and activators that bind near the transcription start site (see Figure 9-4).
- Genes transcribed by  $\sigma^{54}$ -RNA polymerase are regulated by activators that bind to enhancers located about 100 base pairs upstream from the start site. When the activator and  $\sigma^{54}$ -RNA polymerase interact, the DNA between their binding sites forms a loop (see Figure 9-5).
- In two-component regulatory systems, one protein acts as a sensor, monitoring the level of nutrients or other components in the environment. Under appropriate conditions, the

$\gamma$ -phosphate of an ATP is transferred first to a histidine in the sensor protein and then to an aspartic acid in a second protein, the response regulator. The phosphorylated response regulator then performs a specific function in response to the stimulus, such as binding to DNA regulatory sequences, thereby stimulating or repressing transcription of specific genes (see Figure 9-6).

- Transcription in bacteria can also be regulated by control of transcriptional elongation in the promoter-proximal region. This control can be exerted by ribosome binding to the nascent mRNA, as in the case of the *E. coli trp* operon (see Figure 9-7), or by riboswitches, RNA sequences that bind small molecules, as for the *B. subtilis xpt-pbuX* operon (see Figure 9-8), to determine whether a stem-loop followed by a string of uracils forms, causing the bacterial RNA polymerase to pause and terminate transcription.

## 9.2 Overview of Eukaryotic Gene Control

In bacteria, gene control serves mainly to allow a single cell to adjust to changes in its environment so that its growth and division can be optimized. In multicellular organisms, environmental changes also induce changes in gene expression. An example is the response to low oxygen concentrations

(hypoxia), in which a specific set of genes is rapidly induced that helps the cell survive under the hypoxic conditions. These genes include those encoding secreted angiogenic proteins that stimulate the growth and penetration of new capillaries into the surrounding tissue. However, the most characteristic and biologically far-reaching purpose of gene control in multicellular organisms is execution of the genetic program that underlies embryological development. Generation of the many different cell types that collectively form a multicellular organism depends on the right genes being activated in the right cells at the right time during the developmental period.

In most cases, once a developmental step has been taken by a cell, it is not reversed. Thus these decisions are fundamentally different from the reversible activation and repression of bacterial genes in response to environmental conditions. In executing their genetic programs, many differentiated cells (e.g., skin cells, red blood cells, and antibody-producing cells) march down a pathway to final cell death, leaving no progeny behind. The fixed patterns of gene control leading to differentiation serve the needs of the whole organism and not the survival of an individual cell.

Despite the differences in the purposes of gene control in bacteria and eukaryotes, two key features of transcriptional control first discovered in bacteria and described in the previous section also apply to eukaryotic cells. First, protein-binding regulatory DNA sequences, or transcription-control regions, are associated with genes. Second, specific proteins that bind to a gene's transcription-control regions determine where transcription will start and either activate or repress transcription. One fundamental difference between transcriptional control in bacteria and in eukaryotes is a consequence of the association of eukaryotic chromosomal DNA with histone octamers, forming nucleosomes that associate into chromatin fibers that further associate into chromatin of varying degrees of condensation (see Figures 8-24, 8-25, 8-27, and 8-28). Eukaryotic cells exploit chromatin structure to regulate transcription, a mechanism of transcriptional control that is not available to bacteria. In multicellular eukaryotes, many inactive genes are assembled into condensed chromatin, which inhibits binding of the RNA polymerases and general transcription factors required for transcription initiation (see Figure 9-3). Activator proteins, which bind to transcription-control regions near the transcription start site of a gene as well as kilobases away, promote chromatin decondensation, binding of RNA polymerase to the promoter, and transcriptional elongation. Repressor proteins, which bind to alternative control elements, cause condensation of chromatin and inhibition of polymerase binding or elongation. In this section, we discuss the general principles of eukaryotic gene control and point out some similarities and differences between bacterial and eukaryotic systems. Subsequent sections of this chapter will address specific aspects of eukaryotic transcription in greater detail.

## Regulatory Elements in Eukaryotic DNA Are Found Both Close to and Many Kilobases Away from Transcription Start Sites

Direct measurements of the transcription rates of multiple genes in different cell types have shown that regulation of transcription, either at the initiation step or during elongation in the promoter-proximal region, is the most widespread form of gene control in eukaryotes, as it is in bacteria. In eukaryotes, as in bacteria, a DNA sequence that specifies where RNA polymerase binds and initiates transcription of a gene is called a *promoter*. Transcription from a particular promoter is controlled by DNA-binding proteins that are functionally equivalent to bacterial repressors and activators. However, eukaryotic transcriptional regulatory proteins can often function either to activate or to repress transcription, depending on their associations with other proteins. Consequently, they are more generally called *transcription factors*.

The DNA control elements in eukaryotic genomes to which transcription factors bind are often located much farther from the promoter they regulate than is the case in bacterial genomes. In some cases, transcription factors bind at regulatory sites tens of thousands of base pairs either **upstream** (opposite to the direction of transcription) or **downstream** (in the same direction as transcription) from the promoter. As a result of this arrangement, transcription of a single gene may be regulated by the binding of multiple different transcription factors to alternative control elements, which direct expression of the same gene in different types of cells and at different times during development.

For example, several separate transcription-control regions regulate expression of the mammalian gene encoding the transcription factor *Pax6*. As mentioned in Chapter 1, *Pax6* protein is required for development of the eye. *Pax6* is also required for the development of certain regions of the brain and spinal cord, and the cells in the pancreas that secrete hormones such as insulin. As also mentioned in Chapter 1, heterozygous humans with only one functional *Pax6* gene are born with *aniridia*, a lack of irises in the eyes (see Figure 1-30d). In mammals, the *Pax6* gene is expressed from at least three alternative promoters that function in different cell types and at different times during embryogenesis (Figure 9-9a).

Researchers often analyze transcription-control regions by preparing recombinant DNA molecules that combine a fragment of DNA to be tested with the coding region for a **reporter gene** whose expression is easily assayed. Typical reporter genes include the gene that encodes luciferase, an enzyme that generates light that can be assayed with great sensitivity and over many orders of magnitude of intensity using a luminometer. Other frequently used reporter genes encode green fluorescent protein (GFP), which can be visualized by fluorescence microscopy (see Figures 4-9d and 4-16), and *E. coli*  $\beta$ -galactosidase, which generates an intensely blue insoluble precipitate when incubated with the colorless soluble lactose analog X-gal. When transgenic mice (see Figure 6-40) containing a  $\beta$ -galactosidase

reporter gene fused to 8 kb of DNA upstream from *Pax6* exon 0 were produced,  $\beta$ -galactosidase was observed in the developing lens, cornea, and pancreas of the embryo halfway through gestation (Figure 9-9b). Analysis of transgenic mice with smaller fragments of DNA from this region allowed the mapping of the separate transcription-control regions regulating transcription in the pancreas, and in both the lens and cornea. Transgenic mice with other reporter gene constructs revealed additional transcription-control regions (see Figure 9-9a). These regions control transcription in the developing retina and in different regions of the developing brain (encephalon). Some of these transcription-control regions are in introns between exons 4 and 5 and between exons 7 and 8. For example, a reporter gene under control of the region labeled Retina in Figure 9-9a between exons 4 and 5 led to reporter-gene expression specifically in the retina (Figure 9-9c).

Control regions for many genes are found hundreds of kilobases away from the coding exons of the gene. One method for identifying such distant control regions is to compare the sequences of distantly related organisms. Transcription-control regions for a conserved gene are also often conserved and can be recognized in the background of nonfunctional sequences that diverge during evolution.

For example, there is a human DNA sequence, which is highly conserved between humans, mice, chickens, frog, and fish, about 500 kb downstream of the *SALL1* gene (Figure 9-10a). *SALL1* encodes a transcription factor required for normal development of the limbs. When transgenic mice were produced containing this conserved DNA sequence linked to a  $\beta$ -galactosidase reporter gene (Figure 9-10b), the transgenic embryos expressed a very high level of  $\beta$ -galactosidase in the developing limb buds (Figure 9-10c). Human patients with deletions in this region of the genome develop with limb abnormalities. These results indicate that this conserved region directs transcription of the *SALL1* gene in the developing limb. Presumably, other transcription-control regions control expression of this gene in other types of cells, where it functions in the normal development of the ears, the lower intestine, and kidneys.

Because the sequences and functions of transcription-control regions are often conserved through evolution, the transcription factors that bind to these transcription-control regions to regulate gene expression in specific cell types are presumably conserved during evolution as well. This has made it possible to assay control regions in human DNA by

**FIGURE 9-10 The human *SALL1* enhancer activates expression of a reporter gene in limb buds of the developing mouse embryo.** (a) Graphic representation of the conservation of DNA sequence in a region of the human genome (in the interval of chromosome 16 from 50214 kb to 50220.5 kb) about 500 kb downstream from the *SALL1* gene, which encodes a zinc-finger transcription repressor. A region of roughly 500 bp of nonprotein-coding sequence is conserved from zebrafish to human. Nine hundred base pairs of human DNA including this conserved region were inserted into a plasmid next to the coding region for *E. coli*  $\beta$ -galactosidase. (b) The plasmid was microinjected into a pronucleus of a fertilized mouse egg and implanted in the uterus of a pseudopregnant mouse to generate a transgenic mouse embryo with the reporter-gene-containing plasmid incorporated into its genome (see Figure 5-43). (c) After 11.5 days of development, at the time when limb buds develop, the fixed and permeabilized embryo was incubated in X-gal, which is converted by  $\beta$ -galactosidase into an insoluble, intensely blue compound. The results showed that the conserved region contains an enhancer that stimulates strong transcription of the  $\beta$ -galactosidase reporter gene specifically in limb buds. [Part (a) data from A. Visel et al., 2007. VISTA Enhancer Browser—a database of tissue-specific human enhancers. *Nucleic Acids Res.* **35**:D88–92. Part (b) ©Deco/Alamy. Part (c) republished with permission of *Nature*, from Pennacchio, L.A., et al., "In vivo enhancer analysis of human conserved non-coding sequences", *Nature*, 444, 499–506, 2006; permission conveyed through Copyright Clearance Center, Inc.]

reporter-gene expression in transgenic zebrafish, a procedure that is far simpler, faster, and less expensive than preparing transgenic mice (Figure 9-9d). After discussing the proteins that function with RNA polymerase to carry out transcription in eukaryotic cells and eukaryotic promoters, we will return to a discussion of how such distant transcription-control regions, called *enhancers*, are thought to function.

### Three Eukaryotic RNA Polymerases Catalyze Formation of Different RNAs

The nuclei of all eukaryotic cells examined so far (e.g., vertebrate, *Drosophila*, yeast, and plant cells) contain three different RNA polymerases, designated I, II, and III. These enzymes are eluted at different salt concentrations during ion-exchange chromatography, reflecting the differences in their net charges. The three nuclear RNA polymerases also differ in their sensitivity to  $\alpha$ -amanitin, a poisonous cyclic octapeptide produced by some mushrooms (Figure 9-11). RNA polymerase I is insensitive to  $\alpha$ -amanitin, but RNA polymerase II is very sensitive—the drug binds near the active site of the enzyme and inhibits translocation of the enzyme along the DNA template. RNA polymerase III has intermediate sensitivity.

Each eukaryotic RNA polymerase catalyzes transcription of genes encoding different classes of RNA (Table 9-2). *RNA polymerase I* (Pol I), located in the nucleolus, transcribes genes encoding precursor rRNA (*pre-rRNA*), which is processed into 28S, 5.8S, and 18S rRNAs. *RNA polymerase III* (Pol III) transcribes genes encoding tRNAs, 5S rRNA, and an array of small stable RNAs, including one involved in RNA splicing (U6) and the RNA component of the signal recognition particle (SRP) involved in directing nascent proteins to the endoplasmic reticulum (see Chapter 13). *RNA polymerase II* (Pol II) transcribes all protein-coding genes: that is, it functions in production of mRNAs. RNA polymerase II

**EXPERIMENTAL FIGURE 9-11** Liquid chromatography separates and identifies the three eukaryotic RNA polymerases, each with its own sensitivity to  $\alpha$ -amanitin. A protein extract from the nuclei of cultured eukaryotic cells was passed through a DEAE Sephadex column and adsorbed protein eluted (black curve) with a solution of constantly increasing NaCl concentration. An aliquot of each fraction of eluate collected from the column was assayed for RNA polymerase activity without (red curve) and with (green shading) 1  $\mu$ g/ml  $\alpha$ -amanitin. This concentration of  $\alpha$ -amanitin inhibits polymerase II activity but has no effect on polymerases I and III. Polymerase III is inhibited by 10  $\mu$ g/ml of  $\alpha$ -amanitin, whereas polymerase I is unaffected even at this higher concentration. See R. G. Roeder, 1974, *J. Biol. Chem.* **249**:241.

also produces four of the five small nuclear RNAs (snRNAs) that take part in RNA splicing and micro-RNAs (miRNAs) involved in translation control, as well as the closely related endogenous small interfering RNAs (siRNAs) (see Chapter 10).

**TABLE 9-2** Classes of RNA Transcribed by the Three Eukaryotic Nuclear RNA Polymerases and Their Functions

Polymerase	RNA Transcribed	RNA Function
RNA polymerase I	Pre-rRNA (28S, 18S, 5.8S rRNAs)	Ribosome components, protein synthesis
RNA polymerase II	mRNA snRNAs siRNAs miRNAs	Encodes protein RNA splicing Chromatin-mediated repression, translation control Translation control
RNA polymerase III	tRNAs 5S rRNA snRNA U6 7S RNA  Other small stable RNAs	Protein synthesis Ribosome component, protein synthesis RNA splicing Signal recognition particle for insertion of polypeptides into the endoplasmic reticulum Various functions, unknown for many

**FIGURE 9-12 Comparison of three-dimensional structures of bacterial and eukaryotic RNA polymerases.** (a, b) These space-filling models are based on x-ray crystallographic analysis. (a) RNA polymerase from the bacterium *T. aquaticus*. The five subunits of the bacterial enzyme are distinguished by color. Only the N-terminal domains of the  $\alpha$  subunits are included in this model. (b) Core RNA polymerase II from *S. cerevisiae*. Ten of the 12 subunits constituting yeast RNA polymerase II are shown in this model. Subunits that are similar in conformation to those in the bacterial enzyme are shown in the same colors. The C-terminal domain of the large subunit RPB1 was not observed in the crystal structure, but it is known to extend from the position

marked with a red arrow. (RPB is the abbreviation for “RNA polymerase B,” which is an alternative way of referring to RNA polymerase II.) DNA entering the polymerases as they transcribe to the right is diagrammed. (c) Space-filling model of yeast RNA polymerase II including subunits 4 and 7. These subunits extend from the core portion of the enzyme shown in (b) near the region of the C-terminal domain of the large subunit. [Part (a) data courtesy of Seth Darst; see N. Korzhova et al., 2000, *Science* **289**:619–625. Part (b) data from P. Cramer et al., 2001, *Science* **292**:1863, PDB ID 1i50. Part (c) data from K. J. Armache et al., 2003, *P. Natl. Acad. Sci. USA* **100**:6964, and D. A. Bushnell and R. D. Kornberg, 2003, *P. Natl. Acad. Sci. USA* **100**:6969.]

Each of the three eukaryotic RNA polymerases is more complex than *E. coli* RNA polymerase, but all four of these multisubunit RNA polymerases have a similar overall design (Figure 9-12a, b). All three eukaryotic RNA polymerases contain two large subunits and 10–14 smaller subunits, some of which are common between two or all three of the polymerases. The best-characterized eukaryotic RNA polymerases are from the yeast *Saccharomyces cerevisiae*. Each of the yeast genes encoding the polymerase subunits has been subjected to gene-knockout mutations and the resulting phenotypes characterized. In addition, the three-dimensional structure of yeast RNA polymerase II has been determined (Figure 9-12b, c). The three nuclear RNA polymerases from all eukaryotes so far examined are very similar to those of yeast. Plants contain two additional nuclear RNA polymerases (RNA polymerases IV and V), which are closely related to their RNA polymerase II but have a unique large subunit and some additional unique subunits. These two polymerases function in transcriptional repression directed by nuclear siRNAs in plants.

The two large subunits of all three eukaryotic RNA polymerases (and RNA polymerases IV and V of plants) are related

to one another and are similar to the *E. coli*  $\beta'$  and  $\beta$  subunits, respectively (see Figure 9-12a, b). Each of the eukaryotic RNA polymerases also contains an  $\omega$ -like and two nonidentical  $\alpha$ -like subunits (Figure 9-13). The extensive similarity in the structures of these core subunits in RNA polymerases from various sources indicates that RNA polymerase arose early in evolution and was largely conserved. This seems logical for an enzyme catalyzing a process as fundamental as the copying of RNA from DNA. In addition to the core subunits that are related to the *E. coli* RNA polymerase subunits, all three yeast RNA polymerases contain four additional small subunits, common to them but not to the bacterial RNA polymerase. Finally, each eukaryotic nuclear RNA polymerase has several enzyme-specific subunits that are not present in the other two (see Figure 9-13). Three of these additional subunits of Pol I and Pol III are homologous to the three additional Pol II-specific subunits. The other two Pol I-specific subunits are homologous to the Pol II general transcription factor TFIIF, discussed later, and the four additional subunits of Pol III are homologous to the Pol II general transcription factors TFIIF and TFIIE. These are likely stably associated with Pol III in the cell, and do not dissociate from it during purification.

**FIGURE 9-13 Schematic representation of the subunit structure of the *E. coli* RNA core polymerase and yeast nuclear RNA polymerases.**

All three yeast polymerases have five core subunits homologous to the  $\beta$ ,  $\beta'$ , two  $\alpha$ , and  $\omega$  subunits of *E. coli* RNA polymerase. The largest subunit (RPB1) of RNA polymerase II also contains an essential C-terminal domain (CTD). RNA polymerases I and III contain the same two nonidentical  $\alpha$ -like subunits, whereas RNA polymerase II contains two other nonidentical  $\alpha$ -like subunits. All three polymerases share the same  $\omega$ -like subunit and four other common subunits. In addition, each yeast polymerase contains three to seven unique smaller subunits.

The *clamp domain* of subunit RPB1 is so designated because it has been observed in two different positions in crystals of free Pol II (Figure 9-14a) and in a complex that mimics the elongating form of the enzyme (Figure 9-14b). This domain rotates on a hinge that is probably open when downstream DNA is inserted into this region of the polymerase, and then swings shut when the enzyme is in its elongation mode. It is postulated that when the 8–9-bp RNA-DNA hybrid region near the active site (where RNA is base-paired to the template strand; see Figure 9-14b) is bound between RBP1 and RBP2, the clamp is locked in its closed position, anchoring the polymerase to the downstream double-stranded DNA. Furthermore, a transcription elongation factor called DSIF, discussed later, associates with the elongating polymerase, holding the clamp in its closed conformation. As a consequence, the polymerase is extraordinarily processive, which is to say that it continues to polymerize ribonucleotides until transcription is terminated. After termination and release of RNA from the exit

(a) Free RNA polymerase II

(b) Transcribing RNA polymerase II

**FIGURE 9-14 The clamp domain of RPB1.** The structures of the free (a) and transcribing (b) RNA polymerase II differ mainly in the position of a clamp domain in the RPB1 subunit (orange), which swings over the cleft between the jaws of the polymerase during formation of the transcribing complex, trapping the template DNA strand and transcript. Binding of the clamp domain to the 8–9-bp RNA-DNA hybrid may help couple clamp closure to the presence of RNA, stabilizing the closed, elongating complex. RNA is shown in red, and the template strand in light purple. For clarity, downstream nontemplate DNA is not shown. The clamp closes over the incoming downstream DNA. Portions of RBP2 that form one side of the cleft have been removed so that the nucleic acids can be better visualized. The  $Mg^{2+}$  ion that participates in catalysis of phosphodiester bond formation is shown in green. Wall is the domain of RPB2 that forces the template DNA entering the jaws of the polymerase to bend before it exits the polymerase. The bridge  $\alpha$  helix, shown in green, extends across the cleft in the polymerase (see Figure 9-12b) and is postulated to bend and straighten as the polymerase translocates one base down the template strand. The nontemplate strand is thought to form a flexible single-stranded region above the cleft (not shown), extending from three bases downstream of the template base-paired to the 3' base of the growing RNA to where the template strand exits the polymerase, where it hybridizes with the template strand to generate the transcription bubble. [Part (a) data from P. Cramer, D. A. Bushnell, and R. D. Kornberg, 2001, *Science* **292**:1863, PDB ID 1i50. Part (b) data from A. L. Gnatt et al., 2001, *Science* **292**:1876, PDB ID 1i6h.]

channel, the clamp can swing open, releasing the enzyme from the template DNA. This mechanism can explain how human RNA polymerase II can transcribe the longest human gene, encoding dystrophin (*DMD*; see Figure 1-31), which is some 2 million base pairs in length, without dissociating and terminating transcription. Since transcription elongation proceeds at 1–2 kb per minute, transcription of the *DMD* gene requires approximately one day!

Gene-knockout experiments in yeast indicate that most of the subunits of the three nuclear RNA polymerases are essential for cell viability. Disruption of the genes encoding the few polymerase subunits that are not essential for viability (e.g., subunits 4 and 7 of RNA polymerase II) nevertheless results in very poorly growing cells. Thus all the subunits are necessary for eukaryotic RNA polymerases to function normally. Archaea, like eubacteria, have a single type of RNA polymerase involved in gene transcription, but archaeal RNA polymerases, like eukaryotic nuclear RNA polymerases, have on the order of a dozen subunits. Archaea also have general transcription factors, discussed later, that are related to those of eukaryotes, consistent with the closer evolutionary relationship between archaea and eukaryotes than between eubacteria and eukaryotes (see Figure 1-1).

### The Largest Subunit in RNA Polymerase II Has an Essential Carboxy-Terminal Repeat

The carboxyl end of RPB1, the largest subunit of RNA polymerase II, contains a stretch of seven amino acids that is nearly precisely repeated multiple times. Neither RNA polymerase I nor III contains these repeating units. This heptapeptide repeat, with a consensus sequence of Tyr-Ser-Pro-Thr-Ser-Pro-Ser, is known as the *carboxy-terminal domain (CTD)* (see Figure 9-12b, red arrow). Yeast RNA polymerase II contains 26 or more repeats, vertebrate enzymes have 52 repeats, and an intermediate number of repeats occur in RNA polymerase II from nearly all other eukaryotes. The CTD is critical for viability, and at least 10 copies of the repeat must be present for yeast to survive.

In vitro experiments with model promoters first showed that RNA polymerase II molecules that initiate transcription have a nonphosphorylated CTD. Once the polymerase initiates transcription and begins to move away from the promoter, many of the serine and some tyrosine residues in the CTD are phosphorylated. Analysis of polytene chromosomes from *Drosophila* salivary glands prepared just before molting of the larva, a time of active transcription, indicates that the CTD is also phosphorylated during in vivo transcription. The large chromosomal “puffs” induced at this time in development are regions where the genome is very actively transcribed. Staining with antibodies specific for the phosphorylated or nonphosphorylated CTD demonstrated that RNA polymerase II associated with the highly transcribed puffed regions contains a phosphorylated CTD (Figure 9-15).

**EXPERIMENTAL FIGURE 9-15 Antibody staining demonstrates that the carboxy-terminal domain of RNA polymerase II is phosphorylated during in vivo transcription.** Salivary-gland polytene chromosomes were prepared from *Drosophila* larvae just before they molted. The preparation was treated with a rabbit antibody specific for phosphorylated CTD and with a goat antibody specific for nonphosphorylated CTD. The preparation was then stained with fluorescein-labeled anti-goat antibody (green) and rhodamine-labeled anti-rabbit antibody (red). Thus polymerase molecules with a nonphosphorylated CTD stained green, and those with a phosphorylated CTD stained red. The molting hormone ecdysone induces very high rates of transcription in the puffed regions labeled 74EF and 75B; note that only phosphorylated CTD is present in these regions. Smaller puffed regions transcribed at high rates are also visible. Nonpuffed sites that stained red (up arrow) or green (horizontal arrow) are also indicated, as is a site staining both red and green, producing a yellow color (down arrow). [From J. R. Weeks et al., “Locus-specific variation in phosphorylation state of RNA polymerase II in vivo: correlations with gene activity and transcript processing,” *Genes & Development*, 1993, 7(12A):2329–44; courtesy of J. R. Weeks and A. L. Greenleaf; republished with permission from Cold Spring Harbor Press.]

## KEY CONCEPTS OF SECTION 9.2

### Overview of Eukaryotic Gene Control

- The primary purpose of gene control in multicellular organisms is the execution of precise developmental programs so that the proper genes are expressed in the proper cells at the proper times during embryologic development and cellular differentiation.
- Transcriptional control is the primary means of regulating gene expression in eukaryotes, as it is in bacteria.
- In eukaryotic genomes, DNA transcription-control elements may be located many kilobases away from the promoter they regulate. Different control elements can control transcription of the same gene in different cell types.
- Eukaryotes contain three types of nuclear RNA polymerases. All three contain two large and three smaller core

subunits with homology to the  $\beta'$ ,  $\beta$ ,  $\alpha$ , and  $\omega$  subunits of *E. coli* RNA polymerase, as well as several additional small subunits (see Figure 9-13).

- RNA polymerase I synthesizes only pre-rRNA. RNA polymerase II synthesizes mRNAs, some of the small nuclear RNAs that participate in mRNA splicing, and micro- and small interfering RNAs (miRNAs and siRNAs) that regulate the translation and stability of mRNAs. RNA polymerase III synthesizes tRNAs, 5S rRNA, and several other small stable RNAs (see Table 9-2).
- The carboxy-terminal domain (CTD) in the largest subunit of RNA polymerase II becomes phosphorylated during transcription initiation and remains phosphorylated as the enzyme transcribes the DNA template.

### 9.3 RNA Polymerase II Promoters and General Transcription Factors

The mechanisms that regulate transcription initiation and elongation by RNA polymerase II have been studied extensively because this polymerase is the one that transcribes mRNAs. Transcription initiation and elongation by RNA polymerase II are the initial biochemical processes required for the expression of protein-coding genes and are the steps in gene expression that are most frequently regulated to determine when and in which cells specific proteins are synthesized. As noted in the previous section, the expression of eukaryotic protein-coding genes is regulated by multiple protein-binding DNA sequences, generically referred to as transcription-control regions. These sequences include promoters, which determine where transcription of the DNA template begins, and other types of control elements located near transcription start sites, as well as sequences located far from the genes they regulate, called enhancers, which control the type of cell in which the gene is transcribed and how frequently it is transcribed. In this section, we take a closer look at the properties of various transcription-control elements found in eukaryotic protein-coding genes and some techniques used to identify them.

#### RNA Polymerase II Initiates Transcription at DNA Sequences Corresponding to the 5' Cap of mRNAs

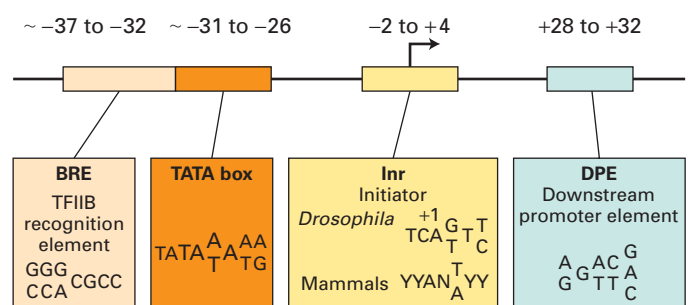

In vitro transcription experiments using purified RNA polymerase II, a protein extract prepared from the nuclei of cultured cells, and DNA templates containing sequences encoding the 5' ends of mRNAs for a number of abundantly expressed genes revealed that the transcripts produced always contained a cap structure at their 5' ends identical to that present at the 5' end of the spliced mRNA normally expressed from the gene in vivo (see Figure 5-14). In these

experiments, the 5' cap was added to the 5' end of the nascent RNA by enzymes in the nuclear extract, which can add a cap only to an RNA that has a 5' tri- or diphosphate. Because a 5' end generated by cleavage of a longer RNA would have a 5' monophosphate, it would not be capped. Consequently, researchers concluded that the capped nucleotides generated in the in vitro transcription reactions must have been the nucleotides with which transcription was initiated. Sequence analysis revealed that, for any given gene, the sequence at the 5' end of the RNA transcripts produced in vitro is the same as that at the 5' end of the mRNAs isolated from cells, confirming that the capped nucleotide of eukaryotic mRNAs coincides with the transcription start site. Today the transcription start site for a newly characterized mRNA is generally determined simply by identifying the DNA sequence encoding the 5'-capped nucleotide of the encoded mRNA.

#### The TATA Box, Initiators, and CpG Islands Function as Promoters in Eukaryotic DNA

Several different types of DNA sequences can function as promoters for RNA polymerase II, telling the polymerase where to initiate transcription of an RNA complementary to the template strand of a double-stranded DNA molecule. These sequences include TATA boxes, initiators, and CpG islands.

**TATA Boxes** The first genes to be sequenced and studied through in vitro transcription systems were viral genes and cellular protein-coding genes that are very actively transcribed, either at particular times of the cell cycle or in specific differentiated cell types. In all these highly transcribed genes, a conserved sequence called the **TATA box** was found about 26–31 bp upstream of the transcription start site (Figure 9-16). Mutagenesis studies have shown that a single-base change in this nucleotide sequence drastically decreases

**FIGURE 9-16 Core promoter elements of non-CpG island promoters in metazoans.** The sequence of each element is shown with the 5' end at the left and the 3' end at the right. The most frequently observed bases in TATA box promoters are shown in larger font. A<sup>+</sup> is the base at which transcription starts, Y is a pyrimidine (C or T), N is any of the four bases. [Data from S. T. Smale and J. T. Kadonaga, 2003, *Annu. Rev. Biochem.* **72**:449.]

in vitro transcription of the gene adjacent to it. If the base pairs between the TATA box and the normal transcription start site are deleted, transcription of the altered, shortened template begins at a new site about 25 bp downstream from the TATA box. Consequently, the TATA box acts similarly to an *E. coli* promoter to position RNA polymerase II for transcription initiation (see Figure 5-12).

**Initiator Sequences** Instead of a TATA box, some eukaryotic genes contain an alternative promoter element called an **initiator**. Most naturally occurring initiator elements have a cytosine (C) at the  $-1$  position and an adenine (A) residue at the transcription start site ( $+1$ ). Directed mutagenesis of mammalian genes with an initiator-containing promoter revealed that the nucleotide sequence immediately surrounding the start site determines the strength of such promoters. In contrast to the conserved TATA box sequence, however, only an extremely degenerate initiator consensus sequence has been defined:

where  $A^{+1}$  is the base at which transcription starts, Y is a pyrimidine (C or T), N is any of the four bases, and T/A is T or A at position  $+3$ . As we will see, other promoter elements, designated BRE and DPE (see Figure 9-16), can be bound by general transcription factors and influence promoter strength.

**CpG Islands** Transcription of genes with promoters containing a TATA box or initiator element begins at a well-defined initiation site. However, the transcription of most protein-coding genes in mammals (~70 percent) occurs at a lower rate than at TATA box-containing and initiator-containing promoters and begins at any of several alternative start sites within regions of about 100–1000 bp that have an unusually high frequency of CG sequences. Many such genes encode proteins that are not required in large amounts (e.g., genes encoding enzymes involved in basic metabolic processes required in all cells, often called “housekeeping genes”). These promoter regions are called **CpG islands** (where “p” represents the phosphate between the C and G nucleotides) because they occur relatively rarely in the genome sequences of mammals.

In mammals, most Cs followed by a G that are not associated with CpG island promoters are methylated at position 5 of the pyrimidine ring (5-methyl C, represented  $C^{Me}$ ; see Figure 2-17). CG sequences are thought to be underrepresented in mammalian genomes because spontaneous deamination of 5-methyl C generates thymidine. Over the time scale of mammalian evolution, this is thought to have led to the conversion of most CGs to TG by DNA-repair mechanisms. As a consequence, the frequency of CG in the human genome is only 21 percent of that expected if Cs were randomly followed by any base. However, the

Cs in active CpG island promoters are unmethylated. Consequently, when they deaminate spontaneously, they are converted to U, a base that is recognized by DNA-repair enzymes and converted back to C. As a result, the frequency of CG sequences within CpG island promoters is close to that expected if C were followed by any of the other three nucleotides randomly.

CG-rich sequences are bound by histone octamers more weakly than CG-poor sequences because more energy is required to bend them into the small-diameter loops required to wrap around the histone octamer forming a nucleosome (see Figure 8-24). As a consequence, CpG islands coincide with nucleosome-free regions of DNA. Much remains to be learned about the molecular mechanisms that control transcription from CpG island promoters, but a current hypothesis is that the general transcription factors discussed in the next section can bind to them because CpG islands exclude nucleosomes.

### Divergent Transcription from CpG Island Promoters

Another remarkable feature of CpG islands is that transcription from these elements is initiated in both directions, even though only transcription of the sense strand yields an mRNA. By a mechanism(s) that remains to be fully elucidated, most RNA polymerase II molecules transcribing in the “wrong” direction—that is, transcribing the antisense strand—pause or terminate transcription about 1–3 kb from the transcription start site. This phenomenon was discovered by taking advantage of the stability conferred on the elongation complex by the RNA polymerase II clamp domain when an RNA-DNA hybrid is bound near the active site (see Figure 9-14b, c).

Nuclei were isolated from cultured human fibroblasts and incubated in a buffered solution containing salt and mild detergent, which removes RNA polymerases except for those in the process of elongation because of their stable association with template DNA. Nucleotide triphosphates were then added, with UTP replaced by bromo-UTP, containing uracil with a Br atom at position 5 on the pyrimidine ring (see Figure 2-17). The nuclei were then incubated at 30 °C long enough for about 100 nucleotides to be polymerized by the RNA polymerase II (Pol II) molecules that were in the process of elongation at the time the nuclei were isolated. RNA was then isolated, and RNA containing bromo-U was immunoprecipitated with an antibody specific for BrU-labeled RNA. Thirty-three nucleotides at the 5' ends of these RNAs were then sequenced by massively parallel DNA sequencing (see Chapter 6) of reverse transcripts, and the sequences were mapped on the human genome.

Figure 9-17 shows a plot of the number of sequence reads per kilobase of total BrU-labeled RNA relative to the major transcription start sites (TSS) of all currently known human protein-coding genes. The results show that approximately equal numbers of RNA polymerase molecules transcribed most promoters (mostly CpG island promoters) in the sense direction, toward the gene (blue, plotted

**EXPERIMENTAL FIGURE 9-17 Analysis of elongating RNA polymerase II molecules in human fibroblasts.** Nuclei from cultured fibroblasts were isolated and incubated in a buffer with a non-ionic detergent that prevents RNA polymerase II from initiating transcription. Treated nuclei were then incubated with ATP, CTP, GTP, and Br-UTP for 5 minutes at 30 °C, a time sufficient to incorporate about 100 nucleotides. RNA was then isolated and broken into fragments of about 100 nucleotides each by controlled incubation at high pH. Specific RNA oligonucleotides were ligated to the 5' and 3' ends of the RNA fragments, which were then subjected to reverse transcription. The resulting DNA was amplified by the polymerase chain reaction and subjected to massively parallel DNA sequencing. The sequences determined were aligned to the transcription start sites (TSS) of all known human genes, and the number of sequence reads per kilobase of total sequenced DNA was plotted for 10-bp intervals of sense transcripts (blue) and antisense transcripts (purple). See text for discussion. [Data from L. J. Core, J. J. Waterfall, and J. T. Lis, 2008, *Science* **322**:1845.]

upward to indicate transcription in the sense direction), and in the antisense direction, away from the gene (purple, plotted downward to represent transcription of the complementary DNA strand in the opposite, antisense direction). A peak of sense transcripts was observed at about +50 relative to the major transcription start site (TSS), indicating that Pol II pauses in the +50 to +200 region before elongating further. A peak at -250 to -500 relative to the major transcription start site of Pol II transcribing in the opposite direction was also observed, revealing paused RNA polymerase II molecules at the other ends of the nucleosome-free regions in CpG island promoters. Note that the number of sequence reads, and therefore the number of elongating polymerases, is lower for polymerases transcribing in the antisense direction more than 1 kb from the transcription start site compared with polymerases transcribing more than 1 kb from the transcription start site in the sense direction. The molecular mechanism(s) potentially accounting for this difference is presented in Figure 10-15, in which transcription termination is discussed. Note that a low number of sequence reads was also observed resulting from transcription upstream of the major transcription start sites (blue sequence reads to the left of 0 and purple sequence reads to the right of 0), indicating

that there is a low level of transcription from seemingly random sites throughout the genome. These recent discoveries of divergent transcription from CpG island promoters and low-level transcription of most of the genomes of eukaryotes have been a great surprise to most researchers.

**Chromatin Immunoprecipitation** The technique of chromatin immunoprecipitation outlined in Figure 9-18a, using an antibody to RNA polymerase II, provided additional data supporting the occurrence of divergent transcription from most CpG island promoters in mammals. The data from this analysis are reported as the number of times a specific sequence from this region of the genome was identified per million total sequences analyzed (Figure 9-18b). At divergently transcribed genes, such as the *Hsd17b12* gene encoding an enzyme involved in intermediary metabolism, two peaks of immunoprecipitated DNA were detected, corresponding to Pol II transcribing in the sense and antisense directions and then pausing. However, Pol II was detected more than 1 kb from the start site only in the sense direction. The number of counts per million from this region of the genome was very low because the gene is transcribed at low frequency. However, the number of counts per million at the transcription start site regions for both sense and antisense transcription was much higher, reflecting the fact that Pol II molecules had initiated transcription in both directions at this promoter, but paused before transcribing farther than 500 bp from the start sites in each direction. In contrast, the *Rpl6* gene, encoding a large ribosomal subunit protein that was abundantly transcribed in the proliferating mouse embryonic stem cells used in the study, was transcribed almost exclusively in the sense direction. The peak in counts per million less than 250 bp from the transcription start site again results from a long pause in transcription in the promoter-proximal region before the polymerase is released to transcribe into the gene. The number of sequence counts per million more than 1 kb downstream from the transcription start site was much higher than for sense-direction transcription of the *Hsd17b12* gene, reflecting the high rate of transcription of the *Rpl6* gene.

### General Transcription Factors Position RNA Polymerase II at Start Sites and Assist in Initiation

Initiation of transcription by RNA polymerase II requires several initiation factors. These initiation factors position Pol II molecules at transcription start sites and help to separate the DNA strands so that the template strand can enter the active site of the enzyme. They are called *general transcription factors* because they are required at most, if not all, promoters of genes transcribed by RNA polymerase II. These proteins are designated *TFIIA*, *TFIIB*, and so on, and most are multimeric proteins. The largest is *TFIID*, which consists

of a single 38-kDa *TATA box-binding protein* (TBP) and 13 TBP-associated factors (TAFs). General transcription factors with similar activities and homologous sequences are found in all eukaryotes. The complex of Pol II and its general transcription factors bound to a promoter and ready to initiate transcription is called a *preinitiation complex* (PIC). Figure 9-19 summarizes the current model for the stepwise assembly of the Pol II transcription preinitiation complex on a promoter containing a TATA box.

The TBP subunit of TFIID is the first protein to bind to a TATA box promoter. All eukaryotic TBPs analyzed to date have very similar C-terminal domains of 180 residues. This domain of TBP folds into a saddle-shaped structure; the two halves of the molecule exhibit an overall dyad symmetry but are not identical. TBP interacts with the minor groove in

**EXPERIMENTAL FIGURE 9-18 The chromatin immunoprecipitation technique localizes where a protein of interest associates with the genome.** (a) step **1**: Live cultured cells or tissues are incubated in 1 percent formaldehyde to covalently cross-link proteins to DNA and proteins to proteins. Step **2**: The preparation is then subjected to sonication to solubilize chromatin and shear it into fragments of 200–500 bp of DNA. Step **3**: An antibody to a protein of interest, here RNA polymerase II, is added, and DNA covalently linked to the protein of interest is immunoprecipitated. Step **4**: The covalent cross-linking is then reversed and the DNA is isolated. The isolated DNA can be analyzed by PCR with primers for a sequence of interest. Alternatively, total recovered DNA can be amplified, labeled by incorporation of a fluorescently labeled nucleotide, and hybridized to a microarray (see Figure 6-27) or subjected to massively parallel DNA sequencing. See A. Hecht and M. Grunstein, 1999, *Method. Enzymol.* **304**:399. (b) Results from DNA sequencing of chromatin from mouse embryonic stem cells immunoprecipitated with antibody to RNA polymerase II are shown for a gene that is divergently transcribed (*left*) and a gene that is transcribed only in the sense direction (*right*). Data are plotted as the number of times a DNA sequence in a 50-bp interval was observed per million base pairs sequenced. The region encoding the 5' end of the gene is shown below, with exons shown as rectangles and introns as lines. [Part (b) data from P. B. Rahl et al., 2010, *Cell* **141**:432.]

DNA, bending the helix considerably (see Figure 5-5). The DNA-binding surface of TBP is conserved in all eukaryotes, explaining the high conservation of the TATA box promoter element (see Figure 9-16).

Once TFIID has bound to the TATA box, TFIIA and TFIIB can bind. TFIIA is a heterodimer larger than TBP, and TFIIB is a monomeric protein, slightly smaller than TBP. TFIIA associates with TBP and DNA on the upstream side of the TBP–TATA box complex. The C-terminal domain of TFIIB makes contact with both TBP and DNA on either side of the TATA box. During transcription initiation, its N-terminal domain is inserted into the RNA exit channel of RNA polymerase II (see Figure 9-12c). The TFIIB N-terminal domain assists Pol II in melting the DNA strands at the transcription start site and interacts with the template strand near the Pol II active site. Following TFIIB binding, a preformed complex of TFIIF (a heterodimer of two different subunits in mammals) and Pol II binds, positioning the polymerase over the start site. Two more general transcription factors must bind before the DNA duplex can be separated to expose the template strand. First to bind is TFIIE, a heterodimer of two different subunits. TFIIE creates a docking site for TFIIH, another multimeric factor containing 10 different subunits. Binding of TFIIH completes assembly of the transcription preinitiation complex (see Figure 9-19).

Figure 9-20 shows a cryoelectron microscopic image of a yeast (*S. cerevisiae*) preinitiation complex assembled in vitro from purified RNA polymerase II and general transcription factors with TBP in place of the complete TFIID complex—a total of thirty-three polypeptides with a mass

**FIGURE 9-19 Model for the sequential assembly of an RNA polymerase II preinitiation complex.** The indicated general transcription factors and purified RNA polymerase II (Pol II) bind sequentially to TATA box DNA to form a preinitiation complex (PIC). ATP hydrolysis then provides the energy for the unwinding of DNA at the transcription start site by a TFIIF helicase subunit that pushes downstream DNA into the polymerase. The DNA is held in position in the PIC by binding of the TATA box by the TBP subunit of TFIID, and the resulting strain on the structure of the duplex DNA assists the N-terminal region of TFIIB and Pol II to melt the DNA at the transcription start site, forming the transcription bubble. As Pol II initiates transcription in the resulting open complex, the polymerase transcribes away from the promoter, its CTD becomes phosphorylated by the TFIIF kinase domain, and the general transcription factors dissociate from the promoter. See S. Sainsbury, C. Berrnicky, and P. Cramer, 2015, *Nat. Rev. Mol. Cell Biol.* **16**:129.

of 1.5 megadaltons (MDa)—about the size of a ribosomal subunit. Such elaborate preinitiation complexes assemble at the promoters of every protein-coding gene expressed by a eukaryotic cell.

The **helicase** activity of one of the core TFIIF subunits (Ssl2 in yeast; see Figure 9-20d) uses energy from ATP hydrolysis to help unwind the DNA duplex at the start site, allowing Pol II to form an *open* complex in which the DNA duplex surrounding the start site is melted and the template strand is bound at the polymerase active site. As the polymerase transcribes away from the promoter region, the N-terminal domain of TFIIB is released from the RNA exit channel as the 5' end of the nascent RNA enters it. Three TFIIF subunits form a kinase module (TFIIF kinase in Figure 9-19) that phosphorylates the Pol II CTD multiple times on serine 5 (underlined) of the Tyr-Ser-Pro-Thr-Ser-Pro-Ser repeat that constitutes the CTD. As we will discuss further in Chapter 10, a multiply phosphorylated CTD is a docking site for the enzymes that form the cap structure (see Figure 5-14) on the 5' end of an RNA transcribed by RNA polymerase II. In the minimal *in vitro* transcription assay with TBP substituted for the full TFIID complex and purified RNA polymerase II, TBP remains bound to the TATA box as the polymerase transcribes away from the promoter region, but the other general transcription factors dissociate.

**Remarkably**, the first subunits of TFIIF to be cloned from humans were identified because mutations in them cause defects in the repair of damaged DNA, such as a base with a covalently linked mutagen or a UV-induced thymine-thymine dimer (see Figure 5-37). In normal individuals, when a transcribing RNA polymerase becomes stalled at a region of damaged template DNA, the core TFIIF complex, lacking the three subunits of the kinase domain (see Figure 9-19) but including the helicase subunit mentioned above, recognizes the stalled polymerase and then associates with other proteins that function with TFIIF in repairing the damaged DNA region. In patients with mutant forms of these TFIIF subunits, such repair of damaged DNA in

**FIGURE 9-20 Model of the yeast preinitiation complex based on cryoelectron microscopy and fitting of known protein x-ray crystal structures.** (a-c) Three views of the nearly complete PIC. The relative positions of Pol II and most of the GTFs are observed, but only about 50% of the mass of TFIID is depicted because a large part of the mass of TFIID is highly flexible and consequently could not be accurately determined by cryo-EM. Also high resolution structures have not been determined for many of the TFIID subunits, and consequently could not be fitted to the TFIID mass detected by cryo-EM. However, the interaction between DNA at the downstream side of the Pol II

cleft and the TFIID Ssl2 helicase subunit required to melt promoter DNA is clearly visualized in (b) and (c). In (c), the interaction between TFIID and TFIIE is not visualized because of the low resolution of the complex in this region. TFIIS is a Pol II elongation factor added to stabilize the PIC. (d) Model of entry of the template strand into the floor of the cleft where RNA polymerization is catalyzed. The Ssl2 helicase pushes DNA that is bound upstream to TBP, TFIIB, and TFIIA, creating torsional stress that contributes to transcription bubble melting.

[Data from K. Murakami, et al. 2015. *Proc. Natl. Acad. Sci. USA*, **112**:13543, PDB ID 5fmf]

transcriptionally active genes is impaired. As a result, affected individuals have extreme skin sensitivity to sunlight (a common cause of DNA damage through the generation of thymine-thymine dimers) and exhibit a high incidence of cancer. Consequently, these subunits of TFIID serve two functions in the cell, one in the process of transcription initiation and a second in the repair of DNA. Depending on the severity of the defect in TFIID function, these individuals may suffer from diseases such as xeroderma pigmentosum (see Chapter 24) and Cockayne syndrome (see Chapter 5). ■

The TAF subunits of TFIID function in initiating transcription from promoters that lack a TATA box. For instance, some TAF subunits contact the initiator element in promoters in which it occurs; their function probably explains how such sequences can replace a TATA box (see Figure 9-16). Additional TFIID TAF subunits can bind to a consensus sequence, A/G-G-A/T-C/T-G/A/C, that is centered about 30 bp downstream from the transcription start site in many genes that lack a TATA box promoter. Because of its position, this regulatory sequence is called the *downstream promoter element (DPE)* (see Figure 9-16). The DPE facilitates transcription of

TATA-less genes that contain it by increasing TFIID binding. In addition, an  $\alpha$  helix of TFIIB binds to the major groove of DNA upstream of the TATA box, and the strongest promoters contain the optimal sequence for this interaction, called the *TFIIB recognition element (BRE)* (see Figure 9-16).

Chromatin immunoprecipitation assays (see Figure 9-18) using antibodies to TBP show that it binds in the region between the divergent transcription start sites in CpG island promoters. Consequently, the same general transcription factors are probably required for initiation from the weaker CpG island promoters as for initiation from promoters containing a TATA box. The absence of the promoter elements summarized in Figure 9-16 may account for the divergent transcription from multiple transcription start sites observed from CpG island promoters, since cues from the DNA sequence are not present to correctly orient the preinitiation complex. TFIID and the other general transcription factors may choose among alternative, nearly equivalent weak binding sites in CpG island promoters, which may explain the low frequency of transcription initiation as well as the alternative transcription start sites in divergent directions generally observed from this class of promoters.

## Elongation Factors Regulate the Initial Stages of Transcription in the Promoter-Proximal Region

In metazoans, at most promoters, Pol II pauses after transcribing fewer than 100 nucleotides, due to the binding of a five-subunit protein called *NELF* (negative elongation factor). *NELF* binds to Pol II along with a two-subunit elongation factor called *DSIF* (DRB sensitivity-inducing factor, so named because an ATP analog called DRB inhibits further transcription elongation in its presence). The inhibition of elongation that results from *NELF* binding to Pol II is relieved when *DSIF*, *NELF*, and serine 2 of the Pol II CTD (Tyr-Ser-Pro-Thr-Ser-Pro-Ser) are phosphorylated by a protein kinase with two subunits, cyclin T–CDK9, also called *P-TEFb*, which associates with the Pol II–*NELF*–*DSIF* complex. The same elongation factors regulate transcription from CpG island promoters. These factors that regulate elongation in the promoter-proximal region provide a mechanism for controlling gene transcription in addition to the regulation of transcription initiation. This overall strategy for regulating transcription at both the initiation and elongation steps in the promoter-proximal region is similar to the regulation of the *trp* operon in *E. coli* (see Figure 9-7), although the molecular mechanisms involved are distinct.

 Transcription of HIV (human immunodeficiency virus), the cause of AIDS, is dependent on the activation of cyclin T–CDK9 by a small viral protein called Tat. Cells experimentally infected with *tat*<sup>−</sup> mutants produce short viral transcripts about 50 nucleotides long. In contrast, cells infected with wild-type HIV synthesize long viral transcripts that encompass the entire integrated proviral genome (see Figure 5-48 and Figure 8-13). Thus Tat functions as an *antitermination factor*, permitting RNA polymerase II to read through a transcriptional block. (Tat is initially made by rare transcripts that fail to terminate when the HIV promoter is transcribed at a high rate in “activated” T-lymphocytes; see Chapter 23.) Tat is a sequence-specific RNA-binding protein. It binds to the RNA copy of a sequence called TAR, which forms a stem-loop structure near the 5′ end of the HIV transcript (Figure 9-21). TAR also binds cyclin T, holding the cyclin T–CDK9 complex close to the polymerase, where it efficiently phosphorylates its substrates, resulting in transcription elongation. Chromatin immunoprecipitation assays done after treating cells with specific inhibitors of CDK9 indicate that the transcription of some 30 percent of mammalian genes is regulated by controlling the activity of cyclin T–CDK9 (*P-TEFb*), although this is probably done most frequently by sequence-specific DNA-binding transcription factors rather than by an RNA-binding protein, as in the case of HIV Tat. ■

**FIGURE 9-21 Model of antitermination complex composed of HIV Tat protein and several cellular proteins.** The TAR element in the HIV transcript contains sequences recognized by Tat and the cellular protein cyclin T. Cyclin T activates and helps position the protein kinase CDK9 near its substrates, the CTD of RNA polymerase II, *NELF*, and *DSIF*. CTD phosphorylation at serine 2 of the Pol II CTD heptad repeat is required for transcription elongation. Cellular proteins *DSIF* and the *NELF* complex are also involved in regulating Pol II elongation, as discussed in the text. See T. Wada et al., 1998, *Gene Dev.* **12**:343; Y. Yamaguchi et al., 1999, *Cell* **97**:451; and T. Yamada et al., 2006, *Mol. Cell* **21**:227.

### KEY CONCEPTS OF SECTION 9.3

#### RNA Polymerase II Promoters and General Transcription Factors

- RNA polymerase II initiates transcription of genes at the nucleotide in the DNA template that corresponds to the 5′ nucleotide that is capped in the encoded mRNA.
- Three principal types of promoter sequences have been identified in eukaryotic DNA. The TATA box is prevalent in highly transcribed genes. Initiator promoters are found in some genes, and CpG islands, the promoters for about 70 percent of protein-coding genes in vertebrates, are characteristic of genes transcribed at a low rate.
- Transcription of protein-coding genes by Pol II is initiated by sequential binding of the following in the indicated order: TFIID, which contains the TBP subunit that binds to TATA box DNA; TFIIA and TFIIB; a complex of Pol II and TFIIF; TFIIE; and finally, TFIIH (see Figure 9-19).
- The helicase activity of a TFIIH subunit helps to separate the DNA strands at the transcription start site in most promoters, a process that requires hydrolysis of ATP. As Pol II begins transcribing away from the start site, its CTD is phosphorylated on serine 5 by the TFIIH kinase domain.
- In metazoans, *NELF* and *DSIF* associate with Pol II after initiation, inhibiting elongation fewer than 100 bp from the transcription start site. Inhibition of elongation is relieved when cyclin T–CDK9 (also called *P-TEFb*) associates with the elongation complex and CDK9 phosphorylates subunits of *NELF*, *DSIF*, and serine 2 of the Pol II CTD.

## 9.4 Regulatory Sequences in Protein-Coding Genes and the Proteins Through Which They Function

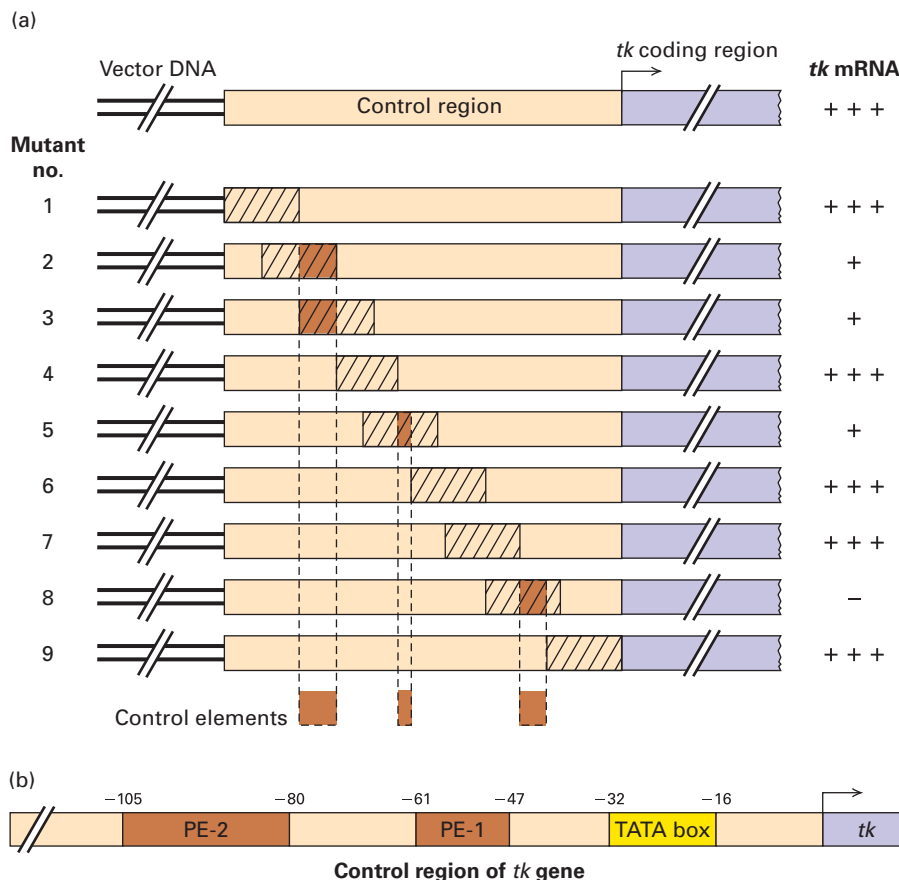

As noted in the previous section, expression of eukaryotic protein-coding genes is regulated by multiple protein-binding DNA sequences, generically referred to as *transcription-control regions*. These regions include promoters and other types of control elements located near transcription start sites, as well as sequences located far from the genes they regulate. In this section, we take a closer look at the properties of various control elements found in eukaryotic protein-coding genes and the proteins that bind to them.

### Promoter-Proximal Elements Help Regulate Eukaryotic Genes

Recombinant DNA techniques have been used to systematically mutate the nucleotide sequences of various eukaryotic genes in order to identify transcription-control regions. The use of *linker scanning mutagenesis*, for example, can pinpoint the sequences within a regulatory region that function to control transcription. In this approach, a set of constructs with contiguous overlapping mutations are assayed for their effect on expression of a reporter gene or production of a specific mRNA (Figure 9-22a). This type of analysis

identified **promoter-proximal elements** of the thymidine kinase (*tk*) gene from herpes simplex type I virus (HSV-I). The results demonstrated that the DNA region upstream of the HSV-I *tk* gene contains three separate transcription-control sequences: a TATA box in the interval from  $-32$  to  $-16$  and two other control elements farther upstream (Figure 9-22b). Experiments using mutants containing single-base-pair changes in promoter-proximal control elements revealed that these elements are generally about 6–10 bp long. Recent results indicate that in human genes, they are found both upstream and downstream of the transcription start site at equal frequency. While, strictly speaking, the term *promoter* refers to the DNA sequence that determines where a polymerase initiates transcription, the term is often used to refer to both a promoter and its associated promoter-proximal control elements.

To test the spacing constraints on control elements in the HSV-I *tk* promoter region identified by analysis of linker scanning mutations, researchers prepared and assayed constructs containing small deletions and insertions between the elements. Changes in spacing between the promoter and promoter-proximal control elements of 20 bp or fewer had little effect. However, insertions of 30–50 bp between a HSV-I *tk* promoter-proximal element and the TATA box was equivalent to deleting the element. Similar analyses of other eukaryotic promoters have also indicated that considerable flexibility in the spacing

**EXPERIMENTAL FIGURE 9-22 Linker scanning mutations identify transcription-control elements.** (a) In linker scanning mutagenesis, a region of eukaryotic DNA (tan) that supports high-level expression of a reporter gene (light purple) is cloned in a plasmid vector as diagrammed at the top. Overlapping linker scanning (LS) mutations (crosshatched areas) are introduced from one end of the region being analyzed to the other. These mutations are created by scrambling the nucleotide sequence in a short stretch of the DNA. After the mutant plasmids are transfected separately into cultured cells, the activity of the reporter-gene product is assayed. In the example shown here, the sequence from  $-120$  to  $+1$  of the herpes simplex virus thymidine kinase gene, LS mutations 1, 4, 6, 7, and 9 have little or no effect on expression of the reporter gene, indicating that the regions altered in these mutants contain no control elements. Reporter-gene expression is significantly reduced in mutants 2, 3, 5, and 8, indicating that control elements (brown) lie in the intervals shown at the bottom. (b) Analysis of these LS mutations identified a TATA box and two promoter-proximal elements (PE-1 and PE-2). See S. L. McKnight and R. Kingsbury, 1982, *Science* **217**:316.

between promoter-proximal elements is generally tolerated, but that separations of several tens of base pairs may decrease transcription.

## Distant Enhancers Often Stimulate Transcription by RNA Polymerase II

As noted earlier, transcription from many eukaryotic promoters can be stimulated by control elements located thousands of base pairs away from the transcription start site. Such long-distance transcription-control elements, referred to as enhancers, are common in eukaryotic genomes but fairly rare in bacterial genomes. Procedures such as linker scanning mutagenesis have indicated that enhancers, usually on the order of 200 bp long, are, like promoter-proximal elements, composed of several functional sequence elements of about 6–10 bp each. As discussed later, each of these regulatory elements is a binding site for a sequence-specific DNA-binding transcription factor.

Analyses of many different metazoan enhancers have shown that they can occur with equal probability upstream from a promoter or downstream from a promoter within an intron, or even downstream from the final exon of a gene, as in the case of the *SALL1* gene (see Figure 9-10a). Many enhancers are cell-type-specific. For example, an enhancer controlling *Pax6* expression in the retina was characterized in the intron between exons 4 and 5 (see Figure 9-9a), whereas an enhancer controlling *Pax6* expression in the

hormone-secreting cells of the pancreas is located in a roughly 200-bp region upstream of exon 0 (so named because it was discovered after the exon called “exon 1”).

## Most Eukaryotic Genes Are Regulated by Multiple Transcription-Control Elements

Initially, enhancers and promoter-proximal elements were thought to be distinct types of transcription-control elements. However, as more enhancers and promoter-proximal elements were analyzed, the distinctions between them became less clear. For example, both types of elements can generally stimulate transcription even when inverted, and both types are often cell-type-specific. The general consensus now is that a spectrum of control elements regulates transcription by RNA polymerase II. At one extreme are enhancers, which can stimulate transcription from a promoter tens of thousands of base pairs away. At the other extreme are promoter-proximal elements, such as the upstream elements controlling the HSV-1 *tk* gene, which lose their influence when moved 30–50 bp farther from the promoter. Researchers have identified a large number of transcription-control elements that can stimulate transcription from distances between these two extremes.

Figure 9-23a summarizes the locations of transcription-control sequences for a hypothetical mammalian gene with a promoter containing a TATA box. The transcription start site encodes the first (5′) nucleotide of the first exon of an

**FIGURE 9-23** General organization of control elements that regulate gene expression in multicellular eukaryotes and yeast.

(a) Mammalian genes with a TATA box promoter are regulated by promoter-proximal elements and enhancers. The promoter elements shown in Figure 9-16 position RNA polymerase II to initiate transcription at the start site and influence the rate of transcription. Enhancers may be either upstream or downstream and as far away as hundreds of kilobases from the transcription start site. In some cases, enhancers lie within introns. Promoter-proximal elements are found upstream and downstream of transcription start sites at equal frequency in mammalian genes. (b) For

mammalian genes with a CpG island promoter, transcription initiates at several sites in both the sense and antisense directions from the ends of the CpG-rich region. Transcripts in the sense direction are elongated and are processed into mRNAs by RNA splicing. These genes express mRNAs with alternative 5′ exons determined by the transcription start site. Genes with CpG island promoters contain promoter-proximal control elements. Currently, it is not clear whether they are also regulated by distant enhancers. (c) Most *S. cerevisiae* genes contain only one regulatory region, called an upstream activating sequence (UAS), and a TATA box, which is about 90 bp upstream from the transcription start site.

mRNA, the nucleotide that is capped. In addition to the TATA box at about  $-31$  to  $-26$ , promoter-proximal elements, which are relatively short ( $\sim 6$ – $10$  bp), are located within the first 200 bp either upstream or downstream of the start site. Enhancers, in contrast, are usually about 50–200 bp long and are composed of multiple elements of about 6–10 bp. Enhancers may be located up to 50 kb or more upstream or downstream from the start site or within an intron. Like the *Pax6* gene, many mammalian genes are controlled by multiple enhancer regions that function in different types of cells.

Figure 9-23b summarizes the promoter region of a mammalian gene with a CpG island promoter. About 70 percent of mammalian genes are expressed from CpG island promoters, usually at much lower levels than genes with TATA box promoters. Multiple alternative transcription start sites are used, generating mRNAs with alternative 5' ends for the first exon derived from each start site. Transcription occurs in both directions, but Pol II molecules transcribing in the sense direction are elongated to 1 kb or more, much more efficiently than transcripts in the antisense direction.

In the important model organism *Saccharomyces cerevisiae* (budding yeast), genes are closely spaced (see Figure 8-4b), and few genes contain introns. In this organism, enhancers, which are referred to as **upstream activating sequences (UASs)**, usually lie within 200 bp upstream of the promoters of the genes they regulate. Most yeast genes contain only one UAS. In addition, *S. cerevisiae* genes contain a TATA box about 90 bp upstream from the transcription start site (Figure 9-23c).

## DNase I Footprinting and EMSA Detect Protein-DNA Interactions

The various transcription-control elements found in eukaryotic DNA are binding sites for regulatory proteins called *transcription factors*. The simplest eukaryotic cells encode hundreds of transcription factors, and the human genome encodes at least 1400. The transcription of each gene in the genome is independently regulated by combinations of *specific transcription factors* that bind to its transcription-control regions. The number of possible combinations of this many transcription factors is astronomical, sufficient to generate unique controls for every gene encoded in the genome.

In yeast, *Drosophila*, and other genetically tractable eukaryotes, numerous genes encoding transcription activators and repressors have been identified by classical genetic analyses like those described in Chapter 6. However, in mammals and other vertebrates, which are less amenable to such genetic analysis, most transcription factors have been detected initially and subsequently purified by biochemical techniques. In this approach, a DNA regulatory element that has been identified by the kinds of mutational analyses described above is used to identify *cognate* proteins—those proteins that bind specifically

to it. Two common techniques for detecting such cognate proteins are DNase I footprinting and the electrophoretic mobility shift assay.

*DNase I footprinting* takes advantage of the fact that when a protein is bound to a region of DNA, it protects that DNA sequence from digestion by nucleases. As illustrated in Figure 9-24a, samples of a DNA fragment that has been labeled with a radioactive atom at one end of one strand are digested under carefully controlled conditions in the presence and absence of a DNA-binding protein, then denatured and electrophoresed, and the resulting gel is subjected to autoradiography. The region protected by the bound protein appears as a gap, or “footprint,” in the array of bands resulting from digestion in the absence of the protein. When footprinting is performed with a DNA fragment containing a known transcription-control element, the appearance of a footprint indicates the presence of a transcription factor that binds that control element in the protein sample being assayed. Footprinting also identifies the specific DNA sequence to which the transcription factor binds.

For example, DNase I footprinting of the strong adenovirus late promoter shows a protected region over the TATA box when TBP is added to the labeled DNA before DNase I digestion (Figure 9-24b). DNase I does not digest all phosphodiester bonds in a duplex DNA at equal rate. Consequently, in the absence of added protein (lanes 1, 6, and 9), a particular pattern of bands is observed that depends on the DNA sequence and results from cleavage at some phosphodiester bonds and not others. However, when increasing amounts of TBP are incubated with the end-labeled DNA before digestion with DNase I, TBP binds to the TATA box, and when sufficient TBP is added to bind all the labeled DNA molecules, it protects the region between about  $-35$  and  $-20$  from digestion (lanes 2–5). In contrast, increasing amounts of TFIID (lanes 7 and 8) protect not only the TATA box region, but also regions near  $-7$ ,  $+1$  to  $+5$ ,  $+10$  to  $+15$ , and  $+20$  from digestion, producing a different “footprint” from TBP. Results such as this tell us that other subunits of TFIID (the TBP-associated factors, or TAFs) also bind to the DNA in the region downstream from the TATA box.

The *electrophoretic mobility shift assay (EMSA)*, also called the *gel-shift* or *band-shift assay*, is more useful than the footprinting assay for quantitative analysis of DNA-binding proteins. In general, the electrophoretic mobility of a DNA fragment is reduced when it is complexed with protein, causing a shift in the location of the fragment band. EMSA can be used to detect a transcription factor in protein fractions incubated with a radiolabeled DNA fragment (the probe) containing a known control element (Figure 9-25). The more transcription factor is added to the binding reaction, the more labeled probe is shifted to the position of the DNA-protein complex.

In the biochemical isolation of a transcription factor, an extract of cell nuclei is commonly subjected sequentially to several

#### EXPERIMENTAL FIGURE 9-24 DNase I footprinting reveals the region of a DNA sequence where a transcription factor binds.

(a) A DNA fragment known to contain a transcription-control element is labeled at one end with  $^{32}\text{P}$  (red dot). Portions of the labeled DNA sample are then digested with DNase I in the presence and in the absence of protein samples containing a sequence-specific DNA-binding protein. DNase I hydrolyzes the phosphodiester bonds of DNA between the 3' oxygen on the deoxyribose of one nucleotide and the 5' phosphate of the next nucleotide. A low concentration of DNase I is used so that, on average, each DNA molecule is cleaved just once (vertical arrows). If the protein sample does not contain a protein that binds to a specific sequence in the labeled DNA, the DNA fragment is cleaved at multiple positions between the labeled and unlabeled ends of the original fragment, as in sample A (left). If the protein sample does contain such a protein, as in sample B (right), the protein binds to its

cognate sequence in the DNA, thereby protecting a portion of the fragment from digestion. Following DNase treatment, the DNA is separated from protein, denatured to separate the strands, and electrophoresed. Autoradiography of the resulting gel detects only labeled strands and reveals fragments extending from the labeled end to the site of cleavage by DNase I. Cleavage fragments containing the transcription-control element show up on the gel for sample A but are missing in sample B because the bound cognate protein has blocked cleavages within that sequence and thus production of the corresponding fragments. The missing bands on the gel constitute the footprint. (b) Footprints produced by increasing amounts of TBP (indicated by the triangle) and of TFIID on the strong adenovirus major late promoter. [Part (b) from Zhou, Q. et al., "Holo-TFIID supports transcriptional stimulation by diverse activators and from a TATA-less promoter," *Genes & Development*, 11/1992; **6**(10):1964–74; republished with permission from Cold Spring Harbor Laboratory Press.]

types of liquid chromatography (see Chapter 3). Fractions eluted from the columns are assayed by DNase I footprinting or EMSA using DNA fragments containing an identified regulatory element (see Figure 9-22). Fractions containing a protein that binds to the regulatory element in these assays contain a putative transcription factor. A powerful technique that is commonly used for the final step in purifying transcription factors is *sequence-specific DNA affinity chromatography*, a particular type of affinity chromatography in which long DNA strands containing multiple copies of the transcription-factor-binding site are coupled to a column matrix.

Once a transcription factor has been isolated and purified, its partial amino acid sequence can be determined and used to clone the gene or cDNA encoding it, as outlined in

Chapter 6. The isolated gene can then be used to test the ability of the encoded protein to activate or repress transcription in an *in vivo* transfection assay (Figure 9-26).

### Activators Are Composed of Distinct Functional Domains

Studies with a yeast transcription activator called Gal4 provided early insight into the domain structure of transcription factors. The gene encoding Gal4, which promotes expression of enzymes needed to metabolize galactose, was identified by complementation analysis of *gal4* mutants that cannot form colonies on an agar medium in which galactose is the only source of carbon and energy (see Chapter 6).

**EXPERIMENTAL FIGURE 9-25** The electrophoretic mobility shift assay can be used to detect transcription factors during purification. In this example, protein fractions separated by column chromatography were assayed for their ability to bind to a radiolabeled DNA-fragment probe containing a known regulatory element. After an aliquot of the protein sample was loaded onto the column (ON) and successive column fractions (numbers) were incubated with the labeled probe, the samples were electrophoresed under conditions that do not disrupt protein-DNA interactions. The free probe not bound to protein migrated to the bottom of the gel. A protein in the preparation applied to the column and in fractions 7 and 8 bound to the probe, forming a DNA-protein complex that migrated more slowly than the free probe. These fractions are therefore likely to contain the regulatory protein being sought. [From Yoshinaga, S. et al., "Purification and characterization of transcription factor IIC2," *J. Biol. Chem.*, 1989, **264**:10726 ©1989 American Society for Biochemistry and Molecular Biology.]

Directed mutagenesis studies like those described previously identified UASs for the genes activated by Gal4. Each of these UASs was found to contain one or more copies of a 17-bp sequence called UAS<sub>GAL</sub>. DNase I footprinting assays with recombinant Gal4 protein produced in *E. coli* from the yeast *GAL4* gene showed that Gal4 binds to UAS<sub>GAL</sub> sequences. When a copy of UAS<sub>GAL</sub> was cloned upstream of a TATA box followed by a  $\beta$ -galactosidase reporter gene, and that construct was introduced into yeast cells, expression of  $\beta$ -galactosidase was activated in galactose media in wild-type cells, but not in *gal4* mutants. These results showed that UAS<sub>GAL</sub> is a transcription-control element activated by the Gal4 transcription factor in galactose media.

A remarkable set of experiments with *gal4* deletion mutants demonstrated that the Gal4 transcription factor is composed of separable functional domains: an N-terminal DNA-binding domain, which binds to specific DNA sequences, and a C-terminal activation domain, which interacts with other proteins to stimulate transcription from a nearby promoter (Figure 9-27). When the N-terminal DNA-binding domain of Gal4 was fused directly to various portions of its own C-terminal region, deleting internal sequences, the resulting truncated proteins retained the ability to stimulate expression of a reporter gene in an in vivo assay like that depicted in Figure 9-26. Thus the internal portion of the protein is not required for the functioning of Gal4 as a transcription factor. Similar experiments with another

yeast activator, Gcn4, which regulates genes required for the synthesis of many amino acids, indicated that it contains a roughly 50-amino-acid DNA-binding domain at its C-terminus and a roughly 20-amino-acid activation domain near the middle of its sequence.

Further evidence for the existence of distinct activation domains in Gal4 and Gcn4 came from experiments in which their activation domains were fused to a DNA-binding domain from an entirely unrelated *E. coli* DNA-binding protein. When these fusion proteins were assayed in vivo, they activated transcription of a reporter gene containing the cognate site for the *E. coli* protein. Thus functional transcription factors can be constructed from entirely novel combinations of prokaryotic and eukaryotic elements.

Studies such as these have now been carried out with many eukaryotic transcription factors. The structural model of eukaryotic activators that has emerged from these studies is a modular one in which one or more activation domains are connected to a sequence-specific DNA-binding domain by intrinsically disordered, flexible protein domains (Figure 9-28). In some cases, amino acids included in the DNA-binding domain also contribute to transcriptional activation. As discussed in a later section, activation domains

**EXPERIMENTAL FIGURE 9-26** An in vivo transfection assay measures transcription activity to evaluate proteins believed to be transcription factors. The assay system requires two plasmids. One plasmid contains the gene encoding the putative transcription factor (protein X). The second plasmid contains a reporter gene (e.g., luciferase) and one or more binding sites for protein X. Both plasmids are simultaneously introduced into cells that lack the gene encoding protein X. The production of reporter-gene RNA transcripts is measured; alternatively, the activity of the encoded protein can be assayed. If reporter-gene transcription is greater in the presence of the X-encoding plasmid than in its absence, then the protein is an activator; if transcription is less, then it is a repressor. By use of plasmids encoding a mutated or rearranged transcription factor, important domains of the protein can be identified.

### EXPERIMENTAL FIGURE 9-27 Deletion mutants of the GAL4 gene in yeast with a UAS<sub>GAL</sub> reporter-gene construct demonstrate the separate functional domains in a transcription activator.

(a) Diagram of DNA construct containing a *lacZ* reporter gene (encoding β-galactosidase) and TATA box ligated to UAS<sub>GAL</sub>, a regulatory element that contains several Gal4-binding sites. The reporter-gene construct and DNA encoding wild-type or mutant (deleted) Gal4 were simultaneously introduced into mutant (*gal4*) yeast cells, and the activity of β-galactosidase expressed from *lacZ* was assayed. Activity should be high if the introduced GAL4 DNA encodes a functional protein. (b) Schematic diagrams of wild-type Gal4 and various mutant forms. Small numbers refer to positions in the wild-type sequence. Deletion of 50 amino acids

from the N-terminal end destroyed the ability of Gal4 to bind to UAS<sub>GAL</sub> and to stimulate expression of β-galactosidase from the reporter gene. Proteins with extensive deletions from the C-terminal end still bound to UAS<sub>GAL</sub>. These results localize the DNA-binding domain to the N-terminal end of Gal4. The ability to activate β-galactosidase expression was not entirely eliminated unless somewhere between 126 and 189 or more amino acids were deleted from the C-terminal end. Thus the activation domain lies in the C-terminal region of Gal4. Proteins with internal deletions (*bottom*) were also able to stimulate expression of β-galactosidase, indicating that the central region of Gal4 is not crucial for its function in this assay. See J. Ma and M. Ptashne, 1987, *Cell* **48**:847; I. A. Hope and K. Struhl, 1986, *Cell* **46**:885; and R. Brent and M. Ptashne, 1985, *Cell* **43**:729.

are thought to function by binding other proteins involved in transcription. The presence of flexible, intrinsically disordered protein domains (see Figure 3-8) connecting the DNA-binding domain to the activation domains may explain why alterations in the spacing between control elements are so well tolerated in eukaryotic control regions. Thus even when the positions of transcription factors bound to DNA are shifted relative to each other, their activation domains may still be able to interact because they are attached to their DNA-binding domains through flexible protein regions.

### Repressors Are the Functional Converse of Activators

Eukaryotic transcription is regulated by repressors as well as activators. For example, geneticists have identified mutations

in yeast that result in continuously high expression of certain genes. This type of unregulated, abnormally high expression, called **constitutive** expression, results from the inactivation of a repressor that normally inhibits the transcription of these genes. Similarly, mutants of *Drosophila melanogaster* and *Caenorhabditis elegans* have been isolated that are defective in embryonic development because they express genes in embryonic cells where those genes are normally repressed. The mutations in these mutants inactivate repressors, leading to abnormal development.

Repressor-binding sites in DNA have been identified by systematic linker scanning mutation analyses similar to the one depicted in Figure 9-22. In this type of analysis, whereas mutation of an activator-binding site leads to decreased expression of the linked reporter gene, mutation of a repressor-binding site leads to increased expression of a reporter gene.

**FIGURE 9-28 Schematic diagrams illustrating the modular structure of eukaryotic transcription activators.** Transcription factors may contain more than one activation domain but rarely contain more than one DNA-binding domain. Gal4 and Gcn4 are yeast transcription activators. The glucocorticoid receptor (GR) promotes transcription of target genes when certain hormones are bound to the C-terminal activation domain. SP1 binds to GC-rich promoter elements in a large number of mammalian genes.

The repressor proteins that bind such sites can be purified and assayed using the same biochemical techniques described earlier for activator proteins.

Eukaryotic transcription repressors are the functional converse of activators. They can inhibit transcription of a gene they do not normally regulate when their cognate binding sites are placed within tens of base pairs to many kilobases of the gene's transcription start site. Like activators, most eukaryotic repressors are modular proteins that have two functional domains: a DNA-binding domain and a **repression domain**. Like activation domains, repression domains continue to function when fused to another type of DNA-binding domain. If binding sites for this second DNA-binding domain are inserted within a few hundred base pairs of a promoter, expression of the fusion protein inhibits transcription from the promoter. Also like activation domains, repression domains function by interacting with other proteins, as discussed later in this chapter.

## DNA-Binding Domains Can Be Classified into Numerous Structural Types

The DNA-binding domains of eukaryotic transcription factors contain a variety of structural motifs that bind specific DNA sequences. The ability of DNA-binding proteins to bind to specific DNA sequences commonly results from noncovalent interactions between atoms in an  $\alpha$  helix in the DNA-binding domain and atoms on the edges of the bases within the major groove in the DNA. Ionic interactions between positively charged residues arginine and lysine and

negatively charged phosphates in the sugar-phosphate backbone, and in some cases, interactions with atoms in the DNA minor groove, also contribute to binding.

The principles of specific protein-DNA interactions were first discovered during the study of bacterial repressors. Many bacterial repressors are dimeric proteins in which an  $\alpha$  helix from each monomer inserts into the major groove in the DNA helix and makes multiple, specific interactions with the atoms there (Figure 9-29). This  $\alpha$  helix is referred to as the *recognition helix* or *sequence-reading helix* because most of the amino acid side chains that contact bases in the DNA extend from this helix. The recognition helix, which protrudes from the surface of a bacterial repressor, is usually supported in the protein structure in part by hydrophobic interactions with a second  $\alpha$  helix just N-terminal to it. This entire structural element, which is present in many bacterial repressors, is called a *helix-turn-helix* motif.

Many additional structural motifs that can present an  $\alpha$  helix to the major groove of DNA are found in eukaryotic transcription factors, which are often classified according to the type of DNA-binding domain they contain. Because most of these motifs have characteristic consensus amino acid sequences, potential transcription factors can be recognized among the cDNA sequences from various tissues that have

**FIGURE 9-29 Interaction of bacteriophage 434 repressor with DNA.** Ribbon diagram of 434 repressor bound to its specific operator DNA. The recognition helices are shown in green. The  $\alpha$  helices N-terminal to the recognition helix and the turn in the polypeptide backbone between the helices in the helix-turn-helix structural motif are shown in yellow and red, respectively. The protein interacts intimately with one side of the DNA molecule over a length of 1.5 turns. [Data from A. K. Aggarwal et al., 1988, *Science* **242**:899, PDB ID 2ori.]

been characterized in humans and other species. Here we introduce several common classes of DNA-binding proteins whose three-dimensional structures have been determined. In all these examples, and in many other transcription factors, at least one  $\alpha$  helix is inserted into the major groove of DNA. However, some transcription factors contain alternative structural motifs (e.g.,  $\beta$  strands and loops; see NFAT in Figure 9-33 below as an example) that interact with DNA.

**Homeodomain Proteins** Many eukaryotic transcription factors that function during development contain a conserved 60-residue DNA-binding motif, called a **homeodomain**, that is similar to the helix-turn-helix motif of bacterial repressors. These transcription factors were first identified in *Drosophila* mutants in which one body part was transformed into another during development (see Figure 9-2b). The conserved homeodomain sequence has also been found in vertebrate transcription factors, including those that have similar master-control functions in human development.

**Zinc-Finger Proteins** A number of different eukaryotic proteins have regions that fold around a central  $\text{Zn}^{2+}$  ion, producing a compact domain from a relatively short length of polypeptide chain. Termed a **zinc finger**, this structural motif was first recognized in DNA-binding domains, but is now known to occur

in other proteins that do not bind to DNA. Here we describe two of the several classes of zinc-finger motifs that have been identified in eukaryotic transcription factors.

The  $\text{C}_2\text{H}_2$  *zinc finger* is the most common DNA-binding motif encoded in the human genome and the genomes of other mammals. It is also common in multicellular plants, but is not the dominant type of DNA-binding domain in plants, as it is in animals. This motif has a 23–26-residue consensus sequence containing two conserved cysteine (C) and two conserved histidine (H) residues, whose side chains bind one  $\text{Zn}^{2+}$  ion (see Figure 3-10c). The name “zinc finger” was coined because a two-dimensional diagram of the structure resembles a finger. When the three-dimensional structure was solved, it became clear that the binding of the  $\text{Zn}^{2+}$  ion by the two cysteine and two histidine residues folds the relatively short polypeptide sequence into a compact domain, which can insert its  $\alpha$  helix into the major groove of DNA. Many transcription factors contain multiple  $\text{C}_2\text{H}_2$  zinc fingers, which interact with successive groups of base pairs, within the major groove, as the protein wraps around the DNA double helix (Figure 9-30a).

A second type of zinc-finger structure, designated the  $\text{C}_4$  *zinc finger* (because it has four conserved cysteines in contact with the  $\text{Zn}^{2+}$ ), is found in some 50 human

**FIGURE 9-30 Eukaryotic DNA-binding domains that use an  $\alpha$  helix to interact with the major groove of specific DNA sequences.**

(a) The GL1 DNA-binding domain is monomeric and contains five  $\text{C}_2\text{H}_2$  zinc fingers. The  $\alpha$  helices are shown as cylinders, the  $\text{Zn}^{2+}$  ions as spheres. Finger 1 does not interact with DNA, whereas the other four fingers do. (b) The glucocorticoid receptor is a homodimeric  $\text{C}_4$  zinc-finger protein, one monomer in green, one in yellow. The  $\alpha$  helices are shown as cylinders, the  $\beta$  strands as white arrows, the  $\text{Zn}^{2+}$  ions as spheres. Two  $\alpha$  helices (darker shade), one in each monomer, interact with the DNA. Like all  $\text{C}_4$  zinc-finger homodimers, this transcription factor has twofold rotational symmetry. (c) In leucine zipper proteins, basic residues in the extended  $\alpha$ -helical regions of the monomers interact with the DNA backbone at adjacent sites in the major groove. The coiled-coil dimerization domain is stabilized by hydrophobic interactions between the monomers. (d) In bHLH proteins, the DNA-binding helices at the right (N-termini of the monomers) are separated by nonhelical loops from a leucine zipper-like region containing a coiled-coil dimerization domain. [Part (a), see N. P. Pavletich and C. O. Pabo, 1993, *Science* **261**:1701, PDB ID 2gli. Part (b), see B. F. Luisi et al., 1991, *Nature* **352**:497, PDB ID 1glu. Part (c), data from T. E. Ellenberger et al., 1992, *Cell* **71**:1223, PDB ID 1ysa. Part (d), data from P. Brownlie et al., 1997, *Structure* **5**:509, PDB ID 1hlo.]

transcription factors. The first members of this class were identified as specific intracellular high-affinity binding proteins, or “receptors,” for steroid hormones, which led to the name *steroid receptor superfamily*. Because similar intracellular receptors for nonsteroid hormones were subsequently found, these transcription factors are now commonly called **nuclear receptors**. The characteristic feature of  $C_4$  zinc fingers is the presence of two groups of four critical cysteines, one toward each end of the 55–56-residue domain. Although the  $C_4$  zinc finger was initially named by analogy with the  $C_2H_2$  zinc finger, the three-dimensional structures of proteins containing these DNA-binding motifs were later found to be quite distinct. A particularly important difference between the two is that  $C_2H_2$  zinc-finger proteins generally contain three or more repeating finger units and bind as monomers, whereas  $C_4$  zinc-finger proteins generally contain only two finger units and generally bind to DNA as homodimers or heterodimers. Homodimers of  $C_4$  zinc-finger DNA-binding domains have twofold rotational symmetry (Figure 9-30b). Consequently, homodimeric nuclear receptors bind to consensus DNA sequences that are inverted repeats.

**Leucine-Zipper Proteins** Another structural motif present in the DNA-binding domains of a large class of transcription factors contains the hydrophobic amino acid leucine at every seventh position in the sequence. These proteins bind to DNA as dimers, and mutagenesis of the leucines showed that they were required for dimerization. Consequently, the name **leucine zipper** was coined to denote this structural motif of a coiled coil of two  $\alpha$  helices.

The DNA-binding domain of the yeast Gcn4 transcription factor mentioned earlier is a leucine-zipper domain. X-ray crystallographic analysis of complexes between DNA and the Gcn4 DNA-binding domain has shown that the dimeric protein contains two extended  $\alpha$  helices that “grip” the DNA molecule, much like a pair of scissors, at two adjacent sites in the major groove separated by about half a turn of the double helix (Figure 9-30c). The portions of the  $\alpha$  helices contacting the DNA include positively charged (basic) residues that interact with phosphates in the DNA backbone and additional residues that interact with specific bases in the major groove.

Gcn4 forms dimers via hydrophobic interactions between the C-terminal regions of the  $\alpha$  helices, forming a **coiled-coil** structure. This structure is common in proteins containing amphipathic  $\alpha$  helices in which hydrophobic amino acid residues are regularly spaced alternately three or four positions apart in the sequence, forming a stripe down one side of the  $\alpha$  helix. These hydrophobic stripes make up the interacting surfaces between the  $\alpha$ -helical monomers in a coiled-coil dimer (see Figure 3-10a).

Although the first leucine-zipper transcription factors to be analyzed contained leucine residues at every seventh position in the dimerization region, additional DNA-binding proteins containing other hydrophobic amino acids in these positions were subsequently identified. Like leucine-zipper proteins, they form dimers containing a C-terminal coiled-coil dimerization region and an N-terminal DNA-binding

domain. The term *basic zipper (bZIP)* is now frequently used to refer to all proteins with these common structural features. Many basic-zipper transcription factors are heterodimers of two different polypeptide chains, each containing one basic-zipper domain.

**Basic Helix-Loop-Helix (bHLH) Proteins** The DNA-binding domain of another class of dimeric transcription factors contains a structural motif that is very similar to the basic-zipper motif except that a nonhelical loop of the polypeptide chain separates two  $\alpha$ -helical regions in each monomer (Figure 9-30d). Termed a **basic helix-loop-helix (bHLH)**, this motif was predicted from the amino acid sequences of these proteins, which contain an N-terminal  $\alpha$  helix with basic residues that interact with DNA, a middle loop region, and a C-terminal region, with hydrophobic amino acids spaced at intervals characteristic of an amphipathic  $\alpha$  helix, that dimerizes into a coiled coil. As with basic-zipper proteins, different bHLH proteins can form heterodimers.

## Structurally Diverse Activation and Repression Domains Regulate Transcription

Experiments with fusion proteins composed of the Gal4 DNA-binding domain and random segments of *E. coli* proteins demonstrated that a diverse group of amino acid sequences (~1 percent of all *E. coli* sequences) can function as activation domains, even though they evolved to perform other functions. Many transcription factors contain activation domains marked by an unusually high percentage of particular amino acids. Gal4, Gcn4, and most other yeast transcription factors, for instance, have activation domains that are rich in acidic amino acids (aspartic and glutamic acids). These so-called *acidic activation domains* are generally capable of stimulating transcription in nearly all types of eukaryotic cells—fungal, animal, and plant cells. Activation domains from some *Drosophila* and mammalian transcription factors are glutamine-rich, and some are proline-rich; still others are rich in the closely related amino acids serine and threonine, both of which have hydroxyl groups. However, some strong activation domains are not particularly rich in any specific amino acid.

Biophysical studies indicate that acidic activation domains have an unstructured, random-coil, intrinsically disordered conformation. These domains stimulate transcription when they are bound to a protein **co-activator**. The interaction with a co-activator causes the activation domain to assume a more structured  $\alpha$ -helical conformation in the activation domain–co-activator complex. A well-studied example of a transcription factor with an acidic activation domain is the mammalian CREB protein, which is phosphorylated in response to increased levels of cAMP. This regulated phosphorylation is required for CREB to bind to its co-activator CBP (CREB binding protein), resulting in the transcription of genes whose control regions contain a CREB-binding site (see Figure 15-30). When the phosphorylated random-coil activation domain of CREB interacts with CBP, it undergoes a conformational change to form two  $\alpha$  helices linked by a

short loop, which wrap around the interacting domain of CBP (Figure 9-31a).

Some activation domains are larger and more highly structured than acidic activation domains. For example, the ligand-binding domains of nuclear receptors function as activation domains when they bind their specific hormone ligand (Figure 9-31b, c). Binding of ligand induces a large

conformational change in the nuclear receptor that allows the ligand-binding domain with bound hormone to interact with a short  $\alpha$  helix in a co-activator; the resulting complex can then activate transcription of genes whose control regions bind the nuclear receptor.

Thus the acidic activation domain in CREB and the ligand-binding activation domains in nuclear receptors represent two structural extremes. The CREB acidic activation domain is an intrinsically disordered random coil that folds into two  $\alpha$  helices when it binds to the surface of a globular domain in a co-activator. In contrast, the nuclear-receptor ligand-binding activation domain is a structured globular domain that interacts with a short  $\alpha$  helix in a co-activator, which probably is a random coil before it is bound. In both cases, however, specific protein-protein interactions between a co-activator and the activation domain permit the transcription factor to stimulate gene expression.

Currently, less is known about the structure of repression domains. The globular ligand-binding domains of some nuclear receptors function as repression domains in the absence of their specific hormone ligand. Like activation domains, repression domains may be relatively short, comprising 15 or fewer amino acids. Biochemical and genetic studies indicate that repression domains also mediate protein-protein interactions and bind to *co-repressor* proteins, forming a complex that inhibits transcription initiation by mechanisms that are discussed later in the chapter.

**FIGURE 9-31 Activation domains may be random coils until they interact with co-activator proteins or folded protein domains.** (a) The acidic activation domain of CREB (cyclic AMP response element-binding protein) is activated by phosphorylation at serine 123. It is a random coil until it interacts with a domain of its co-activator, CBP (shown as a space-filling surface model with negatively charged regions in red and positively charged regions in blue). When the CREB activation domain binds to CBP, it folds into two amphipathic  $\alpha$  helices. Side chains in the activation domain that interact with the surface of the CBP domain are labeled. (b) The ligand-binding activation domain of the estrogen receptor is a folded-protein domain. When estrogen is bound to the domain, the green  $\alpha$  helix interacts with the ligand, generating a hydrophobic groove in the ligand-binding domain (dark brown helices), which binds an amphipathic  $\alpha$  helix in a co-activator subunit (blue). (c) The conformation of the estrogen receptor in the absence of hormone is stabilized by binding of the estrogen antagonist tamoxifen. In this conformation, the green helix of the receptor folds into a conformation that interacts with the co-activator-binding groove of the active receptor, sterically blocking binding of co-activators. [Part (a) data from I. Radhakrishnan et al., 1997, *Cell* **91**:741, PDB ID 1kdx. Parts (b) and (c) data from A. K. Shiau et al., 1998, *Cell* **95**:927, PDB ID 3erd and 3ert.]

## Transcription Factor Interactions Increase Gene-Control Options

Two types of DNA-binding proteins discussed previously—bZIP and bHLH proteins—often exist in alternative heterodimeric combinations of monomers. Other classes of transcription factors not discussed here also form heterodimeric proteins. In some heterodimeric transcription factors, each monomer recognizes the same sequence. In these cases, the formation of alternative heterodimers does not increase the number of different sites on which the monomers can act, but rather allows the activation domains associated with each monomer to be brought together in alternative combinations that bind to the same site (Figure 9-32a). As we will see later, and in subsequent chapters, the activities of individual transcription factors can be regulated by multiple mechanisms. Consequently, a single bZIP- or bHLH-binding DNA regulatory element in the transcription-control region of a gene may elicit different transcriptional responses depending on which bZIP or bHLH monomers are expressed in the cell and how their activities are regulated.

In some heterodimeric transcription factors, however, each monomer has a different DNA-binding specificity. The resulting combinatorial possibilities increase the number of potential DNA sequences that a family of transcription factors can bind. Three different transcription-factor monomers could theoretically combine to form six different homo- and heterodimeric transcription factors, as illustrated in Figure 9-32b. Four different monomers could form a total of ten

**FIGURE 9-32 Combinatorial possibilities due to formation of heterodimeric transcription factors.** (a) In some heterodimeric transcription factors, the activation domain of each monomer recognizes the same DNA sequence. In the hypothetical example shown, transcription-factor monomers A, B, and C can all interact with one another, creating six different alternative combinations of activation domains that can all bind at the same site. Each composite binding site is divided into two half-sites, and each heterodimeric factor contains the activation domains of its two constituent monomers. (b) When transcription-factor monomers recognize different DNA sequences, six alternative combinations of the transcription-factor monomers A, B, and C, each with a unique pair of activation domains, can bind to six different DNA sequences (sites 1–6). (c) Expression of an inhibitory factor (red) that interacts only with the dimerization domain of A inhibits binding; hence transcriptional activation at sites 1, 4, and 5 is inhibited, but activation at sites 2, 3, and 6 is unaffected.

dimeric factors; five monomers, sixteen dimeric factors; and so forth. In addition, inhibitory factors are known that bind to some bZIP and bHLH monomers, thereby blocking their binding to DNA. When these inhibitory factors are expressed, they repress transcriptional activation by the factors with which they interact (Figure 9-32c). Thus the rules governing the interactions of members of a heterodimeric transcription factor family are complex. This combinatorial complexity expands both the number of DNA sites from which these factors can activate transcription and the ways in which they can be regulated.

Similar combinatorial transcription regulation is achieved through the interaction of structurally unrelated

transcription factors bound to closely spaced binding sites in DNA. An example is the interaction of two transcription factors, NFAT and AP1, that bind to neighboring sites in a composite promoter-proximal element regulating the gene encoding interleukin-2 (IL-2). Expression of the *IL-2* gene is critical to the immune response, but abnormal expression of IL-2 can lead to autoimmune diseases such as rheumatoid arthritis (see Chapter 23). Neither NFAT nor AP1 binds to its site in the *IL-2* control region in the absence of the other. The affinities of these factors for these particular DNA sequences are too low for the individual factors to form a stable complex with DNA. However, when both NFAT and AP1 are present, protein-protein interactions between them stabilize the ternary complex composed of NFAT, AP1, and DNA (Figure 9-33a). Such *cooperative DNA binding* by various transcription factors results in considerable combinatorial complexity of transcriptional control. As a result, the 1400 or so transcription factors encoded in the human genome can bind to DNA through a much larger number of cooperative interactions, resulting in unique transcriptional control for each of the roughly 21,000 human genes. In the case of *IL-2*, transcription occurs only when NFAT is activated, which results in its transport from the cytoplasm to the nucleus, and the two subunits of AP1 are synthesized. These two events are controlled by distinct signal transduction pathways (see Chapters 15 and 16), allowing stringent control of IL-2 expression.

Cooperative binding by NFAT and AP1 occurs only when their weak binding sites are positioned quite close to each other in DNA. The sites must be located at a precise distance from each other for effective binding. The requirements for cooperative binding are not so stringent in the case of some other transcription factors and transcription-control regions. For example, the *EGR-1* control region contains a composite binding site to which the SRF and SAP1 transcription factors bind cooperatively (Figure 9-33b). Because SAP1 has a long, flexible domain that interacts with SRF, the two proteins can bind cooperatively when their individual sites in DNA are separated by any distance up to about 30 bp or are inverted relative to each other.

## Multiprotein Complexes Form on Enhancers

As noted previously, enhancers generally range in length from about 50 to 200 bp and include binding sites for several transcription factors. Analysis of the roughly 50-bp enhancer that regulates expression of  $\beta$ -interferon, an important protein in defense against viral infections in vertebrates, provides a good example of the structure of the DNA-binding domains of several transcription factors bound to the several transcription-factor-binding sites that constitute an enhancer (Figure 9-34). The term **enhanceosome** has been coined to describe such large DNA-protein complexes that assemble from transcription factors as they bind to the multiple binding sites in an enhancer.

Because of the presence of flexible regions connecting the DNA-binding domains and activation or repression domains in transcription factors (see Figure 9-28), and because

**FIGURE 9-33 Cooperative binding of two unrelated transcription factors to neighboring sites in a composite control element.** (a) By themselves, both monomeric NFAT and heterodimeric AP1 transcription factors have low affinity for their respective binding sites in the *IL-2* promoter-proximal region. Protein-protein interactions between NFAT and AP1 add to the overall stability of the NFAT-AP1-DNA complex, so that the two proteins bind to the composite site cooperatively. (b) Cooperative DNA binding by dimeric SRF and monomeric SAP1 can occur when their binding sites are separated by 5–30 bp and when the SAP1 binding site is inverted because the domain of SAP1 that interacts with SRF is connected to the DNA-binding domain of SAP1 by a flexible linker region of the SAP1 polypeptide chain (dotted line). [Part (a) data from L. Chen et al., 1998, *Nature* **392**:42, PDB ID 1a02; part (b) data from M. Hassler and T. J. Richmond, 2001, *EMBO J.* **20**:3018, PDB ID 1hbx.]

of the ability of interacting proteins bound to distant sites to produce loops in the DNA between their binding sites (see Figure 9-5), considerable leeway in the spacing between regulatory elements in transcription-control regions is permissible. This tolerance for variable spacing between binding sites for specific transcription factors, and between promoter binding sites for the general transcription factors and for Pol II, probably contributed to rapid evolution of gene

control in eukaryotes. Transposition of DNA sequences and recombination between repeated sequences over evolutionary time probably created new combinations of control elements that were subjected to natural selection and retained if they proved beneficial. The latitude in spacing between regulatory elements probably allowed many more functional combinations to be subjected to this evolutionary experimentation than would be the case if constraints on the spacing between regulatory elements were strict, as for most genes in bacteria.

**FIGURE 9-34 Model of the enhanceosome that forms on the  $\beta$ -interferon enhancer.** Two heterodimeric factors, Jun/ATF-2 and p50/RelA (NF- $\kappa$ B), and two copies each of the monomeric transcription factors IRF-3 and IRF-7, bind to the six overlapping binding sites in this enhancer. See D. Penne, T. Manniatis, and S. Harrison, 2007, *Cell* **129**:1111.

## KEY CONCEPTS OF SECTION 9.4

### Regulatory Sequences in Protein-Coding Genes and the Proteins Through Which They Function

- Expression of eukaryotic protein-coding genes is generally regulated through multiple protein-binding transcription-control regions that are located close to or distant from the transcription start site (see Figure 9-23).
- Promoters direct binding of RNA polymerase II to DNA, determine the site of transcription initiation, and influence the frequency of transcription initiation.
- Promoter-proximal elements occur within about 200 bp of a start site. Several such elements, containing 6–10 bp, may help regulate a particular gene.

- Enhancers, which contain multiple short control elements, may be located from 200 bp to tens of kilobases upstream or downstream from a promoter, within an intron, or downstream from the final exon of a gene.
- Promoter-proximal elements and enhancers are often cell-type-specific, functioning only in specific differentiated cell types.
- Transcription factors, which activate or repress transcription, bind to promoter-proximal regulatory elements and enhancers in eukaryotic DNA.
- Transcription activators and repressors are generally modular proteins containing a single DNA-binding domain and one or a few activation domains (for activators) or repression domains (for repressors). The different domains are frequently linked by flexible, intrinsically disordered polypeptide regions (see Figure 9-28).
- Among the most common structural motifs found in the DNA-binding domains of eukaryotic transcription factors are the homeodomain, C2H2 zinc finger, basic zipper (leucine zipper), and basic helix-loop-helix (bHLH). All these and many other DNA-binding motifs contain one or more  $\alpha$  helices that interact with the major groove in their cognate site in DNA.
- Activation and repression domains in transcription factors exhibit a variety of amino acid sequences and three-dimensional structures. In general, these functional domains interact with co-activators or co-repressors, which are critical to the ability of transcription factors to modulate gene expression.
- The transcription-control regions of most genes contain binding sites for multiple transcription factors. Transcription of such genes varies depending on the particular repertoire of transcription factors that are expressed and activated in a particular cell at a particular time.
- Combinatorial complexity in transcriptional control results from alternative combinations of monomers that form heterodimeric transcription factors (see Figure 9-32) and from cooperative binding of transcription factors to composite control sites (see Figure 9-33).
- Binding of multiple transcription factors to multiple sites in an enhancer forms a DNA-protein complex called an enhanceosome (see Figure 9-34).

## 9.5 Molecular Mechanisms of Transcription Repression and Activation

The repressors and activators that bind to specific sites in DNA and regulate expression of the associated protein-coding genes do so by three general mechanisms. First, these regulatory proteins act in concert with other proteins to modulate

chromatin structure, inhibiting or stimulating the ability of general transcription factors to bind to promoters. Recall from Chapter 8 that the DNA in eukaryotic cells is not free, but is associated with a roughly equal mass of protein in the form of chromatin. The basic structural unit of chromatin is the nucleosome, which is composed of about 147 bp of DNA wrapped tightly around a disk-shaped core of *histone* proteins. Residues within the N-terminal region of each histone, and the C-terminal regions of histones H2A and H2B, called *histone tails*, extend from the surface of the nucleosome and can be reversibly modified (see Figure 8-26b). Such modifications influence the relative condensation of chromatin and thus its accessibility to proteins required for transcription initiation. Second, activators and repressors interact with a large multiprotein complex called the *mediator of transcription complex*, or simply **Mediator**. This complex, in turn, binds to Pol II and directly regulates assembly of the preinitiation complex. In addition, some activation domains interact with TFIID-TAF subunits or other components of the preinitiation complex, and these interactions contribute to preinitiation complex assembly. Finally, activation domains may also interact with the elongation factor P-TEFb (cyclin T-CDK9) and other as yet unknown factors to stimulate elongation by Pol II away from the promoter region.

In this section, we review the current understanding of how repressors and activators control chromatin structure and preinitiation complex assembly. In the next section of the chapter, we discuss how the concentrations and activities of activators and repressors themselves are controlled, so that gene expression is precisely attuned to the needs of the cell and organism.

### Formation of Heterochromatin Silences Gene Expression at Telomeres, near Centromeres, and in Other Regions

For many years it has been clear that inactive genes in eukaryotic cells are often associated with heterochromatin, regions of chromatin that are more highly condensed and stain more darkly with DNA dyes than euchromatin, in which most transcribed genes are located (see Figure 8-28a). Regions of chromosomes near the centromeres and telomeres, as well as additional specific regions that vary in different cell types, are organized into heterochromatin. The DNA in heterochromatin is less accessible to externally added proteins than is DNA in euchromatin and consequently is often referred to as “closed” chromatin. For instance, in an experiment described in Chapter 8, the DNA of inactive genes was found to be far more resistant to digestion by DNase I than the DNA of transcribed genes (see Figure 8-27).

Study of DNA regions in *S. cerevisiae* that behave like the heterochromatin of higher eukaryotes provided early insight into the *chromatin-mediated repression* of transcription. This yeast can grow either as haploid or diploid cells. Haploid cells exhibit one of two possible mating types, called  $\alpha$  and  $a$ . Cells of different mating type can “mate,” or fuse,

to generate a diploid cell (see Figure 1-23). When a haploid cell divides by budding, the larger “mother” cell switches its mating type. Genetic and molecular analyses have revealed that three genetic loci on yeast chromosome III control the mating type of yeast cells (Figure 9-35). The central mating-type locus, termed *MAT*—the only one of the three that is actively transcribed—encodes transcription factors ( $\alpha$ 1, or  $\alpha$ 1 and  $\alpha$ 2) that regulate genes that determine the mating type. In any one cell, either an  $\alpha$  or  $\alpha$  DNA sequence is located at the *MAT*. The two additional loci, termed *HML* and *HMR*, near the left and right telomere, respectively, contain “silent” (nontranscribed) copies of the  $\alpha$  or  $\alpha$  genes. These sequences are transferred alternately from *HML* $\alpha$  or *HMR* $\alpha$  into the *MAT* locus by a type of nonreciprocal recombination between homologous sequences during cell division. When the *MAT* locus contains the DNA sequence from *HML* $\alpha$ , the cells behave as  $\alpha$  cells. When the *MAT* locus contains the DNA sequence from *HMR* $\alpha$ , the cells behave like  $\alpha$  cells.

Our interest here is in how transcription of the silent mating-type genes at *HML* and *HMR* is repressed. If these genes are expressed, as they are in yeast mutants with defects in the repressing mechanism, both  $\alpha$  and  $\alpha$  proteins are expressed, causing the cells to behave like diploid cells, which cannot mate. The promoters and UASs controlling transcription of the  $\alpha$  and  $\alpha$  genes lie near the center of the DNA sequence that is transferred and are identical whether the sequences are at the *MAT* locus or at one of the silent loci. This arrangement indicates that the function of the transcription factors that interact with these sequences must somehow be blocked at *HML* and *HMR*, but not at the *MAT* locus. This repression of the silent loci depends on **silencer sequences** located next to the region of transferred DNA at *HML* and *HMR* (see Figure 9-35). If the silencer is deleted, the adjacent locus is transcribed. Remarkably, any gene placed near the yeast mating-type silencer sequence by recombinant DNA techniques is repressed, or “silenced,” even a tRNA gene transcribed by RNA polymerase III, which uses a different

set of general transcription factors than RNA polymerase II uses, as discussed later.

Several lines of evidence indicate that repression of the *HML* and *HMR* loci results from a condensed chromatin structure that sterically blocks transcription factors from interacting with the DNA. In one telling experiment, the gene encoding an *E. coli* enzyme that methylates adenine residues in the sequence GATC was introduced into yeast cells under the control of a yeast promoter so that the enzyme was expressed. Researchers found that GATC sequences within the *MAT* locus and most other regions of the genome in these cells were methylated, but not those within the *HML* and *HMR* loci. These results indicate that the DNA of the silent loci is inaccessible to the *E. coli* methylase, and presumably to proteins in general, including transcription factors and RNA polymerase. Similar experiments conducted with various yeast histone mutants indicated that specific interactions involving the histone tails of H3 and H4 are required for formation of a fully repressed chromatin structure. Other studies have shown that the telomeres of every yeast chromosome also behave like silencer sequences. For instance, when a gene is placed within a few kilobases of any yeast telomere, its expression is repressed. In addition, this repression is relieved by the same mutations in the H3 and H4 histone tails that interfere with repression at the silent mating-type loci.

Genetic studies led to identification of several proteins, RAP1 and three SIR proteins, that are required for repression of the silent mating-type loci and the telomeres in yeast. RAP1 was found to bind within the DNA silencer sequences associated with *HML* and *HMR* and to a sequence that is repeated multiple times at each yeast-chromosome telomere. Further biochemical studies showed that the SIR2 protein is a *histone deacetylase*; it removes acetyl groups on lysines of the histone tails. Furthermore, the RAP1 and SIR2, 3, and 4 proteins bind to one another, and SIR3 and SIR4 bind to the N-terminal tails of histones H3 and H4, which are maintained in a largely nonacetylated state by the deacetylase

**FIGURE 9-35 Arrangement of mating-type loci on chromosome III in the yeast *S. cerevisiae*.** Silent (unexpressed) mating-type genes (either  $\alpha$  or  $\alpha$ ) are located at the *HML* locus. The opposite mating-type gene is present at the silent *HMR* locus. When the  $\alpha$  or  $\alpha$  sequences are present at the *MAT* locus, they can be transcribed into mRNAs whose

encoded proteins specify the mating-type phenotype of the cell. The silencer sequences near *HML* and *HMR* bind proteins that are critical for repression of these silent loci. Haploid cells can switch mating types in a process that transfers the DNA sequence from *HML* or *HMR* to the transcriptionally active *MAT* locus.

**EXPERIMENTAL FIGURE 9-36 Antibody and DNA probes colocalize SIR3 protein with telomeric heterochromatin in yeast nuclei.**

(a) Confocal micrograph 0.3 mm thick through three diploid yeast cells, each containing 68 telomeres. Telomeres were labeled by hybridization to a fluorescent telomere-specific probe (yellow). DNA was stained red to reveal the nuclei. The 68 telomeres coalesce into a much smaller number of regions near the nuclear periphery. (b, c) Confocal micrographs of yeast cells labeled with a telomere-specific hybridization probe (b) and a fluorescent-labeled antibody specific for SIR3 (c). Note that SIR3 is localized in the repressed telomeric heterochromatin. Similar experiments with RAP1, SIR2, and SIR4 have shown that these proteins also colocalize with the repressed telomeric heterochromatin. (d) Schematic model of the silencing mechanism at yeast telomeres. (Top left) Multiple copies of RAP1

bind to a simple repeated sequence at each telomere region that lacks nucleosomes. SIR3 and SIR4 bind to RAP1, and SIR2 binds to SIR4. SIR2 is a histone deacetylase that deacetylates the tails on the histones neighboring the repeated RAP1-binding site. (Middle) The hypoacetylated histone tails are also binding sites for SIR3 and SIR4, which in turn bind additional SIR2, deacetylating neighboring histones. Repetition of this process results in spreading of the region of hypoacetylated histones with associated SIR2, SIR3, and SIR4. (Bottom) Interactions between complexes of SIR2, SIR3, and SIR4 cause the chromatin to condense and several telomeres to associate, as shown in a–c. The higher-order chromatin structure generated sterically blocks other proteins from interacting with the underlying DNA. See M. Grunstein, 1997, *Curr. Opin. Cell Biol.* **9**:383. [Parts (a)–(c) ©1996 Gotta et al., *The Journal of Cell Biology*, **134**: 1349–1363. doi:10.1083/jcb.134.6.134.]

activity of SIR2. A series of experiments using fluorescence confocal microscopy on yeast cells either stained with fluorescent-labeled antibody to any one of the SIR proteins or RAP1 or hybridized to a labeled telomere-specific DNA probe revealed that these proteins form large, condensed telomeric nucleoprotein structures resembling the heterochromatin found in higher eukaryotes (Figure 9-36a, b, c).

Figure 9-36d depicts a model for the chromatin-mediated silencing at yeast telomeres based on these and other studies. Formation of heterochromatin at telomeres is nucleated by multiple RAP1 protein molecules bound to repeated sequences in a nucleosome-free region at the extreme end of a telomere. A network of protein-protein interactions involving telomere-bound RAP1, three SIR proteins (2, 3, and 4), and hypoacetylated histones H3 and H4 creates a higher-order nucleoprotein complex that includes several telomeres and in which the DNA is largely inaccessible to external proteins. One additional protein, SIR1, is also required for silencing of the mating-type loci. It binds to the silencer regions associated with *HML* and *HMR* together with RAP1 and other proteins to initiate assembly of a similar multiprotein silencing complex that encompasses *HML* and *HMR*.

An important feature of this model is the dependence of repression on *hypoacetylation* of the histone tails. This dependence was demonstrated in experiments with yeast mutants expressing histones in which lysines in histone N-termini were replaced with arginines, glutamines, or glycines. Arginine is positively charged, like lysine, but cannot be acetylated. Glutamine, on the other hand, is neutral and simulates the neutral charge of acetylated lysine, and glycine, with no side chain, also mimics the absence of a positively charged lysine. Repression at telomeres and at the silent mating-type loci was defective in the mutants with glutamine and glycine substitutions for lysine in the H3 or H4 histone tails, but not in the mutants with arginine substitutions. Further, acetylation of H3 and H4 lysines interferes with binding by Sir3 and Sir4 and consequently prevents repression at the silent loci and telomeres. Finally, chromatin immunoprecipitation experiments (see Figure 9-18a) using antibodies specific for acetylated lysines at particular positions in the histone N-terminal tails (see Figure 8-26a) confirmed that histones in repressed regions near telomeres and at the silent mating loci are hypoacetylated, but become hyperacetylated in *sir* mutants when genes in these regions are derepressed.

### Repressors Can Direct Histone Deacetylation at Specific Genes

The importance of *histone deacetylation* in chromatin-mediated gene repression was further supported by studies of eukaryotic repressors that regulate genes at internal chromosomal positions. These proteins are now known to act in part by causing deacetylation of histone tails in nucleosomes that encompass the TATA box and promoter-proximal region of the genes they repress. In vitro studies have shown that when promoter DNA is part of a nucleosome with nonacetylated histones, the general transcription factors cannot bind to the TATA box and promoter-proximal

region. In nonacetylated histones, the N-terminal lysines are positively charged and may interact with DNA phosphates. The nonacetylated histone tails also interact with neighboring histone octamers and other chromatin-associated proteins, favoring the folding of chromatin into condensed higher-order structures whose precise conformation is not well understood. The net effect is that general transcription factors cannot assemble into a preinitiation complex on a promoter associated with hypoacetylated histones. In contrast, binding of general transcription factors is repressed much less by histones with hyperacetylated tails, in which the positively charged lysines are neutralized and electrostatic interactions are eliminated.

The connection between histone deacetylation and repression of transcription at specific yeast promoters became clearer when the cDNA encoding a human histone deacetylase was found to have high homology to the yeast *RPD3* gene, known to be required for the normal repression of a number of yeast genes. Further work showed that the yeast Rpd3 protein has histone deacetylase activity. The ability of Rpd3 to deacetylate histones at a number of promoters depends on two other proteins: Ume6, a repressor that binds to a specific upstream regulatory sequence (URS1), and Sin3, which is part of a large multiprotein complex called Rpd3L that also contains Rpd3 (Figure 9-37a). Sin3 also binds to the repression domain of Ume6, thus positioning the Rpd3 histone deacetylase in the complex so that it can interact with nearby promoter-associated nucleosomes and remove acetyl groups from histone-tail lysines. Additional experiments, using the chromatin immunoprecipitation technique outlined in Figure 9-18a and antibodies to specific histone acetylated lysines, demonstrated that in wild-type yeast, one or two nucleosomes in the immediate vicinity of Ume6-binding sites are hypoacetylated. These sites include the promoters of genes repressed by Ume6. In *sin3* and *rpd3* deletion mutants, not only were these promoters derepressed, but the nucleosomes near the Ume6-binding sites were hyperacetylated. All these findings provide considerable support for the model of repressor-directed deacetylation shown in Figure 9-37a.

In yeast, the Sin3-Rpd3 complex (Rpd3L) functions as a **co-repressor**, a protein or complex of proteins that binds to a repression domain and interacts with chromatin, Pol II, or the general transcription factors to repress transcription. Co-repressor complexes containing histone deacetylases have also been found associated with many repressors from mammalian cells. Some of these complexes contain the mammalian homolog of Sin3 (mSin3), which interacts with the repression domain of repressors, as in yeast. Other histone deacetylase complexes identified in mammalian cells contain additional or different repression domain-binding proteins. These various repressor and co-repressor combinations mediate histone deacetylation at specific promoters by a mechanism similar to the yeast mechanism (see Figure 9-37a). In addition to repressing transcription through the formation of “closed” chromatin structures, some repression domains have also been found to inhibit the assembly of preinitiation complexes in in vitro experiments with purified general

(a) Repressor-directed histone deacetylation

(b) Activator-directed histone hyperacetylation

**FIGURE 9-37 Proposed mechanism of histone deacetylation and hyperacetylation in yeast transcriptional control.**

(a) Repressor-directed deacetylation of histone N-terminal tails. The DNA-binding domain (DBD) of the repressor Ume6 interacts with a specific upstream control element of the genes it regulates, called URS1. The Ume6 repression domain (RD) binds Sin3, a subunit of a multiprotein complex that includes Rpd3, a histone deacetylase. Deacetylation of histone N-terminal tails on nucleosomes in the region of the Ume6-binding site inhibits binding of general transcription factors at the TATA box, thereby repressing gene expression. (b) Activator-directed hyperacetylation of histone N-terminal tails. The DNA-binding domain of the activator Gcn4 interacts with specific upstream activating sequences (UAS) of the genes it regulates. The Gcn4 activation domain (AD) then interacts with a multiprotein histone acetylase complex that includes the Gcn5 catalytic subunit. Subsequent hyperacetylation of histone N-terminal tails on nucleosomes in the vicinity of the Gcn4-binding site facilitates access by the general transcription factors required for initiation. Repression and activation of many genes in higher eukaryotes occur by similar mechanisms.

transcription factors in the absence of histones. This activity probably contributes to the repression of transcription by these repression domains *in vivo* as well.

### Activators Can Direct Histone Acetylation at Specific Genes

Just as repressors function through co-repressors that bind to their repression domains, the activation domains of DNA-binding activators function by binding multisubunit co-activator complexes, protein complexes that interact with or modify chromatin, Pol II, or general transcription factors to activate transcription. One of the first co-activator complexes to be characterized was the yeast *SAGA complex*, which functions with the Gcn4 activator protein described in Section 9.4. Early genetic studies indicated that full activity of the Gcn4 activator required a protein called Gcn5. The clue to Gcn5's function came from biochemical studies of a *histone acetylase* purified from the protozoan *Tetrahymena*, the first histone acetylase to be purified. Sequence analysis revealed homology between the *Tetrahymena* protein and yeast Gcn5, which was soon shown to have histone acetylase activity as well. Further genetic and biochemical studies revealed that Gcn5 is one subunit of a multiprotein

co-activator complex, named the *SAGA complex* after genes encoding some of the subunits. Another subunit of this histone acetylase complex binds to activation domains in multiple yeast activator proteins, including Gcn4. The model shown in Figure 9-37b is consistent with the observation that nucleosomes near the promoter region of a gene regulated by the Gcn4 activator are specifically hyperacetylated compared with most histones in the cell. This activator-directed hyperacetylation of nucleosomes near a promoter region opens the chromatin structure so as to facilitate the binding of other proteins required for transcription initiation. The chromatin structure is less condensed than most chromatin, as indicated by its sensitivity to digestion with nucleases in isolated nuclei.

In addition to leading to the decondensation of chromatin, the acetylation of specific histone lysines generates binding sites for proteins containing bromodomains. A **bromodomain** is a sequence of about 110 amino acids that folds into a domain that binds acetylated lysine. One or more bromodomains are found in several chromosome-associated proteins that contribute to transcriptional activation. For example, a subunit of the general transcription factor TFIID contains two bromodomains, which bind to acetylated nucleosomes with high affinity. Recall that TFIID binding to a

promoter initiates assembly of an RNA polymerase II preinitiation complex (see Figure 9-19). Nucleosomes at promoter regions of virtually all active genes have acetylated lysines in their H3 and H4 histone tails.

A similar activation mechanism operates in higher eukaryotes. Mammalian cells contain multisubunit histone acetylase co-activator complexes that are homologous to the yeast SAGA complex. They also express two related 300-kDa, multidomain proteins called *CBP* and *p300*, which function similarly. As noted earlier, one domain of CBP binds the phosphorylated acidic activation domain in the CREB transcription factor. Other domains of CBP interact with different activation domains in other activators. Yet another domain of CBP has histone acetylase activity, and another CBP domain associates with additional multisubunit histone acetylase complexes. CREB and many other mammalian activators function in part by directing CBP and the associated histone acetylase complex to specific nucleosomes, where they acetylate histone tails, facilitating the interaction of general transcription factors with promoter DNA.

### Chromatin-Remodeling Complexes Help Activate or Repress Transcription

In addition to histone acetylase complexes, multiprotein chromatin-remodeling complexes are required for activation at many promoters. The first of these complexes characterized was the yeast **SWI/SNF chromatin-remodeling complex**. One of the SWI/SNF subunits has homology to DNA helicases, enzymes that use energy from ATP hydrolysis to disrupt interactions between base-paired nucleic acids or between nucleic acids and proteins. In vitro, the SWI/SNF complex is thought to pump or push DNA into the nucleosome so that DNA bound to the surface of the histone octamer transiently dissociates from the surface and translocates, causing the nucleosomes to “slide” along the DNA. The net result of such chromatin remodeling is to facilitate the binding of transcription factors to specific DNA sequences in chromatin. Many activation domains bind to such *chromatin-remodeling complexes*, and this binding stimulates in vitro transcription from chromatin templates in which the DNA is associated with histone octamers. Thus the SWI/SNF complex represents another type of co-activator complex. The experiment shown in Figure 9-38 demonstrates dramatically how an activation domain can cause decondensation of a region of chromatin. This decondensation results from association of the activation domain with chromatin-remodeling and histone acetylase complexes.

Chromatin-remodeling complexes are required for many processes involving DNA in eukaryotic cells, including transcriptional control, DNA replication, recombination, and DNA repair. Several types of chromatin-remodeling complexes are found in eukaryotic cells, all with homologous DNA helicase domains. SWI/SNF complexes and related chromatin-remodeling complexes in multicellular organisms contain subunits with bromodomains that bind to acetylated

**FIGURE 9-38 Expression of fusion proteins demonstrates chromatin decondensation in response to an activation domain.** A cultured hamster cell line was engineered to contain multiple copies of a tandem array of *E. coli lac* operator sequences integrated into a chromosome in a region of heterochromatin. (a) When an expression vector for the *lac* repressor (LacI) was transfected into these cells, *lac* repressor bound to the *lac* operator sites could be visualized in a region of condensed chromatin using an antibody against the *lac* repressor (red). DNA was visualized by staining with DAPI (blue), revealing the nucleus. A diagram of condensed chromatin is shown below. (b) When LacI fused to an activation domain was transfected into these cells, staining as in (a) revealed that the activation domain causes this region of chromatin to decondense into a thinner chromatin fiber that fills a much larger volume of the nucleus. A diagram of a region of decondensed chromatin with bound LacI fusions to the VP16 activation domain (AD) and associated chromatin remodeling and histone acetylase complexes is shown below. [Photos ©1999 Dr. Andrew S. Belmont et al., *The Journal of Cell Biology*, 145:1341–1354. doi: 10.1083/jcb.145.7.1341.]

histone tails. Consequently, SWI/SNF complexes remain associated with activated, acetylated regions of chromatin, presumably maintaining them in a decondensed conformation. Chromatin-remodeling complexes can also participate in transcriptional repression. These complexes bind to the repression domains of repressors and contribute to repression, presumably by folding chromatin into condensed structures. Much remains to be learned about how this important class of proteins alters chromatin structure to influence gene expression and other processes.

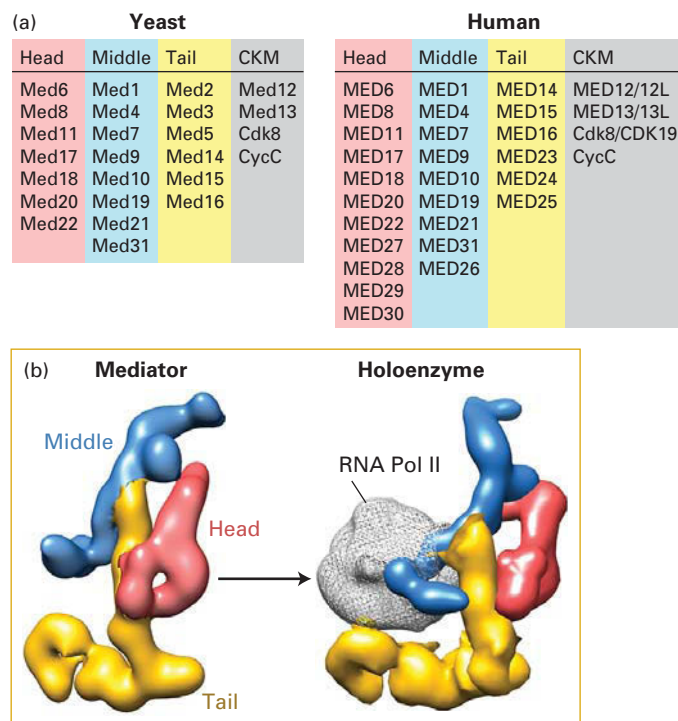

### Pioneer Transcription Factors Initiate the Process of Gene Activation During Cellular Differentiation

As cells differentiate during embryogenesis and during differentiation from stem cells in adult organisms (see Chapter 21), many of the genes induced during the

process are initially in repressed regions of heterochromatin in undifferentiated progenitor cells. Activation of these genes requires that the chromatin environment of their transcription-control regions become decondensed so that transcription factors can bind to enhancers and promoter-proximal control elements and so that the general transcription factors and Pol II can bind to promoters. In many cases, this decondensation is initiated by special *pioneer transcription factors* that can bind to their cognate binding sites in DNA even when those sites are within repressed heterochromatic regions of chromatin. These factors have a DNA-binding domain that binds to one side of the DNA helix in a manner similar to the bacteriophage 434 repressor (see Figure 9-29). This domain allows these factors to bind to their specific binding sites while the DNA is wrapped around a histone octamer with the opposite side of the DNA against the surfaces of histones.

One example of pioneer transcription factors initiating the process of transcriptional activation involves the liver-specific gene *Alb1*, encoding serum albumin, a major constituent of blood serum that is secreted into the blood by hepatocytes. In the developing mouse, the FoxA and GATA-4 or GATA-6 transcription factors are the first transcription factors to bind to an *Alb1* enhancer in undifferentiated gut endodermal cells destined to develop into the liver. FoxA has a “winged helix” DNA-binding domain that binds to one side of the DNA helix containing the FoxA-binding site. GATA factors are also able to bind to their specific sites in DNA when those sites are included in nucleosomal DNA wrapped around a histone octamer. The FoxA and GATA-4/6 activation domains may then interact with chromatin remodeling complexes and histone acetylase complexes to decondense the chromatin of the 120-bp *Alb1* enhancer, allowing the observed subsequent binding of four additional transcription factors in the nascent liver bud that develops later.

**FIGURE 9-39 Structure of yeast and human Mediator complexes.** (a) Subunits of the *S. cerevisiae* and human Mediator complexes. The subunits constituting the head, middle, and tail modules of Mediator are indicated, as well as the subunits of the CDK8-kinase module (CKM) that associates with some Mediator complexes, blocking Pol II binding. (b) Cryoelectron microscopic structure of the yeast Mediator without the CKM. (Left) The head, middle, and tail modules composed of the subunits listed above are color-coded. (Right) The structure of a complex of Mediator with Pol II, called the holoenzyme, suggests that the Mediator modules rotate relative to one another as shown to create a surface that binds Pol II. [Part (b) republished with permission of Elsevier, from Tsai, K.L., “Subunit architecture and functional modular rearrangements of the transcriptional mediator complex,” *Cell*, 2014, **157**(6): 1430–1444; permission conveyed through Copyright Clearance Center, Inc.]

## The Mediator Complex Forms a Molecular Bridge Between Activation Domains and Pol II

Once the interaction of activation domains with histone acetylase complexes and chromatin remodeling complexes converts the chromatin of a promoter region to an “open” structure that allows the binding of general transcription factors, activation domains interact with another multisubunit co-activator complex, the Mediator complex (Figure 9-39). Activation domain–Mediator interactions stimulate assembly of the preinitiation complex on the promoter. Recent cryoelectron microscopy studies show that the head and middle domains of the Mediator complex interact directly with Pol II. Several Mediator subunits bind to activation domains in various activator proteins. Thus Mediator can form a molecular bridge between an activator bound to its cognate site in DNA and Pol II bound to a promoter.

Experiments with temperature-sensitive yeast mutants indicate that some Mediator subunits are required for transcription of virtually all yeast genes. These subunits help maintain the overall structure of the Mediator complex or bind to Pol II; they are therefore required for activation by all activators. In contrast, other Mediator subunits are required for normal activation or repression of specific subsets of genes. DNA microarray analysis (see Figure 6-26) of yeast gene expression in mutants with defects in these nonessential Mediator subunits have indicated that each one influences transcription of 3–10 percent of all genes to the extent that its deletion either increases or decreases mRNA expression by a factor of twofold or more. In many cases, these Mediator subunits have been discovered to interact with specific activation domains; thus when one Mediator subunit is defective, transcription of genes regulated by activators that bind to that subunit is severely depressed, but

transcription of other genes is unaffected. Recent cryo-electron microscopy studies suggest that when activation domains interact with Mediator, the head, middle, and tail domains depicted in Figure 9-39 rotate relative to one another, creating a binding surface for RNA polymerase II. The surface of the polymerase that interacts with general transcription factors in the preinitiation complex (see Figure 9-20) remains exposed in the proposed model of the polymerase-Mediator complex, referred to as the *holoenzyme*.

The various experimental results indicating that individual Mediator subunits bind to specific activation domains suggest that multiple activators may influence transcription from a single promoter by interacting with a Mediator complex simultaneously or in rapid succession (Figure 9-40). Activators bound at enhancers or promoter-proximal elements can interact with Mediator associated with a promoter because chromatin, like DNA, is flexible and can form a loop, bringing the regulatory regions and the promoter close together, as observed for the *E. coli* NtrC activator and  $\sigma^{54}$ -RNA polymerase (see Figure 9-5). The multiprotein complexes that form on eukaryotic promoters may comprise more than 100 polypeptides with a total mass of 3–5 megadaltons (MDa)—as large as a ribosome.

In vivo, assembly of a preinitiation complex on a promoter and initiation of transcription is a highly cooperative process generally requiring that several transcription factors bound to transcription-control elements interact with co-activators that in turn interact with Pol II and general transcription factors. A cell must produce the specific set of activators required for transcription of a particular gene in order to express that gene.

## KEY CONCEPTS OF SECTION 9.5

### Molecular Mechanisms of Transcription Repression and Activation

- Eukaryotic transcription activators and repressors exert their effects largely by binding to multisubunit co-activators or co-repressors that influence the assembly of preinitiation complexes either by modulating chromatin structure or by interacting with Pol II and general transcription factors.
- The DNA in condensed regions of chromatin (heterochromatin) is relatively inaccessible to transcription factors and other proteins, so that gene expression in these regions is repressed.
- The interactions of several proteins with one another and with the hypoacetylated N-terminal tails of histones H3 and H4 are responsible for the chromatin-mediated repression of transcription that occurs in the telomeres and the silent mating-type loci in *S. cerevisiae* (see Figure 9-36).

**FIGURE 9-40 Model of several DNA-bound activators interacting with a single Mediator complex.** The ability of different Mediator subunits to interact with specific activation domains may contribute to the integration of signals from several activators at a single promoter. See the text for discussion.

- Some repression domains function by interacting with co-repressors that are histone deacetylase complexes. The subsequent deacetylation of histone N-terminal tails in nucleosomes near the repressor-binding site inhibits interaction between the promoter DNA and general transcription factors, thereby repressing transcription initiation (see Figure 9-37a).
- Activation domains function by binding multiprotein co-activator complexes such as histone acetylase complexes. The subsequent hyperacetylation of histone N-terminal tails in nucleosomes near the activator-binding site facilitates interactions between the promoter DNA and general transcription factors, thereby stimulating transcription initiation (see Figure 9-37b).
- SWI/SNF chromatin-remodeling factors constitute another type of co-activator. These multisubunit complexes can transiently dissociate DNA from histone cores in an ATP-dependent reaction and may also decondense regions of chromatin, thereby promoting the binding of DNA-binding proteins needed for transcription initiation.
- The Mediator complex, another type of co-activator, is a roughly 30-subunit complex that forms a molecular bridge between activation domains and RNA polymerase II by binding directly to the polymerase and activation domains. By binding to several different activators either simultaneously or in rapid succession, Mediator probably helps integrate the effects of multiple activators on a single promoter (see Figure 9-40).
- Activators bound to a distant enhancer can interact with transcription factors bound to a promoter because chromatin is flexible and the intervening chromatin can form a large loop.
- The highly cooperative assembly of preinitiation complexes in vivo generally requires several activators. A cell must produce the specific set of activators required for transcription of a particular gene in order to express that gene.

## 9.6 Regulation of Transcription-Factor Activity

We have seen in the preceding discussion how combinations of transcription factors that bind to specific DNA regulatory sequences control the transcription of eukaryotic genes. Whether or not a specific gene in a multicellular organism is expressed in a particular cell at a particular time is largely a consequence of the nuclear concentrations and activities of the transcription factors that interact with the transcription-control regions of that gene. (Exceptions are due to the “transcriptional memory” that results from the *epigenetic* mechanisms discussed in the next section.) Which transcription factors are expressed in a particular cell type, and the amounts produced, are determined by multiple regulatory interactions between transcription factors and control regions in genes encoding transcription factors that occur during the development and differentiation of that cell type. Recent advances in the analysis of transcription-factor-binding sites through identification of DNase I hypersensitive sites on a genomic scale have given us the first high-resolution view of how transcription-factor binding changes during the development and differentiation of multiple human cell types.

### DNase I Hypersensitive Sites Reflect the Developmental History of Cellular Differentiation

In Chapter 8, we learned that an expressed gene is far more sensitive to digestion by DNase I (a bovine pancreatic enzyme) than the same gene in a different cell type in which it is not expressed (see Figure 8-34). In addition to this general increase in DNase I sensitivity over long regions, researchers later found that specific short regions of the genome, on the order of a hundred base pairs in length, are extremely sensitive to DNase I digestion and are the first regions cut when isolated nuclei are treated with low levels of DNase I. These sites are known as *DNase I hypersensitive sites (DHSs)*. High-throughput sequencing methods have allowed mapping of DHSs across the genome in multiple differentiated and embryonic cell types. Briefly, after digestion of isolated nuclei with low levels of DNase I, DNA is isolated from the treated chromatin. Oligonucleotide linkers of a known sequence are ligated to the DNA ends generated by DNase I digestion. Then the DNA is sheared into small fragments by sonication, amplified by PCR, and sequenced. Human DNA sequences adjacent to the known sequence of the oligonucleotide linker were thus identified as DHSs.

Figure 9-41a shows plots of the number of times a DHS was sequenced—a measure of the DNase sensitivity of the site—in samples from the human cell types indicated at the left. A roughly 600-kb region of the genome on chromosome 12, located 96.2–96.8 Mb from the left end of the chromosome, is shown. The height of each vertical bar represents the degree of sensitivity of the DNA sequence at that position to digestion in nuclei isolated from each of the cell types.

Mapping of binding sites for specific transcription factors by chromatin immunoprecipitation (see Figure 9-18) has shown that most transcription-factor-binding sites are coincident with DHSs. This may be because the DNA-binding domain of the bound transcription factor exposes DNA flanking the binding site to DNase I digestion, or because the transcription-factor activation domain interacts with chromatin-remodeling complexes that destabilize the interaction of DNA with histone octamers in neighboring nucleosomes, causing the DNA to be more sensitive to DNase I digestion. Because DHSs are coincident with bound transcription factors, the DHS pattern in a region of chromatin represents the positions of bound transcription factors, although the transcription factors bound are not directly identified.

In Figure 9-41a, the type of tissue from which the DHS data were determined is shown on the left, and the embryonic tissues from which these tissue types developed are color-coded as indicated in Figure 9-41b. It is apparent that more closely related cell types, such as fibroblasts from different regions of the body, or endothelial cells that line the inner surfaces of blood vessels from different organs, have more similar DHSs than more distantly related cell types. With computer methods, it is possible to compare the similarity of the DHS maps for each of these cell types across the entire genome. With these computational methods, a dendrogram can be generated showing how closely the DHS map from one cell type resembles those of other cell types (see Figure 9-41b). This dendrogram is similar to the dendrograms used to show the relatedness, and hence the evolution, of gene sequences (see Figure 8-21b).

Importantly, the DHS pattern of embryonic stem cells is at the root of the DHS dendrogram for all cell types (see Figure 9-41b). These cells from the inner cell mass of the early mammalian embryo, discussed in Chapter 21 (see Figure 21-5), are the progenitors of all cells in the adult organism. Embryonic stem cells appear to have the most complex transcriptional control of all cells in that they have the largest number of DHSs: about 257,000 in one study, compared with 90,000–150,000 in differentiated cells. This difference probably reflects the developmental potential of embryonic stem cells. Approximately 30 percent of the DHSs observed in adult differentiated cells are also observed in embryonic stem cells, but a different 30 percent is retained in each adult cell type. An additional 50,000–100,000 new DHSs not found in embryonic stem cells arise during development, but a different set of DHSs arises in each cell type. These DHS patterns reveal the complexity of the combinations of transcription factors that regulate each gene. Approximately a million distinct DHSs were characterized in the cell types shown in Figure 9-41, suggesting that on average, combinations of four or five enhancers regulate the transcription of each of the roughly 21,000 genes in the human genome. This analysis excluded the central nervous system, probably the most complex organ system of all, so the total number of human enhancers may be much larger. But in the tissues analyzed, the maps of DHSs reveal where binding of early embryonic

**FIGURE 9-41 Maps of DNase I hypersensitive sites in embryonic and adult cells reflect their developmental history.** (a) DHSs from each of the human cell types shown at the left are mapped in the interval on chromosome 12 between 96.2 and 96.8 Mb from the left end. The height of each vertical bar in the figure represents the number of times a sequence in a 50-bp interval at that position was sequenced after following the protocol described in the text to ligate a linker of known sequence to DNA ends resulting from low-level DNase I digestion of chromatin. The plots are color-coded according to the embryonic tissue from which they developed, as shown in (b). (b) Dendrogram showing the relationships among the DHS maps for each cell type across the entire genome. The embryonic tissue from which each of these cell types develops is shown at the right. Embryonic stem cells form the root of the dendrogram. The DHS maps for all other cell types are derived from those for the embryonic stem cell by loss of some DHSs and the acquisition of other DHSs. The dendrogram, based on how closely DHS maps from two cell types are related, parallels the developmental relationships among the cell types. [Republished with permission of Elsevier, Stergachis, A.B., et al., "Developmental Fate and Cellular Maturity Encoded in Human Regulatory DNA Landscapes," *Cell*, 2013, **154**: 888-903; permission conveyed through Copyright Clearance Center, Inc.]

transcription factors is lost and where new cell-type-specific combinations of transcription factors bind as a cell differentiates from the embryonic stem cell. Even this estimate fails to capture the complexity of transcriptional control, since many transcription-factor-binding sites detected as one DHS are bound by different related transcription factors expressed in different cell types. Often different related transcription factors bind to the same transcription-control region in different cell types to regulate the appropriate level of transcription for that cell type.

## Nuclear Receptors Are Regulated by Extracellular Signals

In addition to controlling the expression of transcription factors, cells also regulate the activities of many of the transcription factors expressed in a particular cell type. For example, many transcription factors are regulated by intercellular signals. Interactions between the extracellular domains of transmembrane receptor proteins on the surface of the cell and specific protein ligands for these receptors secreted by other cells or expressed on the surfaces of neighboring cells activate the intracellular domains of these transmembrane proteins, transducing the signal received on the outside of the cell to a signal on the inside of the cell. The intracellular signal then regulates the activities of enzymes that modify transcription factors by phosphorylation, acetylation, and other types of post-translational protein modifications. These post-translational modifications activate or inhibit transcription factors in the nucleus. In Chapter 16, we describe the major types of cell-surface receptors for protein ligands and the intracellular signaling pathways that regulate transcription-factor activity.

Here we discuss another major group of extracellular signals that regulate the activities of transcription factors: small, lipid-soluble hormones including many different steroid hormones, retinoids, and thyroid hormones. These lipid-soluble hormones can diffuse through the plasma and nuclear membranes and interact directly with the transcription factors they control (Figure 9-42). As noted earlier, transcription factors regulated by lipid-soluble hormones include the *nuclear-receptor superfamily*. These transcription

factors function as transcription activators only when bound to their ligands.

## All Nuclear Receptors Share a Common Domain Structure

Sequencing of cDNAs derived from mRNAs encoding various nuclear receptors has revealed remarkable conservation in their amino acid sequences. It has also revealed that each of these receptors has three functional regions (Figure 9-43). The first is a unique N-terminal region of variable length (100–500 amino acids). Portions of this variable region function as activation domains in most nuclear receptors. The second is a DNA-binding domain that maps near the center of the primary sequence and contains a repeat of the C<sub>4</sub> zinc-finger motif (see Figure 9-30b). The third region, the hormone-binding domain, located near the C-terminal end, contains a hormone-dependent activation domain (see Figure 9-31b, c). In some nuclear receptors, the hormone-binding domain functions as a repression domain in the absence of ligand.

## Nuclear-Receptor Response Elements Contain Inverted or Direct Repeats

The DNA sites to which nuclear receptors bind are called *response elements*. The characteristic nucleotide sequences of several response elements have been determined. The consensus sequences of response elements for two steroid hormone receptors, the glucocorticoid receptor response element (GRE) and the estrogen receptor response element (ERE) are 6-bp inverted repeats separated by any three base pairs (Figure 9-44a, b). This finding suggested that the cognate steroid hormone receptors would bind to DNA as symmetric dimers (i.e., dimers with twofold rotational symmetry), as was later confirmed by x-ray crystallographic analysis of the homodimeric glucocorticoid receptor's C<sub>4</sub> zinc-finger DNA-binding domain (see Figure 9-30b).

Some nuclear-receptor response elements, such as those for the receptors that bind nonsteroids such as vitamin D<sub>3</sub>, thyroid hormone, and retinoic acid, are direct repeats of the same sequence that is recognized by the estrogen receptor, separated by three, four, or five base pairs (Figure 9-44c–e).

**FIGURE 9-42 Examples of hormones that bind to nuclear receptors.** These and related lipid-soluble hormones diffuse through the plasma and nuclear membranes and bind to receptors located in the cytosol or nucleus. The ligand-receptor complex functions as a transcription activator.

**FIGURE 9-43 General design of transcription factors in the nuclear-receptor superfamily.** The centrally located DNA-binding domain exhibits considerable sequence homology among different receptors and contains two copies of the  $C_4$  zinc-finger motif

(see Figure 9-30b). The C-terminal hormone-binding domain exhibits somewhat less homology. The N-terminal regions of various receptors vary in length, have unique sequences, and may contain one or more activation domains. See R. M. Evans, 1988, *Science* **240**:889.

**FIGURE 9-44 Consensus sequences of DNA response elements that bind five nuclear receptors.** (a, b) The glucocorticoid and estrogen receptors are twofold symmetric dimers that bind, respectively, to the glucocorticoid receptor response element (GRE) and the estrogen receptor response element (ERE). Each of these response elements contains inverted repeats separated by three base pairs. (c–e) The heterodimeric nuclear receptors each contain one RXR subunit associated with another nuclear-receptor subunit that defines the hormone response. RXR-VDR mediates responses to vitamin  $D_3$  by binding to a direct repeat separated by three base pairs (a VDRE). RXR-TR mediates responses to thyroid hormone by binding to the same DNA bases in a direct repeat separated by four base pairs (a TRE). Similarly, RXR-RAR mediates a response to retinoic acid by binding to the same direct repeat separated by five base pairs, comprising a RARE. The repeat sequences bound by the reading helices of these receptors are indicated by red arrows. (f) Crystal structures of the glucocorticoid receptor bound to DNA containing a GRE (top) and of the RXR-TR heterodimer bound to DNA containing a TRE (bottom). Red arrows indicate the orientation from N to C of the helices below them. Note that in the twofold symmetric glucocorticoid receptor, the reading helices are inverted relative to each other so that they “read” an AGAACA on the top strand of the left half-site and on the bottom strand of the right half-site, separated by 3 base pairs. Consequently, the binding site for the glucocorticoid receptor and other twofold symmetric homodimers such as the estrogen receptor is an inverted repeat (see a and b). In contrast, the reading helices in the RXR-TR heterodimer are in the same orientation. Consequently, they read an AGGTCA sequence in the same orientation in the two-half sites separated by four base pairs, a direct-repeat binding site. The interface between the RXR subunit and the vitamin  $D_3$  receptor (VDR) subunit bound to a VDRE brings the two reading helices closer together so that they bind to the same half-sites separated by three rather than four base pairs. Similarly, the interface between the RXR and RAR subunits bound to a RARE positions the two reading helices in the heterodimer farther apart than in the RXR-TR, so that they bind the same AGGTCA sequences separated by five base pairs. See K. Umesonon et al., 1991, *Cell* **65**:1255, and A. M. Naar et al., 1991, *Cell* **65**:1267. [Part (f) top data from B. F. Luisi et al., 1991, *Nature* **352**:497–505, PDB ID 1glu. Part (f) bottom data from F. Rastinejad et al., 1995, *Nature* **375**:203, PDB ID 2nll.]

The specificity of these response elements is determined by the spacing between the repeats. The nuclear receptors that bind to these direct-repeat response elements do so as heterodimers, all of which share a monomer called RXR. The vitamin D<sub>3</sub> response element (VDRE), for example, is bound by the RXR-VDR heterodimer, and the retinoic acid response element (RARE) is bound by RXR-RAR. The monomers composing these heterodimers interact with each other in such a way that the two DNA-binding domains lie in the same rather than inverted orientation, allowing the RXR heterodimers to bind to direct repeats of the binding site for each monomer (Figure 9-44f). In contrast, the monomers in homodimeric nuclear receptors (e.g., GRE and ERE) have an inverted orientation.

### Hormone Binding to a Nuclear Receptor Regulates Its Activity as a Transcription Factor

The mechanism whereby hormone binding controls the activity of nuclear receptors differs between heterodimeric and homodimeric receptors. Heterodimeric nuclear receptors (e.g., RXR-VDR, RXR-TR, and RXR-RAR) are located exclusively in the nucleus. In the absence of their hormone ligand, they repress transcription when bound to their cognate sites in DNA. They do so by directing histone deacetylation at nearby nucleosomes by associating with histone deacetylase complexes, as described earlier for other repressors (see Figure 9-37a). When heterodimeric nuclear receptors bind their ligand, they undergo a conformational change, and as a consequence, they bind histone acetylase complexes, thereby reversing their own repressing effects. In the presence of ligand, the ligand-bound conformation of the receptor also binds Mediator, stimulating preinitiation complex assembly.

In contrast to heterodimeric nuclear receptors, homodimeric receptors are found in the cytoplasm in the absence of their ligands. Hormone binding to these receptors leads to their translocation to the nucleus. The hormone-dependent translocation of the homodimeric glucocorticoid receptor (GR) was demonstrated in the transfection experiments shown in Figure 9-45a–c. The GR hormone-binding domain alone mediates this transport. Subsequent studies showed that in the absence of hormone, GR cannot be transported into the nucleus because its ligand-binding domain is partially unfolded by the major cellular chaperone Hsp70. As long as the receptor is confined to the cytoplasm, it cannot interact with target genes and hence cannot activate transcription. Hormone binding promotes a “handoff” of GR from Hsp70 to Hsp90, which, with coupled hydrolysis of ATP, refolds the GR ligand-binding domain, increasing the affinity for hormone and releasing GR from Hsp70 so that it can enter the nucleus. Once in the nucleus in the conformation induced by ligand binding, it can bind to response elements associated with target genes (Figure 9-45d). Once the receptor with bound hormone binds to a response element, it activates transcription by interacting with chromatin-remodeling and histone acetylase complexes and Mediator.

### Metazoans Regulate the RNA Polymerase II Transition from Initiation to Elongation

A recent unexpected discovery that resulted from application of the chromatin immunoprecipitation technique (see Figure 9-18) is that a large fraction of genes in metazoans have a paused elongating RNA polymerase II within about 100 bp of the transcription start site. Thus expression of the encoded protein is controlled not only by transcription initiation, but also by transcription elongation early in the transcription unit. The first genes discovered to be regulated by control of transcription elongation were *heat-shock genes* (e.g., *hsp70*), which encode molecular chaperones that help to refold denatured proteins and other proteins that help the cell to deal with the effects of heat shock. When heat shock occurs, the heat-shock transcription factor (HSTF) is activated. Binding of activated HSTF to specific sites in the promoter-proximal region of heat-shock genes stimulates the paused polymerase to continue chain elongation and promotes rapid reinitiation by additional Pol II molecules, leading to many transcription initiations per minute. This mechanism of transcriptional control permits a rapid response: these genes are always paused in a state of suspended transcription and therefore, when an emergency arises, no time is required to remodel and acetylate chromatin at the promoter and assemble a transcription preinitiation complex.

Another transcription factor shown to regulate transcription by controlling elongation by Pol II paused near the transcription start site is MYC, which functions in the regulation of cell growth and division. MYC is often expressed at high levels in cancer cells and is a key transcription factor in the reprogramming of somatic cells into pluripotent stem cells capable of differentiation into any cell type. The ability to induce differentiated cells to convert to pluripotent stem cells has elicited enormous research interest because of its potential for the development of therapeutic treatments for traumatic injuries to the nervous system and degenerative diseases (see Chapter 21).

### Termination of Transcription Is Also Regulated

Once Pol II has transcribed about 200 nucleotides from the transcription start site, elongation through most genes is highly processive. Chromatin immunoprecipitation with antibody to Pol II, however, indicates that the amount of Pol II at various positions in a transcription unit in a population of cells varies greatly (see Figure 9-18b, *right*). This finding indicates that the enzyme can elongate through some regions much more rapidly than others. In most cases, Pol II does not terminate transcription until after a sequence is transcribed that directs cleavage and polyadenylation of the RNA at the sequence that forms the 3' end of the encoded mRNA. Pol II can then terminate transcription at any of multiple sites located 0.5–2 kb beyond this poly(A) addition site. Experiments with mutant genes show that termination is coupled to the process that cleaves and polyadenylates the 3' end of a transcript, which is discussed in the next chapter.

**EXPERIMENTAL FIGURE 9-45 Fusion proteins demonstrate that the hormone-binding domain of the glucocorticoid receptor mediates translocation to the nucleus in the presence of hormone.**

Cultured animal cells were transfected with expression vectors encoding the proteins diagrammed at the bottom. Immunofluorescence with a labeled antibody specific for  $\beta$ -galactosidase was used to detect the expressed proteins in transfected cells. (a) In cells that expressed  $\beta$ -galactosidase alone, the enzyme was localized to the cytoplasm in the presence and absence of the glucocorticoid hormone dexamethasone (Dex). (b) In cells that expressed a fusion protein consisting of  $\beta$ -galactosidase and the entire glucocorticoid receptor (GR), the fusion protein was present in the cytoplasm in the absence of hormone but was transported to the nucleus in the presence of hormone. (c) Cells that expressed a fusion protein composed of  $\beta$ -galactosidase and only the GR ligand-binding domain (light purple) also exhibited hormone-dependent transport of the fusion protein to the nucleus. (d) Model of hormone-dependent gene activation by a homodimeric nuclear receptor. In the absence of hormone, the receptor is kept in the cytoplasm by interaction between its ligand-binding domain (LBD) and chaperone proteins. When hormone is present, it diffuses through the plasma membrane and binds to the ligand-binding domain, causing a conformational change that releases the receptor from the chaperone proteins. The receptor with bound ligand is then translocated into the nucleus, where its DNA-binding domain (DBD) binds to response elements, allowing the ligand-binding domain and an additional activation domain (AD) at the N-terminus to stimulate transcription of target genes. [Parts (a)–(c) from Picard, D. and Yamamoto, K. R., "Two signals mediate hormone-dependent nuclear localization of the glucocorticoid receptor," *EMBO J.*, 1987, 6(11):3333–3340; courtesy of the authors.]

## KEY CONCEPTS OF SECTION 9.6

### Regulation of Transcription-Factor Activity

- The activities of many transcription factors are indirectly regulated by binding of extracellular proteins and peptides to cell-surface receptors. These receptors activate intracellular signal transduction pathways that regulate specific transcription factors through a variety of mechanisms discussed in Chapter 16.

- Nuclear receptors constitute a superfamily of dimeric C4 zinc-finger transcription factors that bind lipid-soluble hormones and interact with specific response elements in DNA (see Figures 9-42 and 9-44).
- Hormone binding to nuclear receptors induces conformational changes that modify the interactions of these receptors with other proteins (see Figure 9-31b, c).
- Heterodimeric nuclear receptors (e.g., those for retinoids, vitamin D, and thyroid hormone) are found only in the

nucleus. In the absence of hormone, they repress transcription of target genes with the corresponding response element. When bound to their ligands, they activate transcription.

- Steroid hormone receptors are homodimeric nuclear receptors. In the absence of hormone, they are trapped in the cytoplasm by molecular chaperones. When bound to their ligands, they can translocate to the nucleus and activate transcription of target genes (see Figure 9-45).
- DNase I hypersensitive sites (DHSs) indicate the positions of transcription-factor binding in chromatin, although they do not indicate which transcription factor is bound. Nonetheless, mapping of DHSs in differentiating cells gives an overview of how transcription-factor-binding sites change as a cell differentiates into a specific cell type.
- In metazoans, RNA polymerase II often pauses during elongation within approximately 50–100 base pairs from the transcription start site. Release from this pause contributes to the regulation of gene transcription.
- Resumption of elongation by Pol II paused in the promoter-proximal region is also required for gene transcription and is a regulated step.
- In most cases, Pol II does not terminate transcription until after a sequence is transcribed that directs cleavage and polyadenylation of the RNA.

## 9.7 Epigenetic Regulation of Transcription

The term **epigenetics** refers to the study of inherited changes in the phenotype of a cell that do not result from changes in DNA sequence. For example, during the differentiation of bone marrow stem cells into the several different types of blood cells, a hematopoietic stem cell divides into two daughter cells, one of which continues to have the properties of a hematopoietic stem cell, including the potential to differentiate into all the different types of blood cells. But the other daughter cell becomes either a lymphoid progenitor cell or a myeloid progenitor cell (see Figure 21-17). Lymphoid progenitor cells generate daughter cells that differentiate into lymphocytes, which perform many of the functions involved in immune responses to pathogens (see Chapter 23). Myeloid progenitor cells divide into daughter cells that are committed to differentiating into red blood cells, different kinds of phagocytic white blood cells, or the cells that generate platelets involved in blood clotting. Lymphoid and myeloid progenitor cells both have the same DNA sequence as the zygote (generated by fertilization of an egg cell by a sperm cell) from which they developed, but they have restricted developmental potential because of epigenetic differences between them.

Such epigenetic changes are initially the consequence of the expression of specific master transcription factors that are regulators of cellular differentiation, controlling the expression of other genes that encode transcription factors and proteins involved in cell-cell communication in complex networks of gene control, and which are currently the subject of intense investigation. Changes in gene expression initiated by transcription factors are often reinforced and maintained over multiple cell divisions by post-translational modifications of histones and methylations of DNA at position 5 of the cytosine pyrimidine ring (see Figure 2-17) that are maintained and propagated to daughter cells when cells divide. Consequently, the term *epigenetic marks* is used to refer to such post-translational modifications of histones and 5-methyl C modification of DNA.

### DNA Methylation Represses Transcription

As mentioned earlier, most promoters in mammals fall into the CpG island class. Active CpG island promoters have Cs in their CG sequences that are unmethylated. Unmethylated CpG island promoters have reduced affinity for histone octamers, but nucleosomes immediately neighboring the unmethylated promoters are modified by histone H3 lysine 4 di- or trimethylation and are associated with Pol II molecules that are paused during transcription of both the sense and antisense template DNA strands, as discussed earlier (see Figures 9-18 and 9-19). Recent research indicates that methylation of histone H3 lysine 4 occurs in mouse cells because a protein named Cfp1 (CXXC finger protein 1) binds unmethylated CpG-rich DNA through a zinc-finger domain (CXXC) and associates with a histone methylase specific for histone H3 lysine 4 (Setd1). Chromatin-remodeling complexes and the general transcription factor TFIID, which initiates Pol II preinitiation complex assembly (see Figure 9-19), associate with nucleosomes bearing the H3 lysine 4 trimethyl mark, promoting Pol II transcription initiation.

In differentiated cells, however, a small percentage of specific CpG island promoters, depending on the cell type, have CpGs marked by 5-methyl C. This modification of CpG island DNA triggers chromatin condensation. A family of proteins that bind to DNA that is rich in 5-methyl C–modified CpGs (called methyl CpG-binding proteins, or MBDs) bind to the marked promoters and associate with histone deacetylases and repressive chromatin-remodeling complexes that condense chromatin, resulting in transcriptional repression. The 5-methyl C is added to the CpGs by DNA methyl transferases named DNMT3a and DNMT3b. They are referred to as *de novo* DNA methyl transferases because they methylate an unmethylated C. Much remains to be learned about how DNMT3a and b are directed to specific CpG islands. But once they have methylated a DNA sequence, methylation at that C is passed on through DNA replication through the action of the ubiquitous *maintenance* methyl transferase DNMT1:

(red indicates daughter strands). As a consequence, once a CpG island promoter is methylated by DNMT3a or b, it continues to be methylated by DNMT1 in subsequent daughter cells. Consequently, the promoter remains repressed in all subsequent daughter cells through interactions with MBDs, even after the stimulus for the initial C-methylation by DNMT3a or b has ceased. Therefore, repression of C-methylated promoters is inherited through cell division. This mechanism of epigenetic repression is being intensely investigated because tumor-suppressor genes encoding proteins that function to suppress the development of cancer are often inactivated in cancer cells by abnormal CpG methylation of their promoter regions, as discussed further in Chapter 24.

### Methylation of Specific Histone Lysines Is Linked to Epigenetic Mechanisms of Gene Repression

Figure 8-26b summarized the different types of post-translational modifications that are found on histones, including acetylation of lysines and methylation of lysines on the nitrogen atom of the terminal  $\epsilon$ -amino group of the lysine side chain (see Figure 2-14). Lysines can be modified by the addition of one, two, or three methyl groups to this terminal nitrogen atom, generating mono-, di-, and trimethylated lysine, all of which carry a single positive charge.

The acetylation state at a specific histone lysine on a particular nucleosome results from a dynamic equilibrium between acetylation and deacetylation by histone acetylases and histone deacetylases, respectively. Acetylation of histones in a localized region of chromatin predominates when local DNA-bound activators transiently bind histone acetylase complexes. Deacetylation predominates when repressors transiently bind histone deacetylase complexes. Pulse-chase radiolabeling experiments have shown that acetyl groups on histone lysines turn over rapidly through the sequential actions of histone acetylases and histone deacetylases. In contrast, methyl groups on histones are much more stable. Histone lysine methyl groups can be removed by *histone lysine demethylases*. But the resulting turnover of histone lysine methyl groups is much slower than the turnover of histone lysine acetyl groups, which makes methylation the more appropriate post-translational modification for propagating epigenetic information.

Several other post-translational modifications of histones have been characterized (see Figure 8-26b). These modifications all have the potential to positively or negatively regulate the binding of proteins that interact with the chromatin fiber to regulate transcription as well as other processes, such as chromosome folding into the highly condensed structures that form during mitosis (see Figures 8-35 and 8-36). A picture of chromatin has emerged in which histone tails extending as random coils from the chromatin fiber are

post-translationally modified to generate one of many possible combinations of modifications that regulate transcription and other processes by regulating the binding of a large number of different protein complexes. This control of the interactions of proteins with specific regions of chromatin that results from the combined influences of various post-translational modifications of histones has been called a *histone code*. Some of these modifications, such as histone lysine acetylation, are rapidly reversible, whereas others, such as histone lysine methylation, can be templated through chromatin replication, generating epigenetic inheritance in addition to inheritance of DNA sequence. Table 9-3 summarizes the influence that post-translational modifications of specific histone amino acid residues usually have on transcription.

**Histone H3 Lysine 9 Methylation in Heterochromatin** In most eukaryotes, some co-repressor complexes contain histone methyl transferase subunits that methylate histone H3 at lysine 9, generating di- and trimethyl lysines. These methylated lysines are binding sites for isoforms of HP1 protein that function in the condensation of heterochromatin, as discussed in Chapter 8 (see Figure 8-29). For example, the KAP1 co-repressor complex functions with a class of more than 200 zinc-finger transcription factors encoded in the human genome. This co-repressor complex includes an H3 lysine 9 methyl transferase that methylates nucleosomes over the promoter regions of repressed genes, leading to HP1 binding and repression of transcription. An integrated transgene in cultured mouse fibroblasts that was repressed through the action of the KAP1 co-repressor was associated with heterochromatin in most cells, whereas the active form of the same transgene was associated with euchromatin (Figure 9-46). Chromatin immunoprecipitation assays (see Figure 9-18) showed that the repressed gene was associated with histone H3 methylated at lysine 9 and with HP1, whereas the active gene was not.

Importantly, H3 lysine 9 methylation is maintained following chromosome replication by the mechanism diagrammed in Figure 9-47. When a methylated region of DNA is replicated in S phase, the histone octamers associated with the parent DNA are randomly distributed to the daughter DNA molecules. New histone octamers that are not methylated on lysine 9 also associate randomly with the new daughter chromosomes, but since the parent histone octamers are associated with both daughter chromosomes, approximately half of the daughter chromosomes' nucleosomes are methylated on lysine 9. Association of histone H3 lysine methyl transferases (directly or indirectly) with the parent methylated nucleosomes leads to methylation of the newly assembled histone octamers. Repetition of this process with each cell division results in maintenance of H3 lysine 9 methylation of this region of the chromosome.

**TABLE 9-3 Histone Post-Translational Modifications Associated with Active and Repressed Genes**

Modification	Sites of Modification	Effect on Transcription
Acetylated lysine	H3 (K9, K14, K18, K27, K56) H4 (K5, K8, K13, K16) H2A (K5, K9, K13) H2B (K5, K12, K15, K20)	Activation Activation Activation Activation
Hypoacetylated lysine		Repression
Phosphorylated serine/threonine	H3 (T3, S10, S28) H2A (S1, T120) H2B (S14)	Activation Activation Activation
Methylated arginine	H3 (R17, R23) H4 (R3)	Activation Activation
Methylated lysine	H3 (K4) Me3 in promoter region H3 (K4) Me1 in enhancers H3 (K36, K79) in transcribed region H3 (K9, K27) H4 (K20)	Activation Elongation Repression Repression
Ubiquitinated lysine	H2B (K120 in mammals, K123 in <i>S. cerevisiae</i> ) H2A (K119 in mammals)	Activation Repression

**FIGURE 9-46 Association of a repressed transgene with heterochromatin.** Mouse fibroblasts were stably transformed with a transgene that contained binding sites for an engineered repressor. The repressor was a fusion between a DNA-binding domain, a repression domain that interacts with the KAP1 co-repressor complex, and the ligand-binding domain of a nuclear receptor that allows the nuclear import of the fusion protein to be controlled experimentally (see Figure 9-45). DNA was stained blue with the dye DAPI. Brighter-staining regions are regions of heterochromatin, where the DNA concentration is higher than in euchromatin. The transgene was detected by hybridization of a fluorescently labeled complementary probe (green). When the recombinant

repressor was retained in the cytoplasm, the transgene was transcribed (*left*) and was associated with euchromatin in most cells. When hormone was added so that the recombinant repressor entered the nucleus, the transgene was repressed (*right*) and associated with heterochromatin. Chromatin immunoprecipitation assays (see Figure 9-18) showed that the repressed gene was associated with histone H3 methylated at lysine 9 and HP1, whereas the active gene was not. [From Ayyanathan, K. et al., "Regulated recruitment of HP1 to a euchromatic gene induces mitotically heritable, epigenetic gene silencing: a mammalian cell culture model of gene variation," *Genes and Development*, 2003, **17**:1855–1869. Courtesy of Frank Rauscher; republished with permission from Cold Spring Harbor Laboratory Press.]

## Epigenetic Control by Polycomb and Trithorax Complexes

Another type of epigenetic mark that is essential for repression of genes in specific cell types in multicellular animals and plants involves a set of proteins known collectively as

Polycomb proteins and a counteracting set of proteins known as Trithorax proteins. These names were derived from the phenotypes of mutations in the genes encoding these proteins in *Drosophila*, in which they were first discovered. The Polycomb repression mechanism is essential for maintaining the repression of genes in specific types of cells, and in

**FIGURE 9-47 Maintenance of histone H3 lysine 9 methylation during chromosome replication.** When chromosomal DNA is replicated, the parent histones randomly associate with the two daughter chromosomes, while unmethylated histones synthesized during S phase are assembled into other nucleosomes in those same daughter chromosomes. Association of histone H3 lysine 9 methyl transferases (H3K9 HMT) with parent nucleosomes bearing the histone 3 lysine 9 di- or trimethylation mark methylates the newly added unmodified nucleosomes. Consequently, histone H3 lysine 9 methylation marks are maintained during repeated cell divisions unless they are specifically removed by a histone demethylase.

all the subsequent cells that develop from them, throughout the life of an organism. Important genes regulated by Polycomb proteins include the Hox genes, which encode master regulatory transcription factors. Different combinations of Hox transcription factors help to direct the development of specific tissues and organs in a developing embryo. Early in embryogenesis, expression of Hox genes is controlled by typical activator and repressor proteins. However, the expression of these activators and repressors stops at an early point in embryogenesis. Correct expression of the Hox genes in the descendants of the early embryonic cells is then maintained throughout the remainder of embryogenesis and on into adult life by the Polycomb proteins, which maintain the *repression* of specific Hox genes. Trithorax proteins perform the opposite function, maintaining the *expression* of the Hox genes that were expressed in a specific cell early in embryogenesis in all the subsequent descendants of that cell. Polycomb and Trithorax proteins control thousands of genes, including genes that regulate cell growth and division (i.e., the cell cycle, as discussed in Chapter 19). Polycomb and Trithorax genes are often mutated in cancer cells, contributing importantly to the abnormal properties of these cells (see Chapter 24).

Remarkably, virtually all cells in the developing embryo and adult express a similar set of Polycomb and Trithorax proteins, and all cells contain the same set of Hox genes. Yet only the Hox genes in cells where they were initially

repressed in early embryogenesis remain repressed, even though the same Hox genes in other cells remain active in the presence of the same Polycomb proteins. Consequently, as in the case of the yeast silent mating-type loci, the expression of Hox genes is regulated by a process that involves more than specific DNA sequences interacting with proteins that diffuse through the nucleoplasm.

A current model for repression by Polycomb proteins is depicted in Figure 9-48. Most Polycomb proteins are subunits of one of two classes of multiprotein Polycomb repressive complexes: PRC1 and PRC2. The PRC2 complexes are thought to act initially by associating with the repression domains of specific repressors bound to their cognate DNA sequences early in embryogenesis, or with ribonucleoprotein complexes containing long noncoding RNAs, as discussed in a later section. The PRC2 complexes contain histone deacetylases that inhibit transcription, as discussed above. They also contain a subunit [E(z) in *Drosophila*, EZH2 in mammals] with a *SET domain*, which is the catalytic domain of several histone methyl transferases. This SET domain in PRC2 complexes methylates histone H3 on lysine 27, generating di- and trimethyl lysines. A PRC1 complex then binds the methylated nucleosomes through dimeric Pc subunits (CBXs in mammals), each containing a methyl lysine-binding domain (called a *chromodomain*) specific for methylated H3 lysine 27. Binding of the dimeric Pc to neighboring nucleosomes is proposed to condense the chromatin into a structure that inhibits transcription. This proposal is supported by electron microscopy studies showing that PRC1 complexes cause nucleosomes to associate in vitro (Figure 9-48d, e).

PRC1 complexes also repress transcription through additional mechanisms. The PRC1 complex contains a ubiquitin ligase that *monoubiquitinylates* histone H2A at lysine 119 in the H2A C-terminal tail (see Figure 8-26). This modification of H2A inhibits elongation by inhibiting a histone chaperone that removes histone octamers from DNA as Pol II transcribes through a nucleosome, then replaces them as the polymerase passes. PRC1 also associates with a histone demethylase that specifically removes methyl groups from lysine 4 of histone H3, an activating mark discussed above.

PRC2 complexes associate with nucleosomes bearing the histone H3 lysine 27 trimethylation mark, maintaining methylation of H3 lysine 27 in nucleosomes in the region. This methylation results in association of the chromatin with PRC1 and PRC2 complexes even after expression of the initial repressor proteins shown in Figure 9-48a, b has ceased. This association maintains H3 lysine 27 methylation by a mechanism analogous to that diagrammed in Figure 9-47. This mechanism is a key feature of Polycomb repression, which is maintained through successive cell divisions for the life of an organism (~100 years for some vertebrates, 2000 years for a sugar cone pine!).

Trithorax proteins counteract the repressive mechanism of Polycomb proteins, as shown in studies of expression of the Hox transcription factor Abd-B in the *Drosophila* embryo (Figure 9-49). Abd-B is normally expressed only in posterior segments of the developing embryo. When the

**FIGURE 9-48 Model for repression by Polycomb complexes.**

(a) During early embryogenesis, repressors associate with the PRC2 complex. (b) This association results in methylation (Me) of neighboring nucleosomes on histone H3 lysine 27 (K27) by the SET domain-containing subunit E(z). (c) The PRC1 complex binds nucleosomes methylated at H3 lysine 27 through a dimeric, chromodomain-containing subunit Pc. The PRC1 complex condenses the chromatin into a repressed chromatin structure. PRC2 complexes associate with PRC1 complexes to maintain H3 lysine 27 methylation of neighboring

histones. As a consequence, PRC1 and PRC2 association with the region is maintained when expression of the repressor proteins in (a) ceases. **FIGURE 9-49 Opposing influence of Polycomb and Trithorax complexes on expression of the Hox transcription factor Abd-B in *Drosophila* embryos.**

At the stage of *Drosophila* embryogenesis shown, Abd-B is normally expressed only in posterior segments of the developing embryo, as shown at the top (wt) by immunostaining with a specific anti-Abd-B antibody. In embryos with homozygous mutations of *Scm*, a Polycomb gene (PcG) encoding a protein associated with the PRC1 complex, Abd-B expression is derepressed in all embryo segments. In contrast, in homozygous mutants of *trx*, a Trithorax gene (trxG), Abd-B repression is increased so that the protein is expressed at high concentrations only in the most posterior segment. [From Klymenko, T., and Muller, J., "The histone methyltransferases Trithorax and Ash1 prevent transcriptional silencing by Polycomb group proteins," *EMBO Reports* ©2004 John Wiley and Sons. Reproduced with permission of Wiley-VCH.]

Polycomb system is defective, Abd-B is expressed in all cells of the embryo. When the Trithorax system is defective and cannot counteract repression by the Polycomb system, Abd-B is repressed in most cells, except those in the very posterior of the embryo. Trithorax complexes include a histone methyl transferase that trimethylates histone H3 lysine 4, a histone methylation that is associated with the promoters of actively transcribed genes. This histone modification creates a binding site for histone acetylase and for chromatin-remodeling complexes that promote transcription, as well as for TFIID, the general transcription factor that initiates preinitiation-complex assembly (see Figure 9-19). Nucleosomes with H3 lysine 4 methylation are also binding sites for specific histone demethylases that remove H3 histone K9 and K27 methylation, preventing the binding of HP1 and the Polycomb repressive complexes. Nucleosomes marked with H3 lysine 4 methylation are also thought to be distributed to both daughter DNA molecules during DNA replication, resulting in maintenance of this epigenetic mark by a strategy similar to that diagrammed in Figure 9-47.

## Long Noncoding RNAs Direct Epigenetic Repression in Metazoans

Repressive complexes have been discovered that are composed of multiple repressing proteins bound to RNAs many kilobases in length that do not contain long open reading frames and are consequently called **long noncoding RNAs** or **lncRNAs**. In some cases, these lncRNA-protein complexes repress genes on the same chromosome from which the RNA is transcribed, as in the case of X-chromosome inactivation in female mammals. In other cases, these repressive RNA-protein complexes act in trans, repressing genes on chromosomes other than those from which the lncRNA is transcribed.

**X-Chromosome Inactivation in Mammals** The phenomenon of X-chromosome inactivation in female mammals (see Chapter 8) is one of the most intensely studied examples of epigenetic repression mediated by a lncRNA. X inactivation is controlled by a roughly 100-kb domain on the X chromosome called the *X-inactivation center*. Remarkably, this region encodes several lncRNAs required for the random inactivation of one entire X chromosome early in the development of female mammals. The functions of these lncRNAs are only partially understood. The most intensively studied are transcribed from the complementary DNA strands near the middle of the X-inactivation center: the 40-kb TSIX lncRNA and the XIST RNA, which is spliced and polyadenylated into an RNA of about 17 kb that is not exported to the cytoplasm (Figure 9-50a).

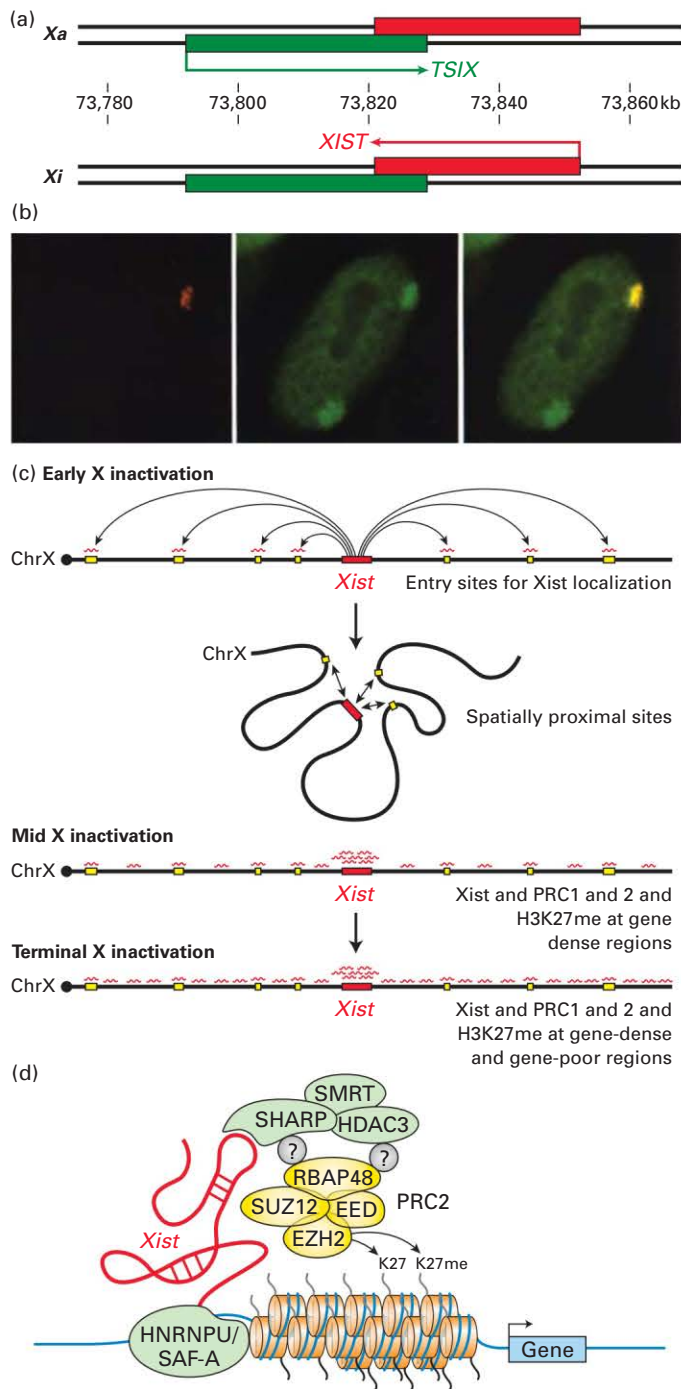

In differentiated female cells, the inactive X chromosome is associated with XIST RNA-protein complexes along its entire length (Figure 9-50b). Targeted deletion of the *Xist* gene (see Figure 6-39) in cultured embryonic stem cells showed that it is required for X inactivation. Unlike most protein-coding genes on the inactive X chromosome, the *Xist* gene is actively transcribed. The XIST RNA-protein complexes do not diffuse to interact with the active X or other chromosomes, but remain

associated with the inactive X chromosome. Since the full length of the inactive X becomes coated by XIST RNA-protein complexes (see Figure 9-50b), these complexes must spread along the chromosome from the X-inactivation center where XIST is transcribed. In contrast to XIST, TSIX is transcribed from the active X chromosome, not from the inactive X chromosome.

In the early female mouse embryo, made up of embryonic stem cells capable of differentiating into all cell types (see Chapter 21), genes on both X chromosomes are transcribed, and the 40-kb TSIX lncRNA (see Figure 9-50a) is transcribed from both copies of the X chromosome. Experiments employing engineered deletions in the X-inactivation center showed that TSIX transcription prevents significant transcription of the XIST RNA from the complementary DNA strand. Later in development, as cells begin to differentiate, TSIX transcription is repressed on one of the X chromosomes. This repression occurs randomly in different cells on the X chromosome derived from the sperm ( $X_p$ ) or on the X chromosome derived from the egg ( $X_m$ ). This inhibition of TSIX transcription determines which of the X chromosomes will be inactivated as the cells differentiate further because inhibition of TSIX transcription allows transcription of the XIST lncRNA on that chromosome.

The transcribed XIST RNA contains RNA sequences that, by unknown mechanisms, cause it to spread along the X chromosome. Recent studies indicate that XIST lncRNA-protein complexes first associate with regions of the X chromosome localized near the X-inactivation center in the three-dimensional, folded structure of the future inactive X (Figure 9-50c), as shown by chromosome conformation capture assays (see Figure 8-34). These initial sites of XIST association are in gene-rich regions of the X chromosome and are postulated to serve as “entry sites” where additional copies of the XIST lncRNA-protein complexes first bind and then spread to neighboring regions. The mechanism of spreading is not currently understood. The inactive X chromosome also becomes associated with PRC2 complexes, which catalyze the trimethylation of histone H3 lysine 27. This methylation results in association of the PRC1 complex and transcriptional repression, as discussed above. These mechanisms of transcriptional repression must be redundant, however, because repression still occurs in the absence of the Polycomb proteins essential for the assembly of PRC1 and PRC2. At the same time, continued transcription of TSIX from the other, active X chromosome continues, represses XIST transcription from that X chromosome, and consequently prevents XIST-mediated repression of the active X. XIST and PRC1 and 2 complexes are then observed to associate with gene-poor regions of the inactive X chromosome as well as with gene-rich regions.

Recent analysis by protein mass spectrometry (see Chapter 3) of proteins associated with XIST lncRNA during the initiation phase of X inactivation in cultured mouse embryonic stem cells revealed that SMRT, a protein first characterized as a co-repressor that interacts with the thyroid hormone nuclear receptor in the absence of hormone, is part of the protein complex that interacts with XIST RNA. SMRT, in turn, interacts with a histone deacetylase (HDAC3). Subsequent knockdown experiments with siRNAs directed against SMRT

**FIGURE 9-50 The Xist long noncoding RNA encoded in the X-inactivation center coats the inactive X chromosome in cells of mammalian females, repressing transcription of most genes on the inactive X.** (a) The region of the human X-inactivation center encoding the noncoding RNAs Xist (transcribed from the inactive X), and Tsix (transcribed from the active X). Numbers are base pairs from the left end of the X chromosome. (b) A cultured fibroblast from a human female was analyzed by in situ hybridization with a probe complementary to Xist RNA labeled with a red fluorescent dye (left), a chromosome paint set of probes for the X chromosome labeled with a green fluorescent dye (center), and an overlay of the two fluorescent micrographs. The condensed inactive X chromosome is associated with Xist RNA. (c) Model for the spreading of the Xist lncRNA-protein complex on the inactive X chromosome during early differentiation of female embryonic stem cells. See E. Heard and A.-V. Gendrel, 2014, *Annu. Rev. Cell Dev. Biol.* **30**:561. (d) Proteins associated with Xist lncRNA. Question marks indicate that it is not yet known how PRC2 complexes associate with HDAC3 and the RNA-binding protein SHARP. X through the multiple cell divisions that occur later during embryogenesis and throughout adult life.

**Trans Repression by Long Noncoding RNAs** Another example of transcriptional repression by a long noncoding RNA was discovered recently by researchers studying the function of noncoding RNAs transcribed from a region encoding a cluster of Hox genes, the *HOXC* locus, in cultured human fibroblasts. Depletion of a 2.2-kb noncoding RNA expressed from the *HOXC* locus by siRNA (see Figure 6-42) unexpectedly led to derepression of the *HOXD* locus, a roughly 40-kb region on another chromosome encoding several Hox proteins and multiple other noncoding RNAs, in these cells. Assays similar to chromatin immunoprecipitation showed that this noncoding RNA, named HOTAIR (for *Hox* Antisense Intergenic RNA), associates with the *HOXD* loci and with PRC2 complexes. This association results in histone H3 lysine 27 di- and trimethylation, PRC1 association, histone H3 lysine 4 demethylation, histone H2A monoubiquitinylation, and transcriptional repression. This process is similar to the recruitment of Polycomb complexes by Xist RNA, except that Xist RNA functions in cis, remaining in association with the chromosome from which it is transcribed, whereas HOTAIR leads to Polycomb repression in trans on both copies of another chromosome. Once again, redundant mechanisms for repression of these *HOXD* loci must exist, because extensive, but less complete, repression at the *HOXD* locus continues in the appropriate cells in mouse embryos with homozygous HOTAIR knockout mutations.

**Cis Activation by Long Noncoding RNAs** Examples of lncRNAs involved in gene activation have been characterized recently. For example, HOTTIP lncRNA, which is transcribed from the 5' end of the *HOXA* locus, is proposed to coordinate the activation of *HOXA* genes by binding to a histone H3 lysine 4 methylase. In addition, nascent

and HDAC3 showed that they are required for X inactivation, as are other identified RNA- and chromatin-binding proteins that link SMRT to XIST RNA and are required for the association of XIST RNA and PRC2 with the inactive X chromosome (Figure 9-50d). A short time later in development, the DNA of the inactive X also becomes methylated at most of its CpG island promoters. Specialized histone octamers in which histone H2A is replaced by a paralog of H2A called *macroH2A* also become associated with the inactive X. DNA methylation and macroH2A contribute to the stable repression of the inactive

transcripts of lncRNA genes have been reported to activate transcription from promoters several kilobases away by interacting with the Mediator complex and delivering it to the promoter by looping of the intervening chromatin.

In humans, but not in mice, a lncRNA called *XACT* has been discovered to associate with multiple sites along the full length of the active X chromosome and is postulated to contribute to maintenance of gene activity on that chromosome. *XACT* is also remarkable for being one of the longest characterized RNAs: 252 kb! It is mostly unspliced.

In *Drosophila*, equal expression of genes encoded on the X chromosome in males and females (dosage compensation) does not result from inactivating one X chromosome in females. Rather, a generalized twofold increase in transcriptional activation of genes on the single X chromosome in males is controlled by two lncRNAs, *roX1* and *roX2*, transcribed from the X chromosome in males only. The *roX1* and *roX2* RNAs associate with several proteins encoded by *MSL* (male-specific-lethal) genes and spread over the X chromosome specifically, much as *Xist* lncRNA-protein complexes spread over the inactive X in mammals.

Recently, sequencing of total cellular RNA in multiple types of human cells identified roughly 15,000 human lncRNAs. Many of these lncRNAs have sequences that are evolutionarily conserved in most mammals, and about 5000 are found only in primates. This conservation of sequence strongly suggests that these lncRNAs, like *XIST*, *HOTAIR*, and *HOTTIP*, have important functions. Multiple lncRNAs are expressed only in specific cell types at specific times during development. For example, multiple lncRNAs are expressed primarily in differentiating red blood cells. Knockdown (see Figure 6-42 and Chapter 10) of several of these lncRNAs inhibits normal red blood cell development, but precisely how these lncRNAs perform their essential functions is not yet clear. The study of these conserved long noncoding RNAs and how they influence gene expression is another area of intense current investigation.

**ENCODE (Encyclopedia of DNA Elements)** encompasses a consortium of international research groups organized and funded by the US National Human Genome Research Institute with the goal of building a comprehensive, publically available database of human DNA control elements and the transcription factors that bind to them in different cell types, histone post-translational modifications mapped by ChIP-seq and other related methods, DNase I hypersensitive sites, and regulatory lncRNAs and their sites of association in the genome, as well as newly discovered regulatory elements “that control cells and circumstances in which a gene is active.” Data sets from human cells and cells of model organisms that are too large to be published are also made publically available at a site called GEO (Gene Expression Omnibus) maintained by the US National Center for Bioinformatics (NCBI). Most journals that publish research based on genomic methods such as RNA-seq and ChIP-seq require that authors upload their original data to GEO. Worldwide public access to these data sets is greatly accelerating the pace of discovery in the area of gene regulation.

## KEY CONCEPTS OF SECTION 9.7

### Epigenetic Regulation of Transcription

- Epigenetic control of transcription refers to repression or activation that is maintained after cells replicate as the result of DNA methylation or post-translational modification of histones, especially histone methylation.
- Methylation of CpG sequences in CpG island promoters in mammals generates binding sites for a family of methyl-binding proteins (MBDs) that associate with histone deacetylases, inducing hypoacetylation of the promoter regions and transcriptional repression.
- Histone H3 lysine 9 di- and trimethylation creates binding sites for the heterochromatin-associated protein HP1, which results in the condensation of chromatin and transcriptional repression. These post-translational modifications are perpetuated following chromosome replication because the methylated histones are randomly associated with the daughter DNA molecules and associate with histone H3 lysine 9 methyl transferases that methylate histone 3 lysine 9 on newly synthesized histone octamers assembled on the daughter DNA.
- Polycomb complexes maintain repression of genes initially repressed by sequence-specific repressors expressed early during embryogenesis. One class of Polycomb repressive complexes, PRC2 complexes, associates with these repressors in early embryonic cells, resulting in methylation of histone H3 lysine 27. This methylation creates binding sites for subunits in the PRC2 complex as well as for PRC1 complexes, which condense chromatin, inhibit the assembly of preinitiation complexes, and inhibit elongation. Since parent histone octamers with H3 methylated at lysine 27 are distributed to both daughter DNA molecules following DNA replication, PRC2 complexes that associate with these nucleosomes maintain histone H3 lysine 27 methylation through cell division.
- Trithorax complexes oppose repression by Polycomb complexes by methylating H3 at lysine 4 and maintaining this activating mark through chromosome replication.
- X-chromosome inactivation in female mammals requires a long noncoding RNA (lncRNA) called *Xist* that is transcribed from the X-inactivation center of one X chromosome and then spreads by a poorly understood mechanism along the length of the same chromosome. *Xist* interacts with a co-repressor that binds a histone deacetylase and PRC2 complexes at an early stage of embryogenesis, initiating X inactivation. X inactivation is maintained throughout the remainder of embryogenesis and adult life by continued association with Polycomb complexes and DNA methylation of CpG island promoters on the inactive X.
- Some lncRNAs have been discovered that lead to repression of genes in trans, as opposed to the cis inactivation imposed by *Xist*. Repression is initiated by their interaction with PRC2 complexes.

- Some lncRNAs are associated with gene activation. Much remains to be learned about how lncRNAs are targeted to specific chromosomal regions, but the discovery of about 15,000 nuclear lncRNAs expressed in specific types of human cells during specific stages of their differentiation suggests that lncRNAs are central to widely used mechanisms of transcription regulation.

## 9.8 Other Eukaryotic Transcription Systems

We conclude this chapter with a brief discussion of transcription initiation by the other two eukaryotic nuclear RNA polymerases, Pol I and Pol III. The distinct polymerases that transcribe mitochondrial and chloroplast DNA will be discussed in Chapter 12, on cellular energetics. Although these systems, and particularly their regulation, are less thoroughly understood than transcription by RNA polymerase II, they are equally fundamental to the life of eukaryotic cells.

### Transcription Initiation by Pol I and Pol III Is Analogous to That by Pol II

The formation of transcription initiation complexes involving Pol I and Pol III is similar in some respects to assembly of Pol II initiation complexes (see Figure 9-19). However, each of the three eukaryotic nuclear RNA polymerases requires its own polymerase-specific general transcription factors and recognizes different DNA control elements. Moreover, neither Pol I nor Pol III requires ATP hydrolysis by a DNA helicase to help melt the DNA template strands to initiate transcription, whereas Pol II does. Transcription initiation by Pol I, which synthesizes pre-rRNA, and by Pol III, which synthesizes

tRNAs, 5S rRNA, and other small stable RNAs (see Table 9-2), is tightly coupled to the rate of cell growth and proliferation.

**Initiation by Pol I** The regulatory elements directing Pol I initiation are similarly located relative to the transcription start site in yeast and in mammals. A *core element* spanning the transcription start site from  $-40$  to  $+5$  is essential for Pol I transcription. An additional *upstream control element* extending from roughly  $-155$  to  $-60$  increases in vitro Pol I transcription tenfold. In humans, assembly of the Pol I preinitiation complex (Figure 9-51) is initiated by the cooperative binding of UBF (upstream binding factor) and SL1 (selectivity factor), a multisubunit factor containing TBP and four Pol I-specific TBP-associated factors (TAF<sub>I</sub>s), to the Pol I promoter region. The TAF<sub>I</sub> subunits interact directly with Pol I-specific subunits, directing this specific nuclear RNA polymerase to the transcription start site. TIF-1A, the mammalian homolog of *S. cerevisiae* RRN3, is another required factor, as are the abundant nuclear protein kinase CK2 (casein kinase 2), nuclear actin, nuclear myosin, the protein deacetylase SIRT7, and topoisomerase I, which prevents DNA supercoils (see Figure 5-8) from forming during rapid Pol I transcription of the 14-kb transcription unit.

Transcription of the 14-kb precursor of 18S, 5.8S, and 28S rRNAs (see Chapter 10) is highly regulated to coordinate ribosome synthesis with cell growth and division. This coordination is achieved through regulation of the activities of the Pol I initiation factors by post-translational modifications, including phosphorylation and acetylation at specific sites, control of the rate of Pol I elongation, and control of the number of the 300 or so human rRNA genes that are transcriptionally active by epigenetic mechanisms that assemble inactive copies into heterochromatin. Switching between the active and heterochromatic silent states of rRNA genes is accomplished by a multisubunit chromatin-remodeling complex called NoRC

**FIGURE 9-51 Transcription of the rRNA precursor RNA by RNA polymerase I.** (Top) Electron micrograph of RNA-protein complexes transcribed from one copy of the repeated rRNA genes. (Middle) A single Pol I transcription unit. Enhancers that stimulate Pol I transcription from a single transcription start site are represented by blue boxes. Pol I transcription termination sites ( $T_0$ ,  $T_1$ – $T_{10}$ ) bound by the Pol I-specific termination factor TTF-1 are shown as red rectangles. pRNA indicates transcription of the noncoding pRNA required for transcriptional silencing. The sequences of regions of DNA shown as yellow rectangles are retained during processing of 18S, 5.8S and the 28S rRNAs. The other regions transcribed from the black arrow to the red termination sites are removed and degraded. (Bottom) The core promoter element and upstream control element are shown with the location of Pol I and its general transcription factors UBF, SL1, and TIF-1A represented, as well as other proteins required for Pol I elongation and control. See I. Grummt, 2010, *FEBS J.* **277**:4626. [Electron micrograph courtesy Ann L. Beyer.]

(“No” for nucleolus, the site of rRNA transcription within nuclei). NoRC localizes a nucleosome over the Pol I transcription start site, blocking preinitiation complex assembly. It also interacts with a DNA methyl transferase that methylates a critical CpG in the upstream control element, inhibiting binding by UBF, as well as with histone methyl transferases that di- and trimethylate histone H3 lysine 9, creating binding sites for heterochromatic HP1, and with histone deacetylases. Moreover, a roughly 250-nt noncoding RNA called pRNA (promoter-associated RNA) transcribed by Pol I from about 2 kb upstream of the rRNA transcription unit (red arrow in Figure 9-51) is bound by a subunit of NoRC and is required for transcriptional silencing. The pRNA is believed to target NoRC to Pol I promoter regions by forming an RNA:DNA triplex with the T<sub>0</sub> terminator sequence. This creates a binding site for the DNA methyl transferase DNMT3b, which methylates the critical CpG in the upstream promoter element.

**Initiation by Pol III** Unlike those of protein-coding genes and pre-rRNA genes, the promoter regions of tRNA and 5S-rRNA genes lie entirely within the transcribed sequence (Figure 9-52a, b). Two such *internal* promoter elements, termed the *A box* and the *B box*, are present in all tRNA genes. These highly conserved sequences not only function as promoters, but also encode two invariant portions of eukaryotic tRNAs that are required for protein synthesis. In 5S-rRNA genes, a single internal control region, the *C box*, acts as a promoter.

Three general transcription factors are required for Pol III to initiate transcription of tRNA and 5S-rRNA genes *in vitro*. Two multimeric factors, TFIIIC and TFIIIB, participate in initiation at both tRNA and 5S-rRNA promoters; a third factor, TFIIIA, is required for initiation at 5S-rRNA promoters. As with assembly of Pol I and Pol II initiation complexes, the Pol III general transcription factors bind to promoter DNA in a defined sequence.

The N-terminal half of one TFIIIB subunit, called *BRF* (for TFIIIB-related factor), is similar in sequence to TFIIIB (a Pol II factor). This similarity suggests that BRF and TFIIIB perform a similar function in initiation, namely, to assist in separating the template DNA strands at the transcription start site. Once TFIIIB has bound to either a tRNA or a 5S-rRNA gene, Pol III can bind and initiate transcription in the presence of ribonucleoside triphosphates. The BRF subunit of TFIIIB interacts specifically with one of the polymerase subunits unique to Pol III, accounting for initiation by this specific nuclear RNA polymerase.

Another of the three subunits composing TFIIIB is TBP, which we can now see is a component of a general transcription factor for all three eukaryotic nuclear RNA polymerases. The finding that TBP participates in transcription initiation by Pol I and Pol III was surprising, since the promoters recognized by these enzymes often do not contain TATA boxes. Nonetheless, in the case of Pol III transcription, the TBP subunit of TFIIIB interacts with DNA about 30 bp upstream of the transcription start site similarly to the way it interacts with TATA boxes.

Pol III also transcribes genes for small stable RNAs with upstream promoters containing a TATA box. One example is the gene for U6 snRNA, which is involved in pre-mRNA splicing, as discussed in Chapter 10. In mammals, this gene contains an upstream promoter element called the PSE in addition to the TATA box (Figure 9-52c). The PSE is bound by a multisubunit complex called SNAP<sub>C</sub>, while the TATA box is bound by the TBP subunit of a specialized form of TFIIIB containing an alternative BRF subunit.

MAF1 is a specific inhibitor of Pol III transcription that functions by interacting with the BRF subunit of TFIIIB and with Pol III. Its function is regulated by control of its import from the cytoplasm into the nucleus by phosphorylations at specific sites in response to signal transduction protein kinase cascades that respond to cell stress and nutrient deprivation

**FIGURE 9-52 Transcription-control elements in genes transcribed by RNA polymerase III.** Both tRNA (a) and 5S-rRNA (b) genes contain internal promoter elements (yellow) located downstream from the start site and named A, B, and C boxes, as indicated. Assembly of transcription initiation complexes on these genes begins with the binding of Pol III–specific general transcription factors TFIIIA, TFIIIB, and TFIIIC to these control elements. Green arrows indicate strong, sequence-specific protein-DNA interactions. Blue arrows indicate interactions between general transcription factors. Purple arrows indicate interactions between general transcription factors and Pol III. (c) Transcription of the U6 snRNA gene in mammals is controlled by an upstream promoter with a TATA box bound by the TBP subunit of a specialized form of TFIIIB with an alternative BRF subunit and an upstream regulatory element called the PSE bound by a multisubunit factor called SNAP<sub>C</sub>. See L. Schramm and N. Hernandez, 2002, *Gene Dev.* **16**:2593.

(see Chapters 16 and 24). In mammals, Pol III transcription is also repressed by the critical tumor suppressors p53 and the retinoblastoma (Rb) family. In humans, there are two genes encoding RNA polymerase III subunit RPC32. One of these is expressed specifically in replicating cells, and its forced expression can contribute to oncogenic transformation of cultured human fibroblasts.

## KEY CONCEPTS OF SECTION 9.8

### Other Eukaryotic Transcription Systems

- The process of transcription initiation by Pol I and Pol III is similar to that by Pol II but requires different general transcription factors, is directed by different promoter elements, and does not require hydrolysis of ATP  $\beta$ - $\gamma$  phosphodiester bonds to separate the DNA strands at the start site as Pol II transcription does.
- Pol I transcribes only a single RNA, the 45S precursor of 18S, 5.8S, and 28S rRNA, from multiple copies of the pre-rRNA gene.
- Pol III transcribes tRNAs from promoters within the genes that encode the tRNA regions common to all tRNAs. This internal promoter is bound by transcription factor TFIIC, which in turn binds TFIIB, a multisubunit factor that includes the TATA box-binding protein, TBP, which associates with the tRNA gene about 30 bp upstream of the transcription start site.
- Pol III transcribes 5s rRNA directed by a promoter within the 5S-rRNA coding region that is bound by transcription factor TFIIA. TFIIA then associates with TFIIC and TFIIB, which interact with Pol III in a manner similar to their interactions in tRNA transcription.
- Additional small stable RNAs, several with as yet unknown functions, are transcribed by Pol III as directed by TBP-containing transcription factors that bind immediately upstream of the genes (see Figure 9-52).
- Pol III transcription is regulated by a specific inhibitor, MAF1, whose transport from the cytoplasm into the nucleus is controlled in response to nutrient availability.

## Review the Concepts

1. Describe the molecular events that occur at the *lac* operon when *E. coli* cells are shifted from a glucose-containing medium to a lactose-containing medium.
2. The concentration of free glutamine affects transcription of the enzyme glutamine synthetase in *E. coli*. Describe the mechanism of this effect.
3. Recall that the *trp* repressor binds to a site in the operator region of tryptophan-producing genes when tryptophan is abundant, thereby preventing transcription. What would happen to the expression of the tryptophan biosynthetic enzyme genes in the following scenarios? Fill in the blanks with one of the following phrases:

never be expressed/always (constitutively) be expressed

- a. The cell produces a mutant *trp* repressor that cannot bind to the operator. The enzyme genes will \_\_\_\_\_.
  - b. The cell produces a mutant *trp* repressor that binds to its operator site even if no tryptophan is present. The enzyme genes will \_\_\_\_\_.
  - c. The cell produces a mutant sigma factor that cannot bind the promoter region. The enzyme genes will \_\_\_\_\_.
  - d. Elongation of the leader sequence is always stalled after transcription of region 1. The enzyme genes will \_\_\_\_\_.
4. Compare and contrast bacterial and eukaryotic gene expression mechanisms.

5. What types of genes are transcribed by RNA polymerases I, II, and III? Design an experiment to determine whether a specific gene is transcribed by RNA polymerase II.
6. The CTD of the largest subunit of RNA polymerase II can be phosphorylated at multiple serine residues. What are the conditions that lead to the phosphorylated versus non-phosphorylated RNA polymerase II CTD?
7. What do TATA boxes, initiators, and CpG islands have in common? Which was the first of these to be identified? Why?
8. Describe the methods used to identify the location of transcription-control elements in promoter-proximal regions of genes.
9. What is the difference between a promoter-proximal element and a distal enhancer? What are the similarities?
10. Describe the methods used to identify the location of DNA-binding proteins in the regulatory regions of genes.
11. Describe the structural features of transcription activator and repressor proteins.
12. Give two examples of how gene expression may be repressed without altering the coding sequence.
13. Using CREB and nuclear receptors as examples, compare and contrast the structural changes that take place when these transcription factors bind to their co-activators.
14. What general transcription factors associate with an RNA polymerase II promoter in addition to the polymerase? In what order do they bind in vitro? What structural change occurs in the DNA when an “open” transcription initiation complex is formed?
15. Expression of recombinant proteins in yeast is an important tool for biotechnology companies that produce new drugs for human use. In an attempt to get a new gene *X* expressed in yeast, a researcher has integrated gene *X* into the yeast genome near a telomere. Will this strategy result in good expression of gene *X*? Why or why not? Would the outcome of this experiment differ if the experiment had been performed in a yeast line containing mutations in the H3 or H4 histone tails?
16. You have isolated a new protein called STICKY. You can predict from comparisons with other known proteins that STICKY contains a bHLH domain and a Sin3-interacting domain. Predict the function of STICKY and explain the importance of these domains in STICKY function.
17. Prokaryotes and lower eukaryotes such as yeast have transcription-control elements called upstream activating sequences. What are the comparable sequences found in higher eukaryotic species?
18. You are curious to identify the region of the gene *X* sequence that serves as an enhancer for gene expression. Design an experiment to investigate this issue.
19. Some organisms have mechanisms in place that will override transcription termination. One such mechanism

using the Tat protein is employed by the HIV retrovirus. Explain why Tat is therefore a good target for HIV vaccination.

20. Upon identification of the DNA regulatory sequence responsible for translating a given gene, you note that it is enriched with CG sequences. Is the corresponding gene likely to be a highly expressed transcript?

21. Name four major classes of DNA-binding proteins that are responsible for controlling transcription, and describe their structural features.

# Post-transcriptional Gene Control

In the previous chapter, we saw that most genes are regulated at the first step in gene expression, transcription, by regulation of the assembly of the transcription preinitiation complex on a promoter DNA sequence and of transcription elongation in the promoter-proximal region. Once transcription has been initiated, synthesis of the encoded RNA requires that RNA polymerase transcribe the entire gene and not terminate transcription prematurely. Moreover, the initial **primary transcripts** produced from eukaryotic genes must undergo various processing reactions to yield the corresponding functional RNAs. For mRNAs, the 5' cap structure necessary for translation must be added (see Figure 5-14), introns must be spliced out of pre-mRNAs, and the 3' end must be polyadenylated (see Figure 5-15). Once formed in the nucleus, mature, functional RNAs are exported to the cytoplasm as components of ribonucleoproteins. Both the processing of RNAs and their export from the nucleus offer opportunities for further regulation of gene expression after the initiation of transcription.

Recently, the vast amount of sequence data on human mRNAs expressed in different tissues and at various times during embryogenesis and cellular differentiation has revealed that some 95 percent of human genes give rise to alternatively spliced mRNAs. These **alternatively spliced** mRNAs encode related proteins with differences in their sequences that are limited to specific functional domains. In many cases, alternative RNA splicing is regulated to meet the need for a specific protein isoform in a specific cell type. Given the complexity of pre-mRNA splicing, it is not surprising that mistakes are occasionally made, giving rise to mRNA precursors with improperly spliced exons. However, eukaryotic cells have evolved RNA surveillance mechanisms that prevent the export of incorrectly processed RNAs to the cytoplasm or lead to their degradation if they are exported.

Additional control of gene expression can occur in the cytoplasm. In the case of protein-coding genes, for instance, the amount of protein produced depends on the stability of the corresponding mRNAs in the cytoplasm and the

**FIGURE 10-1 Overview of RNA processing and post-transcriptional gene control.** Nearly all cytoplasmic RNAs are processed from primary transcripts in the nucleus before they are exported to the cytoplasm. For protein-coding genes transcribed by RNA polymerase II, gene control can be exerted through step **1** the choice of alternative exons during pre-mRNA splicing and step **2** the choice of alternative poly(A) sites. Improperly processed mRNAs are blocked from export to the cytoplasm and degraded step **3** by a large complex called the exosome that contains multiple ribonucleases. Once the mRNA has been exported to the cytoplasm, step **4** translation initiation factors bind to the 5' cap cooperatively with poly(A)-binding protein I bound to the poly(A) tail and initiate translation (see Figure 4-28). Step **5** mRNA is degraded in the cytoplasm by deadenylation and decapping followed by degradation by cytoplasmic exosomes.

These processes occur rapidly in dense regions of the cytoplasm called P bodies that function in translational repression. The degradation rate of each mRNA is controlled, thereby regulating the mRNA concentration and, consequently, the amount of protein translated. Some mRNAs are synthesized without long poly(A) tails. Their translation is regulated by step **6** control of the synthesis of a long poly(A) tail by a cytoplasmic poly(A) polymerase. Step **7** Translation is also regulated by other mechanisms, including miRNAs. When expressed, these ~22-nucleotide RNAs inhibit translation of mRNAs to which they hybridize, usually in the 3' untranslated region. tRNAs and rRNAs are also synthesized as precursor RNAs that must be step **8** processed before they are functional. Regions of precursors cleaved from the mature RNAs are degraded by nuclear exosomes step **9**. See Houseley et al., 2006, *Nat. Rev. Mol. Cell Biol.* 7:529.

rate of their translation. For example, during an immune response, lymphocytes communicate by secreting polypeptide hormones called cytokines that signal neighboring lymphocytes through cytokine receptors that span their plasma membranes (see Chapter 23). It is important for lymphocytes to synthesize and secrete cytokines in short bursts. This is possible because cytokine mRNAs are extremely unstable; consequently, the concentration of these mRNAs in the cytoplasm falls rapidly once their synthesis is stopped. In contrast, mRNAs encoding proteins required in large amounts that function over long periods, such as ribosomal proteins, are extremely stable, so that multiple polypeptides are transcribed from each mRNA.

Just as pre-mRNA processing, nuclear export, and translation are regulated, so is the cellular localization of many, if not most, mRNAs, so that newly synthesized protein is concentrated where it is needed. Particularly striking examples of this type of regulation occur in the nervous systems of multicellular animals. Some neurons in the human brain generate more than a thousand separate synapses with other neurons. During the process of learning, synapses that fire more frequently than others increase in size many times, while other synapses made by the same neuron do not. This can occur because mRNAs encoding proteins critical for synapse enlargement are stored at all synapses, but translation of these localized, stored mRNAs is regulated at each synapse independently by the frequency at which the synapse signals. In this way, synthesis of synapse-associated proteins can be regulated independently at each of the many synapses made by the same neuron (see Chapter 22).

Another type of gene regulation involves micro-RNAs (miRNAs), which regulate the translation and stability of specific target mRNAs in multicellular animals and plants. Analysis of these short miRNAs in various human tissues indicate that about 1900 miRNAs are expressed in the multiple types of human cells. Although some have recently been discovered to function through inhibition of target-gene expression in the appropriate tissue and at the appropriate time in development, the functions of the vast majority of human miRNAs are unknown and are the subject of a growing new area of research. If most miRNAs do indeed have significant functions, miRNA genes constitute an important subset of the 25,000 or so human genes. A closely related process, called RNA interference (RNAi), leads to the degradation of viral RNAs in infected cells and the degradation of transposon-encoded RNAs in many eukaryotes. This discovery is of tremendous significance to biological researchers because it is possible to design short interfering RNAs (siRNAs) to inhibit the translation of specific mRNAs experimentally by a process called *RNA knockdown*. This method makes it possible to inhibit the function of any desired gene, even in organisms that are not amenable to classical genetic methods for isolating mutants.

We refer to all the mechanisms that regulate gene expression following transcription as *post-transcriptional gene control* (Figure 10-1). Because the stability and translation rate of an mRNA contribute to the amount of protein expressed from a gene, these post-transcriptional processes are important components of gene control. Indeed, the protein

output of a gene is regulated at every step in the life of an mRNA, from the initiation of its synthesis to its degradation. Thus genetic regulatory processes act on RNA as well as on DNA. In this chapter, we consider the events in the processing of mRNA that follow transcription initiation and promoter-proximal elongation as well as the various mechanisms that are known to regulate these events. In the last section, we briefly discuss the processing of primary transcripts produced from genes encoding rRNAs and tRNAs.

## 10.1 Processing of Eukaryotic Pre-mRNA

In this section, we take a closer look at how eukaryotic cells convert the initial primary transcript synthesized by RNA polymerase II into a functional mRNA. Three major events occur during the process: *5' capping*, *3' cleavage and polyadenylation*, and *RNA splicing* (Figure 10-2). Adding these specific modifications to the 5' and 3' ends of the pre-mRNA protects it from enzymes that quickly digest uncapped RNAs generated by RNA processing, such as spliced-out introns and RNA transcribed downstream from a polyadenylation site. Thus the 5' cap and 3' poly(A) tail distinguish pre-mRNA molecules from the many other kinds of RNAs in the nucleus (Table 10-1). Pre-mRNA molecules are bound by nuclear proteins that function in mRNA export to the cytoplasm. Prior to nuclear export, introns must be removed to generate the correct coding region of the mRNA. In higher eukaryotes, including humans, alternative splicing is intricately regulated in order to substitute different functional domains into proteins, producing a considerable expansion of the proteome of these organisms.

The pre-mRNA processing events of capping, polyadenylation, and splicing occur in the nucleus as the nascent mRNA precursor is being transcribed. Thus pre-mRNA processing is *co-transcriptional*. As the RNA emerges from the surface of RNA polymerase II, its 5' end is immediately modified by the addition of the 5' cap structure found on all mRNAs (see Figure 5-14). As the nascent pre-mRNA continues to emerge from the surface of the polymerase, it is immediately bound by members of a complex group of RNA-binding proteins that assist in RNA splicing and export of the fully processed mRNA through nuclear pore complexes into the cytoplasm. Some of these proteins remain associated with the mRNA in the cytoplasm, but most either remain in the nucleus or shuttle back into the nucleus shortly after the mRNA is exported to the cytoplasm. Cytoplasmic RNA-binding proteins are exchanged for the nuclear ones. Consequently, mRNAs never occur as free RNA molecules in the cell, but are always associated with proteins as **ribonucleoprotein (RNP) complexes**, first as nascent *pre-mRNPs* that are capped and spliced as they are transcribed. Then, following cleavage and polyadenylation, they are referred to as *nuclear mRNPs*. Following the exchange of proteins that accompanies export to the cytoplasm, they are called *cytoplasmic mRNPs*. Although we frequently refer to pre-mRNAs and mRNAs, it is important to remember that they are always associated with proteins as RNP complexes.

**FIGURE 10-2 Overview of mRNA processing in eukaryotes.**

Shortly after RNA polymerase II initiates transcription at the first nucleotide of the first exon of a gene, the 5' end of the nascent RNA is capped with 7-methylguanylate (step **1**). Transcription by RNA polymerase II terminates at any one of multiple termination sites downstream from the poly(A) site, which is located at the 3' end of the final exon. After the primary transcript is cleaved at the poly(A) site (step **2**), a string of adenosine (A) residues is added (step **3**). The poly(A)

tail contains ~250 A residues in mammals, ~150 in insects, and ~100 in yeasts. For short primary transcripts with few introns, splicing (step **4**) usually follows cleavage and polyadenylation, as shown. For large genes with multiple introns, introns are often spliced out of the nascent RNA during its transcription, before transcription of the gene is complete. Note that the 5' cap and the sequence adjacent to the poly(A) tail are retained in mature mRNAs. The diagram shown represents processing of human  $\beta$ -globin RNA.

## The 5' Cap Is Added to Nascent RNAs Shortly After Transcription Initiation

As a nascent eukaryotic RNA transcript emerges from the RNA exit channel of RNA polymerase II (see Figure 9-12) and reaches a length of about 25 nucleotides, a protective cap composed of 7-methylguanosine and methylated riboses

is added to the 5' end of the mRNA (see Figure 5-14). This 5' *cap* marks RNA molecules as mRNA precursors and protects them from RNA-digesting enzymes (5'-exoribonucleases) in the nucleus and cytoplasm. This initial step in RNA processing is catalyzed by a dimeric capping enzyme, which associates with the phosphorylated carboxy-terminal domain (CTD) of RNA polymerase II. Recall that the TFIIF general

**TABLE 10-1 RNAs Discussed in Chapter 10**

mRNA	Fully processed messenger RNA with 5' cap, introns removed by RNA splicing, and a poly(A) tail.
pre-mRNA	An mRNA precursor containing introns and not cleaved at the poly(A) site.
hnRNA	Heterogeneous nuclear RNAs. These RNAs include pre-mRNAs and RNA-processing intermediates containing one or more introns.
snRNA	Five small nuclear RNAs that function in the removal of introns from pre-mRNAs by RNA splicing, plus two small nuclear RNAs that substitute for the first two at rare introns.
pre-tRNA	A tRNA precursor containing additional transcribed bases at the 5' and 3' ends compared with the mature tRNA. Some pre-tRNAs also contain an intron in the anticodon loop.
pre-rRNA	The precursor to mature 18S, 5.8S, and 28S ribosomal RNAs. The mature rRNAs are processed from this long precursor RNA molecule by cleavage, removal of bases from the ends of the cleaved products, and modification of specific bases.
snoRNA	Small nucleolar RNAs. These RNAs base-pair with complementary regions of the pre-rRNA molecule, directing cleavage of the RNA chain and modification of bases during maturation of the rRNAs.
siRNA	Short interfering RNAs, ~22 bases long, that are each perfectly complementary to a sequence in an mRNA. Together with associated proteins, siRNAs cause cleavage of the "target" RNA, leading to its rapid degradation.
miRNA	Micro-RNAs, ~22 bases long, that base-pair extensively, but not completely, with mRNAs, especially over bases 2 to 7 at the 5' end of the miRNA (the "seed" sequence). This pairing inhibits translation of the "target" mRNA and targets it for degradation.

transcription factor phosphorylates the CTD multiple times on serine 5 of the CTD heptapeptide repeat during transcription initiation (see Figure 19-20). Binding of the capping enzyme to the serine 5-phosphorylated CTD stimulates the activity of the enzyme so that it is focused on RNAs containing a 5' triphosphate that emerge from RNA polymerase II, and not on RNAs transcribed by RNA polymerases I or III, which do not have a CTD. This is important because pre-mRNA synthesis accounts for only about 80 percent of the total RNA synthesized in replicating cells. About 20 percent is pre-ribosomal RNA, which is transcribed by RNA polymerase I, and 5S rRNA, tRNAs, and other small stable RNAs, which are transcribed by RNA polymerase III. These two mechanisms, (1) binding of the capping enzyme to RNA polymerase II specifically through its unique CTD phosphorylated on serine 5 of the heptapeptide repeat during transcription initiation by TFIIF, and (2) activation of the capping enzyme by the serine 5-phosphorylated CTD, result in specific capping of RNAs transcribed by RNA polymerase II.

One subunit of the capping enzyme removes the  $\gamma$  phosphate from the 5' end of the nascent RNA (Figure 10-3). Another domain of this subunit transfers the GMP moiety from GTP to the 5' diphosphate of the nascent transcript,

**FIGURE 10-3 Synthesis of the 5' cap on eukaryotic mRNAs.** The 5' end of a nascent RNA contains a 5' triphosphate from the initiating rNTP. The  $\gamma$  phosphate is removed in the first step of capping, while the remaining  $\alpha$  and  $\beta$  phosphates (orange) remain associated with the cap. The third phosphate of the 5',5' triphosphate bond is derived from the  $\alpha$  phosphate of the GTP that donates the guanine. The methyl donor for methylation of the cap guanine and the first one or two riboses of the mRNA is S-adenosylmethionine (S-Ado-Met). See S. Venkatesan and B. Moss, 1982, *Proc. Natl. Acad. Sci. USA* **79**:340.

creating the unusual guanosine 5'-5' triphosphate structure. In the final steps, separate enzymes transfer methyl groups from S-adenosylmethionine to the N<sup>7</sup> position of the guanine and to the 2' oxygens of riboses of the first one or two nucleotides at the 5' end of the nascent RNA.

Considerable evidence indicates that capping of the nascent transcript is coupled to elongation by RNA polymerase II so that all of its transcripts are capped during the earliest phase of elongation. As discussed in Chapter 9, in metazoans, during the initial phase of transcription, the polymerase elongates the nascent transcript very slowly due to the association of NELF (negative elongation factor) with RNA polymerase II in the promoter-proximal region (see Figure 9-21). Once the 5' end of the nascent RNA is capped, phosphorylation of the RNA polymerase CTD at serine 2 in the heptapeptide repeat and of NELF and DSIF (DRB-sensitivity-inducing factor) by the cyclin T-CDK9 protein kinase (also known as P-TEFb) causes the release of NELF. (DRB is an analog of ATP that inhibits CDK9, preventing transcription elongation from the promoter-proximal region.) This allows RNA polymerase II to enter into a faster mode of elongation that rapidly transcribes away from the promoter. The net effect of this mechanism is that the polymerase waits for the nascent RNA to be capped before elongating at a rapid rate.

## A Diverse Set of Proteins with Conserved RNA-Binding Domains Associate with Pre-mRNAs
